involves examination of the urine obtained from bladder or ureter directly by catheterisation. Indirect/non-invasive methods include detection of antibodies in serum or urine and demonstrating a reduction in the maximum concentrating ability in cases of upper UTI. Increase in urinary β2 microglobulin and LDH-5 also helps to confirm upper tract involvement. In women of the child bearing age group, detailed investigations are often not necessary for the first attack of urinary infection or when it occurs infrequently. In the case of infants or young children of both sexes and adult males, any attack of documented UTI warrants further investigations. Ideally, imaging studies are done after 4 to 6 weeks of treatment of acute infection with a view to identify predisposing factors or presence of renal damage. In the acute phase, ultrasonography is performed with a view to rule out obstruction or abscess formation. Plain radiograph of the abdomen is done to show the presence and extent of calcification of the kidneys or urinary tract and number and position of calculi. Ultrasonogram combined with plain radiograph is the preliminary imaging method in patients with recurrent infection. It can detect pelvicalyceal dilatation, calculi, pus or fluid collection, scars and enable actual measurements of the kidney. The bladder, post void residual urine and prostate can also be assessed.

Intravenous urography (IVU) provides anatomical details of kidneys, minor and major calyces, renal pelvis, ureter and bladder. It is also useful to assess post-void residual bladder urine. Conditions like medullary sponge kidney, renal papillary necrosis causing obstruction to ureters and radiolucent staghorn calculi are better diagnosed by IVU or computed tomography (CT) urogram. These procedures also give an idea about the overall kidney function. CT and CT urogram are more sensitive for detection of all types of calculi, renal/perinephric collections and presence of gas.

Isotope renography for renal imaging can be performed with either technetium labelled dimercaptosuccinic acid (DMSA), diethylene triamine pentaacetic acid (DTPA) or ethylcystine (EC). DMSA helps to identify parenchymal changes particularly scars. DTPA scans helps to measure the glomerular filtration rate (GFR), percentage of individual kidney function and level of obstruction. In case of pelviureteric junction obstruction, DTPA renogram with diuretic administration is performed to identify if the obstruction is significant. EC renogram can assess the renal function even in those with compromised renal function.

Voiding cystourethrography is a useful investigation to assess the urinary bladder and urethra, especially in children with posterior urethral valve, vesicoureteric reflux, neurogenic bladder, diverticulae and vesical fistulae.

TREATMENT

For those with symptomatic UTI infection, a 3-day course of antibiotics (cotrimoxazole or quinolones) is adequate. Such a course often eradicates vaginal colonisation also. Acute urethritis due to *Chlamydial* infection is treated with azithromycin or doxycycline (100 mg twice daily) for 7 days.

Acute uncomplicated pyelonephritis in women is treated with a 14-day course of oral quinolones or other antibiotics based on sensitivity of the organism. Parenteral quinolones, cephalosporins or aminoglycosides may be used for the first 72 hours in severe infections.

Antibiotic treatment is not necessary in asymptomatic individuals with indwelling catheters, stone, or obstruction even if urine culture is positive. In the case of asymptomatic bacteriuria during pregnancy and bacteriuria following catheter removal, treatment to re-establish sterile urine is essential.

Prostatitis is generally treated with a 6-week course of antibiotics like quinolones or co-trimoxazole, which are concentrated in the prostate.

Relapsing infection is defined as occurrence of bacteriuria with the same organism within 2 weeks of successful completion of the course of treatment. Relapse occurs due to failure of eradication of infection and occur in those with stones, renal scars, polycystic disease, chronic prostatitis or an immunocompromised state. Such patients should be investigated further and appropriate corrective measures should be taken.

Re-infection is defined as occurrence of infection with a different or similar organism after the original causative organism has been eradicated fully by the treatment. Re-infection occurs more than 2 weeks of discontinuing treatment. Meticulous perineal and perianal care helps to reduce chances of recurrence particularly in women. Maintaining high urine output, voiding after sexual intercourse or post-coital antibiotic prophylaxis with a single dose of co-trimoxazole (40 mg trimethoprim and 200 mg sulphamethoxazole) can be tried.

COMPLICATIONS

Parenchymal infections and injury to the kidney due to VUR and intra-renal reflux can lead to irreversible renal damage and scars. Severe infection in diabetics may lead to renal papillary necrosis, associated with haematuria or obstruction to the urine flow. Parenchymal abscesses may rupture into the perirenal space resulting in perinephric abscess. Infections in patients with diabetes or urinary obstruction lead to emphysematous pyelonephritis. Renal malakoplakia is a chronic granulomatous disorder characterised by an inflammatory reaction to the calcified bacterial debris. The inflammatory process results in a peculiar chronic inflammatory granuloma containing monocytes and macrophages. Chronic UTI associated with calculi may result in XGP.

PROGNOSIS AND PREVENTION

The prognosis for the first attack or infrequent UTI in adult females is favourable. In newborns and infants with developmental defects, like PUV, VUR, or both, infection induced renal scars affect renal growth. These children often develop hypertension, proteinuria and progressive renal failure in the second or third decade of life. Therefore, identification of PUV and VUR before scarring occurs is important. In children with lower grades of VUR, antibiotic chemoprophylaxis is advised while in those with grades 4 and 5 VUR, surgery is indicated. Asymptomatic bacteriuria during pregnancy may be associated with foetal growth retardation or low birth weight.

19.8 Nephrolithiasis and Urinary Tract Obstruction

PD Gulati

INTRODUCTION AND EPIDEMIOLOGY

The term 'nephrolithiasis' is derived from the Greek words 'nephros' which means 'kidney' and 'lithos' which means 'stone'. Nephrolithiasis is common worldwide; this is the third commonest disorder of the urinary tract after urinary tract infection and prostatic hyperplasia. In USA, 13% men and 7% women develop renal stones during their lifetime. Globally, its incidence is increasing; an analysis from India shows an increase from 0.9% to 9.0% over 20 years. There is geographical variation in stone composition; in north America 75% stones are composed of calcium oxalate alone or mixed with calcium phosphate, 5% pure calcium phosphate, 5% to 10 % uric acid, 10% infection (struvite) and 1% cystine. A similar analysis from north India shows calcium oxalate 93.4% (monohydrate 80%, dihydrate 20%), mixed (calcium oxalate, phosphate, urate) 2.76% struvite (magnesium, ammonium, phosphate) 1.42%, uric acid 0.95%, cystine 0.05%.

In India, maximum prevalence occurs in Jammu and Kashmir, Punjab, Haryana, Delhi, Rajasthan, Madhya Pradesh and Gujarat (stonebelt of India); peak age is 20 to 30 years. Recurrence is common; it is 15% at one year, 30% to 40% at 5 years and 50% at 10 years.

AETIOPATHOGENESIS

Basics in Stone Formation

Normal urine contains both solvents and solutes; imbalance of their relative concentrations results in precipitation of solutes leading to *pathological crystallisation* which occurs in three stages: *Stage I* 'under saturation' when crystals remain dissolved; *Stage II* 'saturation' in which urine is saturated with crystals; and *Stage III* 'super saturation' when urine becomes oversaturated with crystals. 'Nucleation' is an important initial step, followed by crystal aggregation and stone formation; anchoring of crystals on tubular epithelium may occur, e.g. calcium oxalate anchoring on calcium phosphate (Randall's plaque).

Role of Stone Promoters and Inhibitors

Calcium, oxalates, phosphates, uric acid are stone promoters; their supersaturation is prevented by inhibitors like citrate, magnesium and pyrophosphate; citrate forms a soluble complex with calcium; magnesium and pyrophosphate inhibit calcium crystallisation. Organic inhibitors like nephrocalcin, Tamm-Horsfall protein, glycosaminoglycans and osteopontin inhibit calcium oxalate crystal growth. Small intracellular nanobacteria may also form a calcium phosphate *nidus*.

Risk Factors for Nephrolithiasis

Diet

(i) Calcium deficient diet leads to upregulation of oxalate absorption; (ii) High animal protein intake lowers urine pH favouring crystallisation; (iii) High salt intake increases urinary calcium excretion; (iv) Oxalate rich foods (vide infra) and vitamin C intake may increase stone formation since vitamin C gets metabolised to oxalate; and (v) Low potassium diet reduces citrate excretion.

Fluids

Urine output less than one litre per day, due to less fluid intake, increases stone risk; trace elements like fluorides in water, increase stone tendency by 5-fold.

Genetic factors

One in four persons with renal stone has a family history of nephrolithiasis; cystinuria and familial renal tubular acidosis are known examples.

Systemic diseases

Renal stones occur in 20% cases of primary hyperparathyroidism and in 60% of gout; patients of Crohn's disease, diabetes mellitus, hypertension are at increased risk.

Infection

Urinary infection, caused by urease producing organisms (*Proteus, Klebsiella, Pseudomonas, Ureaplasma*) makes urine alkaline (urease acts on urine to produce ammonia) and increases the risk of struvite stones. Matrix stones seen in proteus infections are composed of coagulated mucoids.

Miscellaneous

(i) pH of urine-uric acid and cystine stones are pH dependent, (ii) anatomical abnormalities like pelviureteric junction (PUJ) obstruction, horse shoe kidney, calyceal diverticulum, ureterocoele, vesico-ureteral reflux, medullary sponge kidney, make one stone prone; and (iii) medications like triamterene, indinavir act as stone nidus.

Metabolic factors

Nephrolithiasis occurs due to primary metabolic abnormality in 95% cases; systemic diseases account for only 5% cases. Calcium stones are the commonest with multifactorial aetiology (**Table 1**).

CLINICAL FEATURES

Clinical presentation depends upon size, position and type of stone. Large staghorn stones are usually asymptomatic. Common presentation is renal or ureteric colic; acute loin pain radiating to the groin with nausea, vomiting is classical; haematuria, microscopic or macroscopic, is invariably present. Stone moving down the ureter causes intermittent ureteric obstruction; presents with acute colicky pain. Urgency, frequency, strangury occur with stone at ureter ovesical junction, presence of fever indicates infection. Ureteric stone in a single kidney or bilateral ureteric stones can cause complete anuria and rapid deterioration of renal function.

Physical examination may reveal: (a) typical costovertebral tenderness; and (b) distinct tender renal lump suggesting infection-pyonephrosis or perinephric abscess.

MODALITIES OF DIAGNOSIS

Laboratory Investigations

Urinalysis reveals microscopic haematuria (78% cases), crystalluria, pyuria.

Blood investigations including complete blood counts, estimation of urea, creatinine, electrolytes, renal function (GFR), serum calcium, phosphorous, alkaline phosphatase, uric acid estimations, may reveal aetiology.

Table 1: Multifactor Aetiology of Calcium Stones

Hypercalciuria	Urine calcium excretion of >4 mg/kg per day (>200 mg per 24 hours) occurs in 60% of calcium stone formers *Idiopathic hypercalciuria* occurs in 30% to 50% cases of calcium stones; three types exist: Absorptive due to excessive absorption of calcium from the gut by 1,25 dihydroxyl vitamin D; Renal due to impaired renal tubular absorption of calcium (2% in recurrent stone formers) Resorptive due to increased resorption of bones in primary hyperparathyroidism (5% of recurrent stones)
Hyperoxaluria	Hyperoxaluria occurs in 25%. Normal urinary oxalate excretion is <45 mg per day *Dietary hyperoxaluria*: Due to consumption of oxalate rich diet and vitamin C rich fruits which increase oxaluria; grape fruit juice increases both oxalate and citrate excretion; stone tendency remains unaffected *Enteric hyperoxaluria*: Normally bile is absorbed in proximal intestine; if not absorbed, it reaches distal intestine where it binds calcium and decreases free calcium, available to bind oxalate leading to hyperoxaluria *Genetic hyperoxaluria*: (>100 mg per day) due to enzyme defect
Hyperuricosuria	In normal, urinary uric acid excretion is <600 mg per day In hyperuricosuria, excretion is >800 mg per day. It occurs in 10% of calcium stones Low urine pH precipitates urate crystals
Hypocitraturia	Normal urine citrate excretion is 600 mg per day. It occurs in 15% to 60% cases. Citrate is complexed with calcium and reduces calcium oxalate crystallisation.
Cystinuria	Normal urine cystine is 30 to 50 mg per day. It is an autosomal recessive disorder; urine excretion >250 mg per day causes stone formation.
Urine glycoprotein	Nephrocalcin, Tamm-Horsfall proteins deficiency promotes nephrolithiasis.

Specific investigations are listed in **Table 2.**

Stone analysis by X-ray crytallography/infrared spectroscopy gives chemical composition of stone and determines metabolic abnormality.

DIFFERENTIAL DIAGNOSIS

The *triad* of flank pain, haematuria and positive radiograph abdomen (KUB) is seen in 90% patients of renal stone. Atypical renal pain has to be differentiated from intestinal obstruction, acute appendicitis, clot colic of renal cell carcinoma, acute pyelonephritis and ectopic pregnancy.

Table 2: Investigations of Nephrolithiasis

Modality	Utility
Plain X-ray abdomen (KUB)	90% calcium containing stones are seen and are radio-opaque 10% radiolucent not seen like uric acid, cystine, xanthine
Intravenous urography (IVU)	Show stones—position, obstructive features and functions
Renal Ultrasound	Useful in stones more than 2 mm size May show back pressure effect
CT Scan	Plain CT: 90% accuracy and also shows radiolucent calculi CE CT: More accuracy than plain CT and shows obstruction
Renal scintigraphy	Technetium 99 mm mercaptoacetyltriglycine, with frusemide challenge, evaluates function of individual kidney and obstructive uropathy

TREATMENT

There are three major aspects of treatment of nephrolithiasis as described below:

1. Management of Acute Stone Episode

Renal stone when complicated, needs urgent intervention; uncomplicated stone can be treated conservatively with fluids and analgesics. Calcium channel blockers like nifedipine relax the ureteral smooth muscle as also tamsulosin; antibiotics are added to control the infection.

2. Prevention of Recurrent Stone Formation: Medical Treatment (Table 3)

3. Surgical Treatment

Indication

Endoscopic or surgical removal is recommended for: (a) persistent pain not relieved by analgesia, (b) stone obstructing single kidney, or bilateral ureteral obstruction and/or pyonephrosis.

Choice of intervention

1. *Extracorporeal shock wave lithotripsy (ESWL)* is ideal for renal stone of less than 2.5 cm size with 70% success. For stones of large size (staghorn/struvite), multiple sessions of ESWL with percutaneous nephrolithotomy or uretroscopic removal, are often required; ureteric colic due to residual stones in ureter ('steinstrasse'); ureteric obstruction and perirenal haematoma may occur. Pre-existent hypertension and renal insufficiency may get aggravated. ESWL is contraindicated in obstructive uropathy, abnormal anatomy of urinary tract, large stone burden and pregnancy.
2. *Ureteroscopic stone removal (USR)* using Holmium YAG laser technique carries a success rate of 95% to 100% in ureteric stones of size greater than 5 mm; however, it may be complicated by stricture or reflux.
3. *Percutaneous nephrolithotomy* gives excellent results in stones greater than 2 mm size with hydronephrosis, stone in calyceal diverticuli, horseshoe or ectopic kidney.
4. *Open surgery* is indicated for anatomic abnormality or when other options have failed. Nephrectomy is indicated for pyonephrosis.

Table 3: Prevention of Recurrent Stone Formation: Medical Treatment

General Measures	**Fluids** Increasing *fluid intake* to achieve a urine output >2.5 litres per day reduces recurrence by 50% **Diet** Low calcium intake may cause hyperoxaluria; so calcium intake should be increased Avoiding *oxalate* rich foods with optimal calcium intake *Animal proteins:* Animal foods are rich in purines—a precursor of uric acid, can cause hyperuricosuria (by increasing acid load), hypocitraturia (increased tubular absorption) and should be avoided *Fibre:* Rice bran, fruits and vegetables, decrease both calcium and oxalate excretion
Specific Measures	**Calcium stones** Calcium containing stones are the commonest; hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia all contribute **Hypercalciuria** Potassium citrate be taken 60 mEq per day orally; monitor urinary calcium, phosphorus, sodium and citrate. In case hypercalciuria persists; potassium sparing diuretic amiloride 5 mg daily can be given **Absorptive hypercalciuria** *Cellulose phosphate* (10 to 15 g daily) non-absorbable exchange resin which binds calcium in the gut and prevents absorption; contraindicated in children *Hydrochlorothiazide* (12.5 mg daily) reduces calcium excretion. **Renal leak** *Diminished calcium intake* (<400 mg per day) reduces calcium excretion **Resorptive hypercalciuria** *Orthophosphate* (250 to 2,000 mg/ day) inhibits vitamin D synthesis and decreases absorption of calcium; it increases urinary pyrophosphate **Hyperoxaluria** Restriction of *oxalate rich foods*—spinach, beets, rhubarb, tea, chocolates, nuts, peanuts, strawberry, soya food, wheat bran, possibly linked to deficiency of oxalate dehydrogenase producing *Oxalobacter* increasing gut absorption of oxalate; cranberry juice decreases oxalate and phosphate excretion and increases citrate excretion *Pyridoxine* (2.5 to 6.0 mg/kg body weight) reduces oxalate production Raise *urine pH* to >6.5; it makes calcium oxalate more soluble *Calcium supplement* (500 mg per day) controls enteric hyperoxaluria *Cholestyramine* may reduce intestinal absorption of oxalate *Probiotic* containing *Oxalobacter* formigenes may reduce oxalate excretion *Gluten free diet* in malabsorption reduces hyperoxaluria *Oestrogens* may inhibit urinary oxalate excretion by increasing osteopontin. **Hyperuricosuria** Increased *fluid intake* to achieve urine output of 2.5 litres per day Raise *urine pH* to >6.5 by giving potassium citrate (40-50 mMol per day) Avoid *purine rich foods* like meat products, kidney, liver, brain, heart, shell fish, peas, spinach, mushroom, lentils, kidney beans *Allopurinol* 100 to 300 mg per day, inhibits uric acid synthesis and reduces hyperuricosuria; *febuxostat (80 mg per day)* has less side effects **Hypocitraturia** *Potassium citrate* (60 mEq per day) gets metabolised to bicarbonate, making urine alkaline, thus preventing calcium oxalate stone formation. In *distal renal tubular acidosis* large doses of potassium citrate 120 mEq per day, are required. If hypomagnesuria is present, *magnesium citrate* 10 mg 2 to 3 times per day raises urinary magnesium and citrate and also pH.
Uric Acid Stones	Treatment is as for hyperuricosuria.
Struvite Stones	These are infection stones containing *triple phosphate* (ammonium, magnesium, calcium) which grow rapidly into large *staghorn* stones in alkaline urine (pH >7.0). Treatment is mostly surgical. Measures like *high fluid intake*, specific *antibiotics;* recently, *urease inhibitors* like acetohydroxamic acid; *chemolysis*, i.e. flushing through nephrostomy or ureteroscopically, with 10% hemiacidrin at pH 3.9, have been used
Cystine Stones	High fluid intake so as to achieve urine output >3 litres per day High citrate diet (citrus fruits), methionine rich foods (meat, poultry, dairy products) Low sodium (<50 mEq per day) reduces cystine excretion Raising urine pH to >7.5 increases cystine solubility Potassium citrate (20 to 40 mEq) corrects hypocitraturia D-Penicillamine (250 to 1000 mg) binds cystine; has serious side effects; maintain urine cystine <200 mg/L; vitamin B6 prevents toxicity Recently less toxic, tiopronin and rimatil are being used ACE inhibitor captopril forms soluble thiol cystine disulfide bond in urine

URINARY TRACT OBSTRUCTION

Definitions

Urinary tract obstruction refers to structural and functional changes in urinay tract that impede urine flow. *Hydronephrosis* refers to reversible dilatation of the urinary tract; if left untreated, it can result in progressive irreversible nephron loss.

Aetiopathogenesis

Aetiology is variable. In urinary tract obstruction, glomerular haemodynamics and tubular functions get disturbed due to release of vaso-constrictors like angiotensin II and thromboxane. In bilateral obstruction, retention of urea and water increases the circulating vasodilator atrial natriuretic peptide, which reduces the vasoconstrictor effect. Urinary concentration, acidification, renal handling of electrolytes especially potassium, are also disturbed.

Clinical Features

Patient may be asymptomatic or may have recurrent urinary infection; obstruction if prolonged and bilateral, may lead to uraemic features. Strangury, frequent micturation suggest lower ureteric stone; straining, poor stream, feeling of incomplete bladder emptying, suggest bladder neck obstruction.

Modalities of Diagnosis

Laboratory investigations

In acute obstruction, urinary sodium may be low (<20 mmol/L) with high osmolality (>500 mmol/L). In chronic obstruction, urinary concentrating ability is decreased, osmolality falls. Blood abnormalities include polycythaemia, elevated blood urea, creatinine, electrolytes, hyperchloraemic hyperkalaemic acidosis in chronic bilateral obstruction.

Imaging modalities

Renal ultrasound reveals hydronephrotic changes (fullness, ballooning of pelvicalyeal system); distended bladder with or without bilateral hydroureteronephrosis suggesting bladder neck obstruction. In latter cases, voiding cysto-urethrogram, urodynamic studies and cystoscopy may clinch the diagnosis. Plain radiograph abdomen may reveal radio-opaque calculus; intravenous urography or CT urography and retrograde pyelography indicate site of obstruction. Non-contrast CT is recommended for patients having renal impairment.

Renal scintigraphy, with frusemide challenge, distinguishes functional from anatomical obstruction.

Treatment

Obstruction in single functioning kidney or bilateral obstruction requires urgent intervention; dialysis may be needed for life-threatening hyperkalaemia/fluid overload.

If obstruction is distal to the bladder, immediate indwelling catheterisation is done followed by definitive procedure for enlarged prostate or stricture urethra. Placement of nephrostomy or cystoscopy with double J stenting will relieve upper urinary tract obstruction; definitive surgical treatment is then decided. Pyonephrosis needs drainage by nephrostomy. Post-obstructive diuresis causes volume depletion and dyselectrolytaemia; careful monitoring and adequate replacement are necessary.

19.9 Vascular Injury to Kidney

AS Narula, AK Hooda

The kidney is a very vascular organ which receives about 25% of the cardiac output through a large network of blood vessels of varying sizes. Diseases of the blood vessels eventually affect the structure of the glomeruli, tubule and the interstitium, causing an impairment of renal functions. The kidney vasculature may be involved in many systemic diseases affecting the vascular endothelium as in hypertension, atheroembolic disease, vasculitis, haemolytic uraemic syndrome, thrombotic thrombocytopaenic purpura and scleroderma, or by diseases limited to the renal blood vessels like arterial/venous thrombosis. In this chapter some of these diseases are discussed.

ATHEROEMBOLIC RENAL DISEASE

Atheroembolic renal disease results from occlusion of small arteries and arterioles by cholesterol containing crystals, which usually slough off from unstable atheromatous plaques in the aorta and other large vessels and travel downstream into the renal arteries. The time from the precipitating event to clinically apparent atheroembolic renal disease is variable and ranges from a day to a month or two. Cholesterol embolisation usually follows invasive angiographic procedures, vascular surgery but in patients with extensive atherosclerosis it can, rarely, occur spontaneously and after administration of oral anti-coagulants or thrombolytic therapy.

Typically, it occurs in males over the age of 50 years with other risk factors for atherosclerosis like diabetes, hypertension, smoking and hypercholesterolaemia.

The symptoms and signs often result from the effects of local ischaemia and the inflammatory reaction in the organ involved. The illness may present with systemic signs like fever, myalgias and weight loss mimicking a vasculitic syndrome. These patients often have associated features of ischaemic heart disease, peripheral vascular disease, transient ischaemic attacks, retinal artery embolisation and ischaemic renal disease. Although the kidney is the most common organ involved, extra-renal cholesterol embolisation often provides clues to the diagnosis. The presentation of renal involvement may be acute with flank pain, accelerated hypertension and rapid deterioration of renal functions. More often, renal involvement is insidious and gradually progresses to chronic renal insufficiency. There may be partial renal recovery over a period of time but most patients go on to develop end-stage renal disease (ESRD) requiring dialysis support.

Skin manifestations are present in up to 60% patients and include purpura, petechiae, livedo reticularis, peripheral gangrene, ulcers and violaceous mottling of toes and feet. Involvement of other organs results in symptoms like abdominal pain, gastrointestinal haemorrhages, nausea, vomiting, hepatitis and neurological deficits. On fundoscopic examination, refractile yellow deposits known as 'Hollenhorst' plaques may be seen at the bifurcation of the retinal vessels. Common laboratory findings include normochromic normocytic anaemia, leucocytosis, thrombocytopaenia, eosinophilia, raised inflammatory markers like erthrocyte sedimentation rate (ESR), C-reactive protein and transient hypocomplementaemia. Depending on the organ involved there may be a rise of serum lactate dehydrogenase, creatinine phosphokinase and amylase. Urinalysis may show mild proteinuria, microhaematuria, pyuria and eosinophiluria. Definitive diagnosis is made on biopsy of the involved organ, showing cholesterol clefts within the vascular lumen representing atherosclerotic debris which have embolised with adjacent infarcted areas.

There is no satisfactory therapy for atheroembolic renal disease. Anticoagulation should be avoided as it may prevent thrombus organisation over unstable plaques and predispose to embolisation.

OCCLUSIVE DISEASES OF RENAL ARTERY

Thrombosis of the renal arteries may occur secondary to blunt abdominal trauma or due to non-traumatic causes such as embolic events usually arising from the heart, dissecting aneurysms, atherosclerotic plaques, vasculitis and hyper-coagulable states like factor V, protein C and S deficiencies and anti-phospholipid syndromes.

The clinical presentation depends on whether the occlusion is unilateral or bilateral, involves the major renal artery or its branches and whether it is acute or gradual in onset.

Insidious onset of occlusion may go undetected and commonly presents as impaired renal function in the elderly. Acute renal artery occlusion with renal infarction is almost always symptomatic, presenting with fever, pain in the flanks, low back or abdomen, associated with nausea vomiting, occasionally gross haematuria and hypertension. When occlusion is bilateral or to a single functioning kidney as in a renal transplant, the patient may present with oliguric ARF. Rarely, oliguria may be seen in unilateral occlusion with a normal contralateral kidney. This has been attributed to arteriolar spasm in the unaffected kidney which usually passes off in a few days. Urinalysis may reveal haematuria and proteinuria. Ultrasound Doppler studies for native renal vessels are of limited value and not useful. Imaging with contrast computed tomography (CT), magnetic resonance angiography or conventional angiography are the best means of diagnosis. Isotope renal scans may show absent or reduced perfusion.

Medical management is aimed at relief of pain, control of hypertension and where indicated dialysis. Surgical re-vascularisation is indicated in traumatic bilateral renal artery thrombosis or occlusion to a solitary functioning kidney. In occlusion due to non-traumatic causes, thrombolytic therapy is reported to be equally effective. The chances for success are

more if the obstruction is incomplete, of shorter duration and in presence of collaterals. For unilateral occlusions of a major renal artery due to any cause with normal contralateral kidneys, intra-arterial thrombolytic therapy is preferred. In unilateral segmental occlusion anti-coagulation therapy alone may be necessary. In patients with embolic disease due to atrial fibrillation, long-term anticoagulation is recommended to avoid recurrences.

MALIGNANT ARTERIOLAR NEPHROSCLEROSIS

Malignant arteriolar nephrosclerosis is used to describe the histological changes seen in patients with malignant hypertension characterised by marked elevation of blood pressure (BP) (diastolic blood pressure often >130 mmHg) associated with hypertensive retinopathy with haemorrhages, soft exudates and often papilloedema. Besides the kidneys, there may be involvement of the central nervous system, cardiac failure, and microangiopathic haemolytic anaemia. Malignant hypertension is more common in third to fifth decades of life, males, smokers and in those with underlying hypertension of some duration. It may arise *de novo* in less than 1% cases.

Renal involvement may manifest as urinary abnormalities like proteinuria which is occasionally in nephrotic range. About 20% patients have painless gross haematuria with micro-haematuria reported in about 50% patients. Patients with malignant hypertension may present with oliguric ARF or may have a progressive deterioration of kidney function with progression to ESRD.

Autopsy studies show that the kidneys are characteristically normal in size but may be shrunken in those with pre-existing hypertension of long duration or underlying chronic kidney disease (CKD). Small pin point haemorrhages may be present on the surface of the kidney giving it a 'flea bitten' appearance. The hallmark of malignant nephrosclerosis is fibrinoid necrosis of the afferent arterioles. There is infiltration of the vessel wall with fibrin, and occasionally an inflammatory infiltrate giving the appearance of necrotising arteriolitis. The fibrinoid necrosis may extend into the glomeruli which may develop segmental necrosis, proliferative lesions and even crescents. The inter-lobular arterioles reveal proliferative endarteritis. Secondary to narrowing of the lumen there is ischaemic collapse of the glomerular tuft and necrosis of renal tubules.

It has been proposed that activation of the renin angiotensin system and other neurohumoral factors leads to increased permeability of the vessel wall to plasma components like fibrin, which activates the clotting cascade leading to micro-angiopathic haemolytic anaemia and the vascular lesions. Alternatively, the vascular endothelium may be damaged secondary to the high pressure *per se*.

All patients with malignant hypertension and renal damage should receive aggressive anti-hypertensive therapy to prevent further deterioration of renal function. In patients with impaired renal function [glomerular filtration rate (GFR) less than 20 mL/minute] aggressive lowering of BP may precipitate oliguric ARF. This should not be considered as a contraindication to tight BP control as patients who have ESRD due to malignant nephrosclerosis are reported to have recovered renal function over a period of time despite being on dialysis. The mechanism of recovery of renal function after prolonged renal failure may be related to partial reversal of the vascular lesions leading to reversal of ischaemic tubular necrosis or due to hyperfiltration by the remaining nephrons supplied by the patent interlobular arteries.

BENIGN ARTERIOLAR NEPHROSCLEROSIS

Benign arteriolar nephrosclerosis is a term used to describe histological changes in the kidneys secondary to chronic hypertension. The risk factors for Benign arteriolar nephro-sclerosis include older age, black race and poorly controlled hypertension. The diagnosis is usually based on long standing hypertension being present with associated signs of other end-organ damage in the form of hypertensive retinopathy and left ventricular hypertrophy. The usual renal manifestations are proteinuria of less than 1 g per day with bland urinary sediment and mild to moderate elevation of serum creatinine. The progression of renal impairment , though slow, may lead to ESRD. The adjusted risk for ESRD is reported to increase with levels of BP.

At histology, the arcuate and other larger arteries show fibrous intimal thickening, re-duplication of the internal elastic lamina and thickening of the media. The arterioles show hyaline arteriosclerosis with accumulation of hyaline in subendothelial areas which may extend into the media. This results in narrowing of the vascular lumen leading to ischaemic atrophy of the renal parenchyma. Early in the disease process, the glomeruli may be normal. With time there is complete glomerular obsolescence, tubular atrophy and interstitial fibrosis.

Treatment is aimed at keeping the BP less than 130/80 mmHg. Most patients need a combination of drugs including a diuretic. Non-pharmacological measures like weight loss, exercise, and salt restriction should also be prescribed. The principles of management of CKD due to benign arteriolar nephrosclerosis remain the same as those for any other cause of CKD.

SCLERODERMA RENAL DISEASE

Kidney involvement in systemic sclerosis may present as slowly progressive CKD, or scleroderma renal crisis (SRC). An occasional patient may present with rapidly progressive glomerulo-nephritis.

Factors predictive of SRC are diffuse skin involvement, rapidly progressive skin disease, new onset scleroderma (less than 4 years), anaemia, cardiac involvement, high-dose steroid use (>15 mg prednisolone per day), cyclosporine therapy, and presence of anti-RNA-polymerase antibody. Conversely, patients with anti-centromere antibody (ACA) are relatively protected. Occasionally, skin involvement may be minimal or even absent. In SRC, majority of patients present with accelerated/malignant hypertension, neuroretinopathy, headache, blurring of vision, encephalopathy, seizures, pulmonary oedema, micro-angiopathic haemolytic anaemia and thrombocytopaenia. Renal involvement manifests as oliguric ARF. Urinalysis shows non-nephrotic range proteinuria, haematuria and granular casts.

The characteristic renal lesions occur in the arcuate arteries. There is proliferation of myointimal cells of the vessel wall with luminal narrowing which is indistinguishable from the changes of hyperplastic endarteritis seen in malignant/accelerated hyper-tension. Fibrinoid necrosis of the vessel wall and thrombosis are also common. Patients who have never had a renal crisis may

show on renal histology re-duplication of elastic fibres, sclerosed glomeruli, tubular atrophy and interstitial fibrosis reflecting the chronic changes of scleroderma. Aggressive management of hypertension with angiotensin converting enzyme (ACE) inhibitors has improved the cumulative 1 year survival from 15% to 76%. Angiotensin II receptor blockers, alpha-blockers and calcium antagonists are also helpful for refractory hypertension. Dialysis is required in approximately two-thirds of the patients. Approximately half of these patients will eventually recover sufficiently to discontinue dialysis. Delayed renal recovery may occur more than 24 months after the crisis and so decisions about renal transplantation should be postponed until that time. Recurrence of SRC is uncommon in transplant patients.

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) may occur in a number of clinical conditions (**Table 1**). The most common cause is nephrotic syndrome associated with membranous nephropathy. RVT is known to aggravate proteinuria. In nephrotic syndrome, hypoalbuminaemia (serum albumin less than 2.5 g/dL) is an indicator of an underlying hypercoagulable state and increased risk of RVT.

Table 1: Causes of Renal Vein Thrombosis

Nephrotic syndrome: Increased plasma levels of factor V, VIII, XIII, fibrinogen, thrombocytosis, decreased plasma levels of factor XII, anti-thrombin III
Neoplasms: Renal cell carcinoma, Wilm's tumour
Hypercoagulable states: Deficiency of protein C/protein S, oral contraceptives, cyclosporine
Hypovolaemia
Extrinsic compression: Lymph nodes, tumours, pregnancy
Collagen vascular diseases: Systemic lupus erythematosus
Renal transplant
Blunt trauma
Others: Acute pancreatitis, amyloidosis, tricuspid insufficiency, constrictive pericarditis

The clinical features of RVT depend on the rapidity of onset and whether RVT is unilateral, bilateral or in a solitary functioning kidney. Acute RVT presents with fever, loin pain, haematuria and renal enlargement. Deterioration of renal function has been described in bilateral RVT and in patients with a single kidney. Pain and swelling in the ipsilateral testicle may occur in males. The chronic form is usually clinically silent, but may present with increase in proteinuria and recurrent pulmonary thromboembolism.

Imaging studies are required to establish the diagnosis of RVT. Conventional ultrasonography and renal Doppler studies have a low sensitivity and may show a swollen echogenic kidney with increased resistive indices. CT and magnetic resonance imaging (MRI) often provide a definitive diagnosis, thus avoiding the need for renal venography.

Resolution of acute RVT has been demonstrated with thrombolysis, using either streptokinase or urokinase given systemically. Anticoagulants are recommended for prevention of pulmonary embolism. In nephrotic syndrome, they are continued until the serum albumin is more than 2.5 g/dL. If pulmonary embolism has occurred, initial anticoagulation with heparin for 5 to 7 days followed by oral drugs is recommended. Once oral anti-coagulant therapy is established, the prothrombin time should be kept at about one and one-half to two times normal. Patients with RVT in pregnancy are best treated with heparin alone. If anti-coagulation is contraindicated and pulmonary embolism has occurred, inferior vena cava filters may be used. Thrombectomy in the treatment of RVT has no advantage over anti-coagulation and is indicated only in presence of renal cell carcinoma.

RENAL ARTERY STENOSIS

Renal artery stenosis (RAS) is narrowing of the lumen of the main renal artery or one of its branches leading to impaired blood flow to the kidneys. It may be unilateral or bilateral. The commonest cause in the elderly is atherosclerotic renal artery disease (bilateral in half the cases) while in young females the commonest cause is fibromuscular dysplasia. Non-specific aortoarteritis or Takayasu's arteritis is a common cause of RAS below the age of 40 years in Afro-Asian countries and Japan.

The reported incidence of RAS as cause of hypertension varies between 0.6% and 5% depending on the selection criteria and modalities of diagnosis used. The activation of renin angiotensin system and resultant hyper-reninaemia play a major role in initial phase of renovascular hypertension. Over time, salt and water retention following a sustained hyper-reninaemia state take over as the mechanism for hypertension at which stage renin levels may return to normal. Stenosis in the affected renal artery leads to reduction in post-stenotic pressure and renal perfusion. The kidney tries to restore the perfusion by autoregulation but if the stenosis persists, it leads to progressive loss of kidney function and the clinical entity is called 'ischaemic nephropathy'.

Clinical clues to the presence of RAS include, abrupt onset of hypertension before 30 or after 50 years of age, accelerated/malignant hypertension, treatment-refractory hypertension, worsening of renal function after initiating ACE inhibitors, recurrent flash pulmonary oedema, unilateral small kidney and a biphasic renal bruit with systolic and diastolic components.

A number of non-invasive modalities are used for the diagnosis of RAS with varying sensitivity and specificity (**Table 2**). Renal angiography, however, remains the gold standard as it provides direct visualisation of the affected renal artery and corrective angioplasty and stenting of the stenotic lesion can be performed in the same session. Colour Doppler ultrasonography is the best non-invasive screening test with a sensitivity of about 70%. The major limitation is that it is highly operator dependent and is technically difficult in obese patients. The sensitivity also decreases in the presence of multiple renal arteries, distal lesions, and total occlusion. In functionally significant renal artery stenosis, glomerular filtration rate

Table 2: Investigations in Diagnosis of Renal Artery Stenosis

Test	% Sensitivity	% Specificity
Colour Doppler duplex sonography	Variable	Variable
Radio-isotope renography	65 to 75	65 to 85
Spiral computed tomography angiography	88 to 98	90 to 95
Magnetic resonance angiography	95 to 100	93 to 95
Conventional or digital subtraction angiography	100	100

is maintained by stimulation of the renin-angiotensin-aldosterone axis. ACE-inhibitors cause reduction in renal blood flow and GFR and their use in association with ^{99m}Tc-labeled DTPA or ^{99m}Tc-labeled MAG3 scans are useful for the diagnosis.

Management

Treatment of renovascular hypertension should include ACE inhibitors/angiotensin receptor blockers (ARBs), and address all modifiable cardiovascular risk factors like hyperlipidaemia, obesity and smoking. ACE inhibitors may cause a rise in creatinine in patients with bilateral RAS and in RAS of a single functioning kidney. Revascularisation therapy with angioplasty with/without stent placement is indicated if adequate BP is not achieved despite optimal medical therapy or if the serum creatinine rises despite adequate BP control. A favourable response to intervention is seen in patients with rapid decline of renal function. Despite revascularisation, cure of hypertension is unusual, though seen more often in fibromuscular dysplasia than in atherosclerotic renal artery disease. Renal functional recovery or stabilisation of renal function is seen in approximately 70% of the patients. Surgical revascularisation is indicated in patients with total occlusion of the renal vessel in whom renal angioplasty/stenting is not possible. Nephrectomy has a role to play when a non-functioning kidney is implicated in the cause of RVH. Revascularisation therapy is best avoided if the resistivity index on Doppler sonography is more than 80%. The likely reason for the poor response is structural alterations in smaller arteries and arterioles distal to the RAS which manifests as increased vascular resistance.

19.10 Polycystic Kidney Disease and Inherited Tubular Disorders

PP Varma, Ranjith Nair

DISORDERS OF CYSTIC NATURE

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Definition

Autosomal dominant polycystic kidney disease (ADPKD) is a systemic disorder with autosomal dominant inheritance and is a result of mutation in PKD 1 or PKD 2 gene. The disease manifests with renal and extra-renal manifestations.

Epidemiology

The incidence varies from 1 in 400 to 1 in 1000 individuals and it occurs in all races and ethnicities. It accounts for 5% of all cases of end-stage renal disease (ESRD) across the world.

Genetics

ADPKD is caused by mutations in at least 2 different genes. Mutations in the PKD 1 gene which is present on the short arm of chromosome 16 (16p13), accounts for 85% of all cases, while the PKD 2 gene which is present on the long arm of chromosome 4 (4q21), accounts for the rest. Ninety per cent of all cases are inherited in an autosomal dominant fashion, while the rest are likely to be due to spontaneous mutations.

Polycystin proteins are expressed in virtually all tissues. The PKD 1 gene codes for the protein Polycystin 1 while the PKD 2 gene codes for polycystin 2. Most mutations in either gene are single base changes, insertions or deletions of a small number of base pairs, resulting in truncated proteins and loss of function. These proteins are believed to function either independently or as a part of a complex, to regulate tubular epithelial cell gene transcription, differentiation, cell-to-cell interaction and apoptosis. Disruption of these proteins can lead to epithelial dedifferentiation, uncontrolled epithelial proliferation, apoptosis, altered polarity of tubular cells, with disorganisation of the extracellular matrix and excessive fluid secretion by the epithelial cells. They have also been localised to the primary cilia of the tubular epithelial cell which act as mechanosensors which transduce luminal signals into cellular responses that control cell proliferation, adhesion, differentiation and apoptosis.

The penetration of these mutations is 100%. However, there is marked variability in the phenotypic expression of the disease within individuals of the same family. Less than 5% of nephrons become cystic. This variability in expression and focal nature of the renal disease with its extra-renal manifestations has been explained by the 'two hit hypothesis'. This hypothesis implies that the presence of a germ line mutation is on its own not sufficient for cystogenesis, but a 'second somatic mutation' is essential to inactivate the other PKD allele.

Mutations of the polycystin 2 gene usually result in a milder form of the disease, with an older age at diagnosis and later onset of hypertension and renal failure as compared to PKD 1 mutations.

CYSTOGENESIS

Renal cysts can arise from any segment of the nephron. About 10% of all cysts retain the morphologic characteristics of the segment they arise from. They initially arise as outpouchings from the tubules, which are initially filled with glomerular filtrate, however, they separate from the tubule as they increase in size, and thereafter grow in size due to exaggerated cell proliferation due to loss of cell-to-cell interaction, associated with increased secretion of fluid within the cyst lumen which is exclusively due to transepithelial secretion of water and solutes. Hence, cysts are not dead ends of tubules which store urine generated by proximal segments of the tubules, but they are complex structures that proliferate, synthesise proteins and secrete fluid and electrolytes and show apoptosis. The cysts are present throughout the renal parenchyma and are variable in size. They tend to compress and distort the normal renal parenchyma in between as they enlarge in size.

Clinical Features

There is marked variability in the course of the disease, starting from the age at detection to its course within members of the same family and between PKD 1 and PKD 2 gene mutation carriers. The mean age at presentation is 55 years in PKD 1 and 71 years in PKD 2 disease. However, marked phenotypic variability is the hallmark of ADPKD.

One-third of adults are asymptomatic and their disease is detected during ultrasound of the abdomen conducted for an unrelated cause. With the increasing availability of sonology facilities, this proportion is likely to increase with time. The commonest presenting feature in symptomatic patients is flank or back pain, which can occur in 60% of adults. The pain is usually chronic dull aching in nature. This pain is more common in patients with large kidneys with high cyst burden. The pain could get acute in case of infection or haemorrhage into a cyst or due to renal colic due to a calculus or clot.

Hypertension is detected in 80% of adults and in up to 30% of all children with ADPKD. It is usually due to increased activity of the renin-angiotensin system. Hypertension can precede renal dysfunction by decades in adults. Hypertension in ADPKD correlates with the renal volume.

Gross haematuria can occur in 50% of adults. It is probably caused by cyst rupture into the pelvicalyceal system. More than half of all subjects with gross haematuria relate it to an inciting event such as infection or trauma. In case of associated colicky pain, infection, clot colic or renal calculus needs exclusion. There can be cyst haemorrhage within the kidney which does not communicate with the pelvicalyceal system (PCS) and could be clinically silent but for pain in the flank.

Renal concentration defects can be demonstrated in potentially all adults with ADPKD, even in the presence of normal glomerular filtration rate (GFR). Nephrolithiasis occurs in 20%

of patients. Urinary tract infections are a common occurrence in ADPKD patients. Urine cultures may be sterile in isolated cyst infections, while blood cultures would be positive in such cases. Cyst infections due to gram-negative organisms can be difficult to eradicate, requiring prolonged courses of parenteral antibiotics. Lipophilic antibiotics like fluoroquinolones, trimethoprim, clindamycin and macrolides accumulate well within the cyst, and can be used to eradicate cyst infection.

Extra-renal manifestations are common. Hepatic cysts can occur in 60% to 75% cases. Most patients with hepatic cysts are asymptomatic with normal liver function tests, unless there is haemorrhage or infection in the cysts. Hepatic cysts occur with equal frequency in either gender but they tend to be larger in women. Cysts can also be demonstrated in the seminal vesicles (60%) and prostate (10%) besides pancreas (10%) and arachnoid cysts (5%). Cysts have also been described in the ovaries, testes and the spleen. Colonic diverticuli, abdominal wall and inguinal hernias occur more commonly in ADPKD patients than the general population.

There is four-fold risk of intra-cerebral haemorrhage from an arterial aneurysm in ADPKD patients. Intracranial aneurysms can occur in up to 10% of these patients on routine magnetic resonance angiography (MRA) screening. However, most of these are small and usually do not enlarge or rupture with time. Aneurysmal haemorrhage occurs preferentially in young individuals (<50 years), in those with family history of intracranial haemorrhage, those with aneurysms larger than 10 mm in diameter and those with uncontrolled hypertension. There can also be cardiac involvement in the form of aortic root and annulus dilatation. Mitral valve prolapse can be found in 25% of all cases.

Diagnosis

Ultrasound imaging is the primary tool for diagnosis, in conjunction with family history and gene linkage analysis if needed. The Modified Ravine's criteria can be used to diagnose the disease in younger individuals with a family history of ADPKD. The presence of 2 cysts in one or both kidneys together below 30 years of age, 2 cysts in each kidney in the 30-59 years age group and 4 cysts per kidney in those above 60 years of age has a 95% sensitivity and 92% specificity for the diagnosis of ADPKD 1 in those at risk. For a child younger than 18 years any renal cyst is highly suspect for the disease. False negative ultrasound has not been reported in individuals above 30 years of age from families with ADPKD 1. Presence of hepatic cysts and cysts in other abdominal organs strengthens the diagnosis on ultrasound.

Contrast enhanced computed tomography (CECT) and magnetic resonance imaging (MRI) of the kidney are more sensitive diagnostic tools for the diagnosis of ADPKD. Computed tomography (CT) has the advantage of identifying calcification in the cyst walls and renal calculi, besides haemorrhage within the cysts. MRI can be used to measure the volume of the kidney and predict the decline of renal function with time.

Genetic linkage analysis and mutational screening can be done in isolated cases, especially in young individuals with family history of ADPKD with normal imaging studies who wish to be kidney donors.

Treatment

There is currently no treatment available which has been proved to inhibit cystogenesis or inhibit cyst enlargement. Hence, management of these patients is purely supportive. Control of hypertension is an important measure, with the target of 135/85 mmHg or less as per the JNC VII criteria. All classes of anti-hypertensives can be used, but for diuretics. No single class of anti-hypertensive has been shown to be superior to the other, though many authors prefer to use angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs).

Complications like urinary tract infection and cyst infection should be preferably treated with lipophilic antibiotics like fluoroquinolones, trimethoprim or macrolides. Pain relief due to cyst haemorrhage, clot colic or calculus may need opioids. Occasionally, surgical excision of haemorrhagic or infected cysts may become essential.

There is faster and earlier progression to ESRD in ADPKD 1 as compared to ADPKD 2. Patients of ESRD due to ADPKD have been found to have a survival advantage over patients with ESRD due to other causes while on dialysis (haemodialysis and peritoneal dialysis). However, the survival of these patients post-transplantation is similar. Occasionally nephrectomy may become essential prior to renal transplantation in these patients due to the large size of the native kidneys or because of complications, such as stones or non-resolving cyst infection.

Animal studies show a role for vasopressin 2 (V2) receptor antagonists (Vaptans), anti-proliferative drugs (Sirolimus), statins and Somatostatin in reducing the rate of cyst enlargement. Regression of liver or renal cysts in native kidneys has been observed in renal transplant recipients on sirolimus based regimen *versus* calcineurin inhibitor (CNI) based regimen. These drugs are currently being tried in human trials.

Table 1 compares and contrasts the various inherited disorders which have a cystic presentation.

DISORDERS OF TUBULAR ELECTROLYTE HANDLING WITHOUT HYPERTENSION

Various inherited tubular disorders present with acid-base abnormalities and dyselectrolytaemia without hypertension. Gitelman's syndrome is the commonest inherited tubular disorder of these. It presents in early adulthood with metabolic alkalosis, hypokalaemia, hypomagnesaemia and hypocalciuria. It mimics thiazide diuretic abuse in its clinical presentation, while Bartter's syndrome which is a relatively rare entity, presents in early infancy with polyuria, polydipsia and failure to thrive. It mimics loop diuretic abuse in its clinical presentation. The underlying transport defect in Bartter' syndrome is at the thick ascending limb of the loop of Henle, while in Gitelman's syndrome it is at the level of the distal convoluted tubule (DCT). **Table 2** compares and contrasts these disorders which present without hypertension.

HEREDITARY TUBULAR DISORDERS WITH HYPERTENSION

Liddle's and Gordon's syndrome occur due to salt retention and due to inherited abnormalities in the distal tubule. Liddle's syndrome presents with metabolic alkalosis and hypokalaemia while Gordon's syndrome presents with metabolic acidosis and hyperkalaemia. **Table 3** compares and contrasts both the syndromes.

Blood pressure	Normal or low, resistant to Angiotensin II infusion	Normal or low	Normal	Normal or low
Electrolyte imbalance	Severe hypokalaemia, hyponatraemia	Hypokalaemia, hyponatraemia hypomagnesaemia, hypocalciuria	Hyperkalaemia, hyponatraemia	Hypomagnesaemia, hypocalcaemia
Plasma renin activity	Very high	Very high	High	NA
Treatment	Liberal salt; K^+ and Mg^{2+} intake for life K^+ sparing diuretics in high doses NSAIDs	Liberal salt; K^+ and Mg^{2+} intake for life K^+ sparing diuretics in high doses	Aggressive salt repletion Control hyperkalaemia Fludrocortisone and carbenoxolone in the AD variant	Oral magnesium supplementation
Mimickers	Frusemide abuse	Thiazide abuse	—	Aminoglycoside, Cisplatin toxicity

AR = Autosomal recessive; AD = Autosomal dominant; NA = Not applicable; NSAIDs = Nonsteroidal anti-inflammatary drugs.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA) type 1 and 2 can be inherited or secondary to other causes. Normally bicarbonate is reclaimed back but in type 1 and 2 RTA, HCO_3^- is lost due to tubular defect and in lieu Cl^- is reabsorbed and serum Cl^- levels rise. Due to an excess load of HCO_3^- at the distal tubule, excessive K^+ is lost in the urine. Therefore, patients present with hypokalaemia and hyperchloraemic metabolic acidosis. The most common form of RTA, Type 4 is always acquired secondary to other causes. It is associated with hyperkalaemia and hyperchloraemic metabolic acidosis.

Type 1 RTA

Type 1 or classic distal RTA (dRTA) occurs due to either secretory or permeability defects. In secretory defects there is defective secretion of protons from the collecting duct and in permeability defects though the proton pump functions normally, however,

Table 3: Hereditary Tubular Disorders with Hypertension

	Liddle's Syndrome	Gordon's Syndrome
Mode of inheritance	AD	AD
Chromosome	16p13	12p13, 17q21
Protein	Excessive activity of α, β or γ-sub-units of ENaC	WNK 1 and WNK 4 kinases-increased activity of thiazide sensitive NCCT
Metabolic abnormality	Metabolic alkalosis, hyperaldosteronism	Metabolic acidosis
Electrolyte abnormality	Hypokalaemia	Hyperkalaemia
Plasma renin activity	Very low	Low
Treatment	Na^+ restriction K^+ supplementation Triamterene	Salt restriction Thiazide diuretics

AD = Autosomal dominant; NCCT = NaCl co-transport; ENaC = Epithelial Na^+ channel.

due to the excessive permeability the high intratubular H^+ ion concentration dissipates rapidly. In Type 1 classic dRTA the kidneys cannot acidify the urine to pH<5.5 in the presence of metabolic acidosis. Urinary PCO_2 does not rise despite HCO_3^- supplementation. The chronic metabolic acidosis leads to reduced renal production of citrate. The hypocitraturia in the presence of hypercalciuria predisposes to nephro-calcinosis and nephrolithiasis in Type 1 RTA which leads to osteomalacia or rickets. dRTA could be sporadic or hereditary. Most autosomal recessive varieties present in infancy with severe symptoms of acidosis, dehydration, failure to thrive and nephrolithiasis related kidney dysfunction. However, the autosomal dominant and sporadic varieties usually present in adulthood and are often detected incidentally during evaluation for nephrolithiasis. Sjögren's syndrome is the commonest cause of acquired dRTA in adults. Treatment is done with the help of sodium bicarbonate given in a dose of 1-4 mEq/kg body weight.

Type 2 RTA

Type 2 or proximal RTA occurs due to the excessive loss of bicarbonate from the proximal tubule. The defective acidification can exist in isolation but more commonly it coexists with generalised proximal tubular dysfunction, as a part of Fanconi's syndrome, when it is associated with glycosuria, amino aciduria, enzymuria, hypercitraturia and loss of various electrolytes like Na^+, K^+, Ca^{2+}, and PO_4^{3-}. It could occur as a part of inherited disorders like Wilson disease, cystinosis, tyrosinaemia, galactosaemia, hereditary fructose intolerance, glycogen storage disease type I, and Lowe's syndrome. Acquired forms of Fanconi's syndrome occur with heavy metal toxicity (lead, cadmium), use of outdated tetracyclines, cisplatin, aminoglycosides, ifosfamide, besides dysproteinaemias like multiple myeloma, light chain deposition disease and amyloidosis.

The presence of citrate in the urine in Type 2 RTA prevents the precipitation of calcium and oxalate within the tubules, and hence, nephrolithiasis is not a usual phenomenon. It is difficult to restore the pH to normal despite large amounts of alkali supplementation, consequent to the proportionately higher HCO_3^- loss in urine as the serum HCO_3^- begins to rise. The fractional excretion of HCO_3^- is usually more than 15% until the serum HCO_3^- falls to 15 to 17 mmol/L. At this level a new transport maximum for HCO_3^- is established and all bicarbonate is reabsorbed and the urine can be acidified to pH<5.5 because bicarbonaturia ceases. Thiazides are useful since they cause volume contraction stimulating bicarbonate reabsorption.

Type 4 RTA

Type 4 RTA is a variety of dRTA that is invariably acquired, usually always associated with moderate renal dysfunction and hyperkalaemia. It leads to hyperchloraemic metabolic acidosis and salt wasting, which is evident during salt restriction. It is usually associated with generalised distal nephron dysfunction. It can occur either due to voltage defect or but commonly due to mineralocorticoid deficiency of primary and secondary nature. Possible mechanisms are: (i) destruction of juxtaglomerular cells; (ii) decreased sympathetic denervation of the juxtaglomerular apparatus; (iii) decreased production of prostacyclin, causing a decrease in renin-aldosterone production; and (iv) primary hypoaldosteronism. Aldosterone increases Na^+ absorption and the negative intratubular potential. It also increases luminal membrane permeability to potassium and stimulates basolateral Na^+/K^+/ATPase, causing increased urinary potassium losses. Because aldosterone also directly stimulates the proton pump, aldosterone deficiency or resistance would be expected to cause hyperkalaemia and acidosis. Another major factor in decreasing net acid excretion is the inhibition of ammoniagenesis due to hyperkalaemia. Secondary mineralocorticoid deficiency is usually due to diabetes mellitus, tubulointerstitial nephritis, non-steroidal anti-inflammatory drugs use and monoclonal gammopathy. Hyporeninaemic hypo-aldosteronism usually presents in the elderly (mean age 65 years) with asymptomatic hyperkalaemia in the majority, and arrhythmia and weakness in 25% of cases. It is associated with renal insufficiency in the majority (70%), however, both hyper-chloraemic metabolic acidosis (50%) and hyperkalaemia are disproportionate to the degree of renal dysfunction.

It could occur due to resistance to the action of aldosterone either due to an intra-cellular mineralocorticoid receptor (hMR) resistance [Pseudohypoaldosteronism (PHA) type I] of autosomal dominant inheritance or due to an autosomal recessive inherited defect in the epithelial Na channel (ENaC) subunits (PHA type I). PHA type II is acquired in an autosomal dominant manner and is associated with normal renal function and hypertension, absence of salt wasting and diabetes mellitus and a kaliuretic response to mineralocorticoid administration.

Aldosterone antagonists, drugs like calcineurin inhibitors (CNIs) which interfere with the Na^+K^+ ATPase in the cortical collecting duct (CCD), or drugs like amiloride, triamterene, trimethoprim and pentamidine, which interfere with the Na^+ channel in the CCD also cause voltage defects in the distal tubule and can lead to generalised distal tubule dysfunction. Diseases associated with tubulo-interstitial nephritis and renal insufficiency like lupus nephritis, allergic interstitial nephritis, obstructive uropathy, sickle cell disease can all lead to generalised distal tubule dysfunction.

The decision to treat is often based on the severity of hyperkalaemia. Those with primary glucocorticoid and mineralocorticoid deficiency should receive both in replacement doses. Alkali therapy or loop diuretics will induce

Table 4: Heriditary Renal Tubular Acidosis

Parameter	Type 1 (Distal)	Type 2 (Proximal)	Type 4 (Distal)
Mode of inheritance	AR, AD	AR	AR, AD
Chromosome	7q33, 8q22, 17q21 (AD)	4q21	—
Defective protein	Defective H^+- ATPase in the CCD Defective HCO_3^-/Cl^- exchanger Defective Na^+/H^+ antiporter CA II deficiency	Defective basolateral Na^+-HCO_3^- exchanger in the proximal tubule	Defective α/β/γ-subunits of ENaC Defective intracellular mineralocorticoid receptor (hMR)
Age at presentation	AR: Infancy; AD: adolescence and early adulthood	Young adults	AR: infancy AD: young adults

Electrolyte abnormality	Hypokalaemia	Hypokalaemia	Hyperkalaemia
Associations	Nephrocalcinosis, nephrolithiasis, osteomalacia	Hyperphosphaturia, hyperuricosuria, hypercalciuria, aminoaciduria, glycosuria	Hypotension, renal salt wasting, raised renin and aldosterone
Extra-renal manifestations	Sensorineural deafness inAR form, severe mental retardation in CAII defective form	Ocular phenotype with cataracts, glaucoma, band keratopathy, mental retardation	Vomiting, failure to thrive, respiratory distress in the AR variety
Treatment	Supplementation of 2 mmol/kg/day HCO_3^-, K^+, citrate is preferred	Supplementation of K^+ in large amounts, 5-15 mmol/kg/day HCO_3^-, Vit D, thiazides	High salt intake, supplement K^+

Table 5: Differences in the Various Types of Renal Tubular Acidosis (RTA)

Parameter	Type 1 (Distal)	Type 2 (Proximal)	Type 4 (Distal)
Serum K^+	Low	Low	High
Urine pH in the presence of acidosis	>5.5	<5.5	variable
Fractional HCO_3^- excretion	2 to 5%	10 to 15%	5 to 10%
Fanconi's syndrome	Absent	Present	Absent
Urine net charge	Positive	Positive	Positive
Response to therapy	Responds promptly	Poor response	Moderate response
Associations	Nephro-calcinosis	Fanconi's syndrome	Renal insufficiency

K^+ and Na^+ loss. Drugs if found to be the cause of hyperkalaemia, should be discontinued (which may not always be possible). K^+ binding resins can be utilised to reduce serum K^+ levels. In very severe cases, fludrocortisone 0.1 to 0.3 mg per day can be used with extreme caution once cardiac failure and volume overload are excluded.

Table 4 highlights the salient features of the various inherited forms of RTA.

Table 5 compares and contrasts the different forms of RTA.

HEREDITARY NEPHROGENIC DIABETES INSIPIDUS

It is a rare monogenic disease which manifests in early infancy with severe polyuria, dehydration and failure to thrive. It can be acquired by an X linked (Type 1) or AD/AR (Type 2) mode of inheritance. The X linked variant accounts for >90% of all

Tabel 6: Monogenic Diseases of Tubular Function

Parameter	Cystinuria	Hartnup Disease	Dent's Disease	Renal Glycosuria	Vit D Dependent Rickets
Mode of inheritance	AR	AR	XLR	AR	Type 1: AR
Chromosome	2p16, 19q13	5p15	Xp11	16p11	12q14
Defective protein	Dibasic amino acid transporter	Defective transport of neutral amino acids	Voltage gated Cl^- channels	Na^+-glucose cotransporter	$25(OH)D_3$ 1α hydroxylase
Incidence	1: 7000	Rare	Rare	—	
Clinical manifestations	Cystine stones, ureteral obstruction, urinary infections	Aminoaciduria Extra-renal: cerebellar ataxia, pellagra-like skin lesions	Proteinuria Hypercalciuria Nephrocalcinosis Nephrolithiasis	Usually asymptomatic Rarely polyuria due to glucose load	Rickets, osteomalacia
Treatment	Hydration - urine output >2.5 L/day Urine alkalinisation Na^+ restriction Chelation with Captopril, Penicillamine or Tiopronin D_3	Protein-rich diet Nicotinamide supplements	Na^+ restriction Thiazide diuretics	—	Physiological doses of $1,25(OH)_2$

cases and occurs due to a defect in the type 2 vasopressin receptor in the collecting duct. The rest are due to AD/AR mutations in the aquaporin 2 (AQP2) channels which causes retention of these water channels within the cytoplasm of the cell. These mutations lead to an inability to concentrate the urine despite the presence of high plasma levels of vasopressin.

It occurs in infancy and is associated with hypernatraemia due to free water loss. The hypernatraemia can be associated with seizures and higher mental function changes.

These patients can produce up to 20 litres of urine in a day, and supplementation of adequate fluids along with thiazide diuretics and salt restriction is the only solution to their problem.

MONOGENIC DISEASES OF TUBULAR FUNCTION

Occasional monogenic defects in the proximal tubular absorption of various amino acids, glucose and production of vitamin D can occur. Cystinuria is the most common among these disorders. It presents with cystine and dibasic amino acid stones. Vitamin D dependent rickets occurs due to defective production of activated vitamin D by the tubule. The features of these defects are highlighted in **Table 6**.

19.11 Dialysis for Chronic Renal Failure

NK Hase

INTRODUCTION

Chronic renal failure [Chronic Kidney Disease (CKD) stage 5] is an irreversible deterioration in renal function to a degree incompatible with life, in the absence of some form of renal replacement therapy (RRT), either dialysis or transplant. The kidney function is usually less than 10% to15% of its capacity. The estimated glomerular filtration rate (eGFR) is less than 15 mL/min. The number of patients suffering from CKD is growing in India. Incidence of CKD has doubled in last 15 years. The mortality among CKD patients remains 10 to 20 times higher than general populations. Hence, focus in recent years has shifted towards optimising care of these patients during earlier stages of CKD. It is recommended that all patients with CKD should be referred to a nephrologist early in the course of their disease preferably before plasma creatinine exceeds 1.2 mg/dL and 1.5 mg/dL in women and men, respectively or eGFR is less than 60 mL/min/1.73 m^2. Late referral to nephrologists (i.e. <3 months before the start of dialysis therapy) is associated with higher mortality after initiation of dialysis. The renal replacement therapies, which are well established, are chronic maintenance haemodialysis, chronic peritoneal dialysis and renal transplant. The renal transplant is the treatment of choice for end-stage kidney disease (ESKD).

DIALYSIS

Thomas Graham, Professor of Chemistry at Anderson University in Glasgow coined the term 'dialysis' in 1861. George Haas from Germany performed first successful human dialysis in 1924. Kolf and Berk from Netherlands developed the first practical human haemodialysis machine in 1943. This was rotating drum artificial kidney consisted of 30 to 40 metres of cellophane tubing in a stationary 100 litres tank. From 1943 to 1960, use of dialysis was restricted to acute renal failure (ARF). Discovery of arteriovenous shunt by Quinton and Scribner 1960 and forearm arteriovenous fistula by Brescia and Cimino in 1966 extended this therapy to chronic end-stage renal failure. Chronic maintenance haemodialysis has emerged now as one of the well-established life-sustaining therapy. In India, haemodialysis was first started in 1962 at Christian Medical College, Vellore. Subsequently, several centres in the country developed this facility. Estimates reveal that renal units in this country are offering treatment to 80 to 100 new patients with ESKD per million populations, each year.

Initiation of Dialysis

Indication for dialysis is given in **Table 1**. When dialysis was first available it was only offered to patients who are uraemic and with risk of imminent death. Current trend is to start dialysis early when patient is healthy. The advantages of starting early are improved rehabilitation, less complications, better nutritional status, improved quality of life (QOL) and survival.

Table 1: Indications for Initiating Maintenance Dialysis

Absolute Indication to Start Dialysis

- Fluid overload or pulmonary oedema refractory to diuretics
- Uraemia: Pericarditis, persistent nausea, vomiting, bleeding due to platelet dysfunction, progressive uraemic encephalopathy or neuropathy with signs of confusion, asterixis, myoclonus or seizures
- Accelerated hypertension poorly responsive to anti-hypertensive medication BUN >100 mg/mL and serum creatinine above 10 mg/dL

Other Recommendations

- K/DOQI: Dialysis should be initiated when weekly renal Kt/V urea falls below 2.0 (equivalent to renal clearance of urea of 7 mL/min, renal creatinine clearance of 9 to 14 mL/min and GFR approximately 10.5 mL/min/1.73 m^2, unless complete absence of clinical signs or symptoms of uraemia serum albumin normal and stable and adequate nutrition
- 2005 European Best Practice Guidelines: Dialysis should be initiated: (1) when GFR is <15 mL/min and there are one or more symptoms or signs of uraemia; (2) in all, before GFR has fallen to 6 mL/min/1.73 m^2 irrespective of symptoms; diabetic patients may benefit from an earlier start

Selection of Dialysis

Selecting one of the modalities is influenced by a number of factors, such as availability, convenience, comorbid conditions, socio-economic and haemodynamic stability. Most patients can be treated with either haemodialysis (HD) or peritoneal dialysis (PD). Continuous ambulatory peritoneal dialysis (CAPD) is preferred in young children, elderly patients in whom vascular access is not available and haemodynamically unstable. Home dialysis is optimal in young independent otherwise well patients who are supported by a devoted partner. Current thinking is a concept of integrated care. Rather thinking of one modality of treatment *versus* another it is best to think the patient's life span on RRT. A single patient may utilise all modalities so it is sensible to use each to its optimal benefits. Start with PD when residual kidney function is present in the beginning. Later shift patient on HD when he becomes anuric.

Principles of Dialysis

Diffusion

If two solutions of different concentrations are separated by a semipermeable membrane, solution will move from the side of higher concentration to the side of lower solute concentration. This process of solute movement on a concentration gradient is called diffusion. The rate of diffusion is greatest when concentration is highest. This is the main mechanism for removal of urea, creatinine and for the replenishment of serum bicarbonate. Other determinants of diffusion are temperature of solution, viscosity, size of molecules and membrane characteristics.

Ultrafiltration

This is the convective flow of water and dissolved solutes down the gradient caused by hydrostatic or osmotic forces. Ultrafiltration is mainly for removal of water from body.

Clinically, this movement of diffusion and ultrafiltration takes in and out of blood, across a semipermeable membrane. If blood is exposed to an artificial membrane outside the body, i.e. extracorporeal circulation, the process is called haemodialysis or haemofiltration; if exchange of molecules occurs across the peritoneal membrane, the process is called PD.

HAEMODIALYSIS

Components of Haemodialysis

Haemodialysis system can be broadly divided into a blood circuit and a dialysis solution circuit which meet at the dialyser. The blood circuit begins at vascular access. From vascular access blood is pumped through inflow bloodline called as 'arterial' line to the dialyser, back to vascular access by outflow (venous) blood line (**Figure 1**).

Vascular Access

Vascular access is lifeline for patient and achilles heel of HD. The blood access help to draw blood continuously from the patient at required rate of between 200 to 400 mL per minute and return to the patients after circulating it through artificial kidney.

Temporary vascular access

Patients requiring dialysis for a shorter period, such as those with acute reversible renal failure and patients waiting for permanent access that requires dialysis urgently, need temporary access. Temporary vascular access of choice is right internal jugular double lumen catheter inserted percutaneously. Subclavian veins should be used only when jugular vein options are not available, femoral vein should be used only in emergency when patient is breathless.

Permanent vascular access

Native arteriovenous fistula (AVF), non-dominant radio-cephalic is vascular access of choice for long-term maintenance haemodialysis. AVF has the longest life with least complications. Arm veins should be preserved in all patients likely to require dialysis. AVF should be constructed when GFR falls below 25 mL/min or within one year of anticipated need for dialysis. AVF takes 3 to 4 months for development. AVF should not be used at least one month after creation. Use before the venous wall matures can shorten the life of an AVF. If a native venous fistula cannot be created, tubal material can be grafted under the skin between the artery and the vein. Several graft materials (autologous, heterogeneous and synthetic) have been tried including saphenous vein, bovine carotid artery and polytetrafluoroethylene (PTFE). PTFE grafts are the most commonly used.

Dialyser

A dialyser, artificial kidney (filter) consists of a rigid polyurethane-shell containing hollow fibres (capillaries) or sheets (parallel plates) of dialysis membrane. Commonly used membranes have cuprophan, cellulose acetate and highly porous synthetic copolymer membranes like polyacrylnitrite (PAN), polysulphone, polymethylmethacrylate. The non-

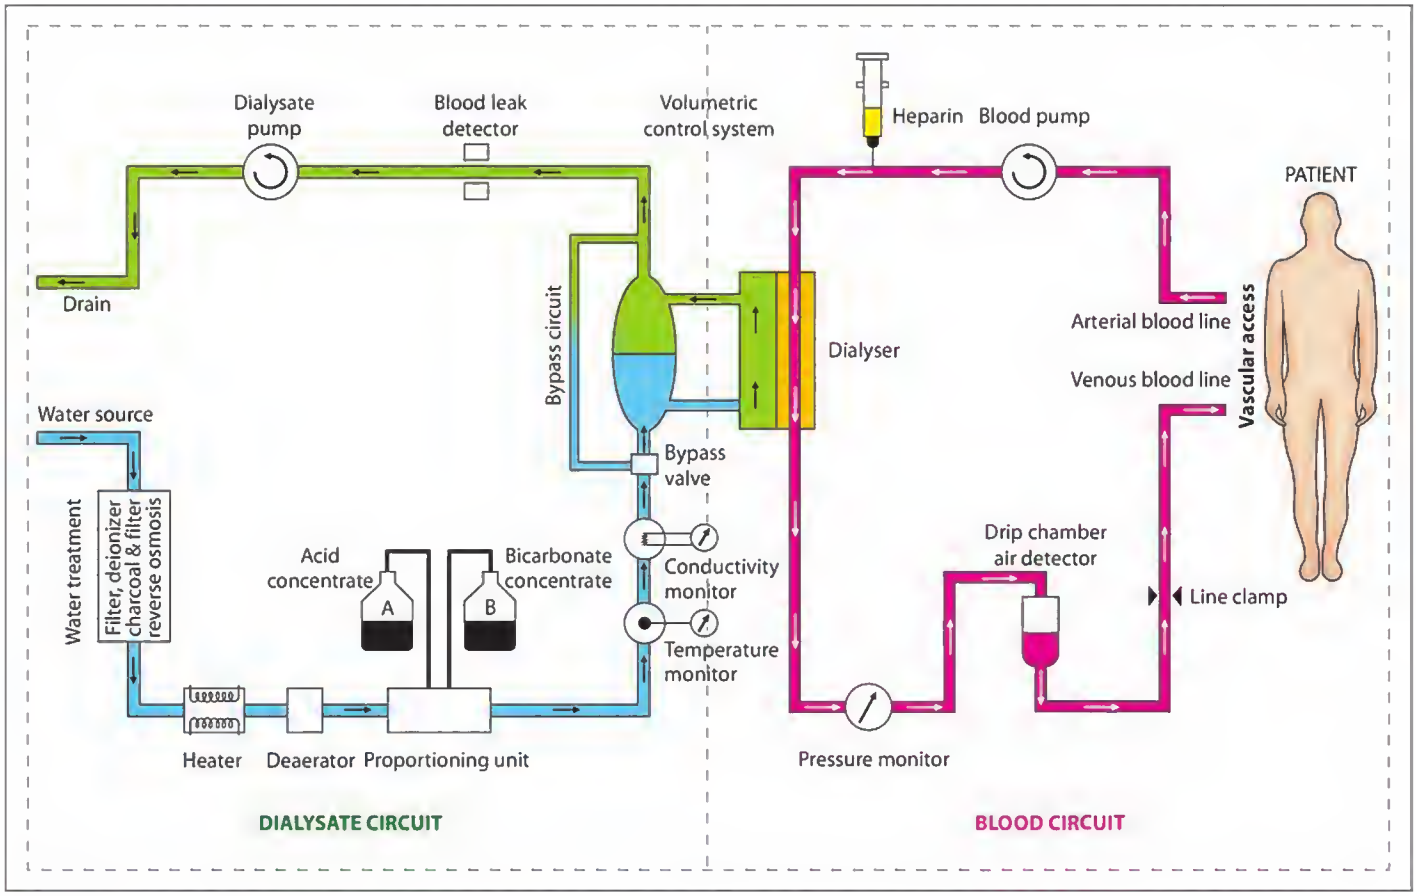

Figure 1: Components of haemodialysis.

synthetic cellulose membranes have become relatively uncommon as they activate the alternate complement pathway, lead to leuco-agglutination and cytokine release, i.e. they are bio-incompatible. The synthetic polymer membranes are preferred, they exhibit better biocompatibility, improved ultrafiltration characteristics and increased solute clearance, especially in middle-molecule weight range. Ideal dialyser should have high clearance for small and middle-molecule toxins, adequate ultrafiltration capacity, non-toxic, minimum priming volume, biocompatible, reusability and low cost. All over the world dialysers are reused.

Haemodialysis Machine

The HD machine prepares and provides dialysate to dialyser, monitors dialysate quality and controls and monitors ultrafiltration from the patients. It can be divided into four major components:

(i) Water preparation system: treated pure water is delivered to machine, is heated to body temperature by heater, deaeriated and then delivered to the proportioning systems;

(ii) Proportioning system mixes dialysate with treated water (1:34) and pumped to the dialyser. Proportionating system monitors electrical conductivity of dialysate;

(iii) Modern machines have volumetric ultrafiltration control to remove precise ultrafiltrate; and

(iv) Sodium profiling, safety monitor like conductivity temperature, blood leak and air detectors to prevent air embolism. Advance machines, have facilities to monitor blood pressure (BP), electrocardiogram (ECG), blood volume, fluid balance, access re-circulation and online monitoring for measuring urea clearance to determine adequacy of dialysis.

Dialysis Water

A large volume of water (more than 100 litres per treatment) is used to prepare dialysate from the concentrate, several methods of purifying dialysis water are employed, the most common of which is reverse osmosis. The Association for Advancement of Medical Instrumentation (AAMI) has recommended minimum standard for water used in dialysis. Bacterial colony count should be less than 100 cfu/mL.

Dialysate

Dialysis solutions are usually prepared from concentrates and contains either acetate or bicarbonate as a buffer. Acetate is now rarely used worldwide. Bicarbonate containing concentrate is preferred as they are more physiological, provide better control of acidosis and produce fewer complications and side effects. Usual composition of dialysate is sodium: 132 to 155 mmol/L, potassium 0 to 4 mmol/L, magnesium 0.25 to 0.75 mmol/L, acetate 35 to 45 mmol/L (only in acetate base dialysate), bicarbonate 27 to 40 mmol/L, dextrose 0 to 5.5 mmol/L and pH 7.1 to 7.3. Low calcium baths may be used in the acute or chronic therapy of hypercalcaemia.

Anti-Coagulation for Haemodialysis

Systemic standard heparinisation, bolus dose followed by continuous infusion of heparin 500 to 2000 units per hour to maintain the activated clotting time upto 200 to 250 seconds is standard practice, to prevent excessive bleeding, heparin must be discontinued 30 to 60 minutes before the termination of the treatment. Patients who are at high risk of bleeding, various alternatives are low dose heparinisation, low molecular weight heparin, regional citrate anti-coagulation, recombinant hirudin, prostacyclin and no anti-coagulation with saline flushes.

Complications of Haemodialysis

The most common complications during haemodialysis are hypotension, cramps, nausea, vomiting, headache, chest pain, back pain, itching, fever with chills, disequilibrium syndrome, dialyser reactions, hypoxia, seizures and cardiac arrhythmias (**Table 2**).

Table 2: Complications of Haemodialysis

Acute vascular access fistula (AVF) related	Haemorrhage, haemothorax, pneumothorax (subclavian, jugular cannulation)
Chronic arteri-ovenous fistula (AVF) related	Infection, aneurysm, steal, venous congestion, high output failure
Extracorporeal circulation procedure related	Dialyser reactions, type A anaphylactic reactions, hypoxia, hypotension, cramps, rigors, headache, fever chills, seizures, cardiac arrhythmias, haemolysis, air embolism, dialysis disequilibrium
Chronic complications	Increased anaemia, hepatitis B and C infection, metabolic bone disease, β2 microglobulin related amyloidosis, acquired renal cystic diseases, dialysis dementia becoming rare, cardiovascular calcification, malnutrition

Frequency of Dialysis

A minimum of three, 4-hour dialysis per week is desirable. Treatment time or frequency should be increased for patients with cardiovascular problems.

Home Dialysis

Done at home for 3 to 5 hours per treatment three times per week, requires special training and machine at home. Survival is generally highest in patients treated with home dialysis up to 89% at five years, 74% at 15 years in non-diabetic and 50% at 15 years overall.

Daily Haemodialysis

Daily nocturnal, daily 4 hours and short hours (1.5 to 2.5 hours) high efficiency 5 to 6 times per week are new options, patients can be monitored remotely. Patients report significantly improved QOL, symptoms and sleep pattern, have a daily Kt/v of 1.00, better BP control, less need for antihypertensive medication, lower serum phosphate, improved nutritional status and can have relaxed dietary restriction. Duration of dialysis may be an important predictor of survival independent of dialysis dose.

Dialysis Adequacy

Adequate dialysis maximises well being, minimises morbidity, improves QOL and helps patients retain social independence. Dialysis prescription should be individualised, monitored and reassessed regularly. The clinical criteria for adequate dialysis include a feeling of well-being with normalisation of BP with or without medications and control of biochemical parameters in the target ranges, i.e. haemoglobin 11 to 13 g/dL, predialysis blood urea <70 mg/dL, s. creatinine <7.0 mg/dL, Ca 10 mg/dL, PO_4 <4.5 mg/dL. Lack of malnutrition, urea reduction ratio >65% and Kt/V (fractional urea removal rate) ≥1.2 per dialysis is recommended by K/DOQI guidelines.

PERITONEAL DIALYSIS

The use of intermittent PD for chronic renal failure started in early 1960s but was handicapped by the need to pierce the peritoneum with hard catheters. The development of soft catheter by Tenckoff in 1973 allowed permanent access to peritoneum. The situation changed dramatically when Popovich and Moncrief introduced concept of a portable wearable equilibrium PD system. Two litres of dialysate were infused intraperitoneally and allowed to equilibrate for 5 hours while patient conducted his normal activities. The dialysis was then drained and replaced. There were 5 exchanges per day and 7 days a week. The name of this method was changed in 1978 to continuous ambulatory peritoneal dialysis or CAPD. Over a period of 25 years, CAPD has become one of the standard care procedure for ESRF (**Figure 2**).

Principles of Peritoneal Dialysis

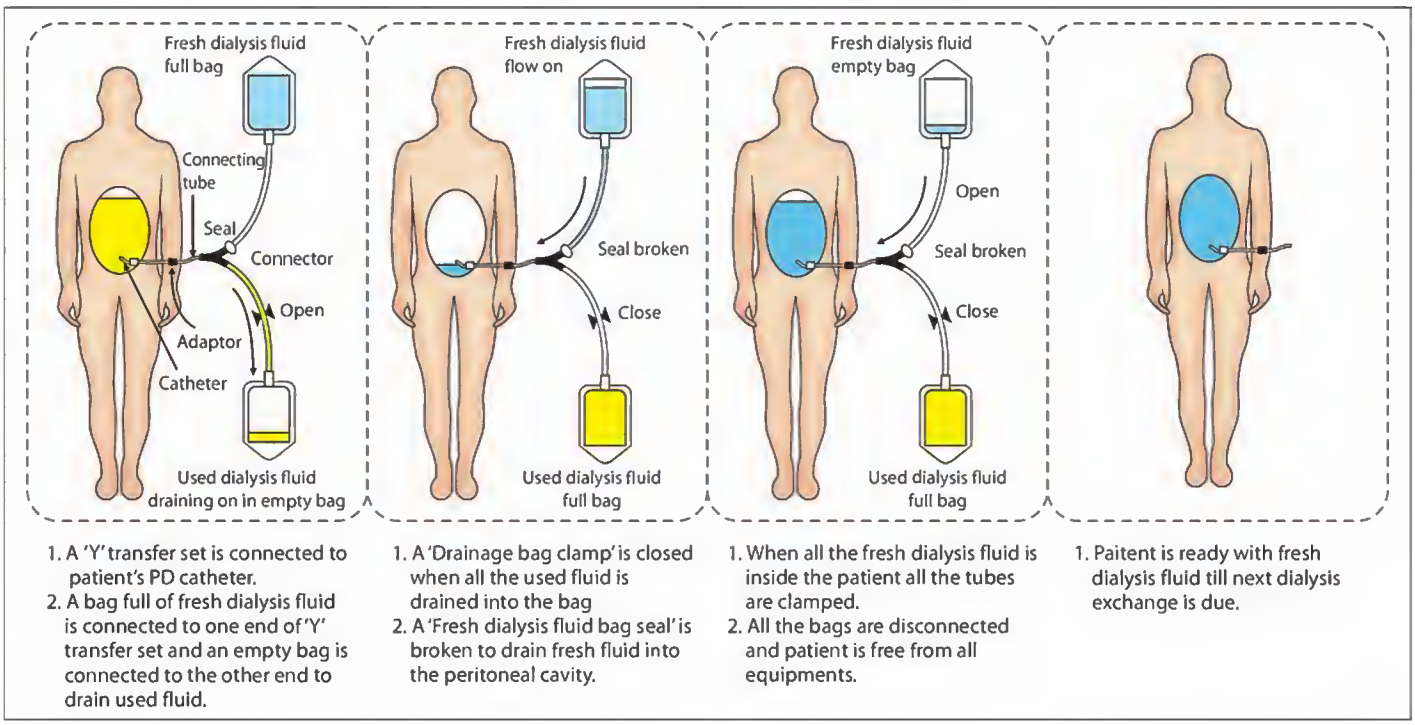
The physiological basis of dialysis across the peritoneum entails the process of diffusion, connective transport and osmosis. In PD, solute and fluid exchange occurs between peritoneal capillary and dialysis solution in the peritoneal cavity. The membrane lining this cavity consists of a vascular wall, interstitium, mesothelium and adjacent fluid film. Efficiency of PD as with HD depends upon the total time on dialysis and the dwell time of each exchange, blood flow, surface area and permeability of peritoneal membrane, dialysate flow and ultrafiltration rate. Ultrafiltration in PD is osmotically mediated.

Components of Peritoneal Dialysis System

Three key components of PD are: PD catheter, PD solution and the peritoneal membrane with its associated vasculature.

Peritoneal dialysis catheters

Several types of catheters are available. Most are made of silastic rubber with two Dacron cuffs, which are placed at either end of a subcutaneous tunnel. Straight Tenckhoff catheter is usually preferred. PD catheters can be inserted surgically or percutaneously using Seldinger technique (with or without laparoscope). Regular peritoneal dialysis can be started 2 to 4 weeks after the insertion of permanent catheter.



Peritoneal dialysis solutions

Standard PD fluid contains dextrose monohydrate 1.5% or, 2.5%, or 4.25%, sodium 130 to 135 mEq/L, potassium 0 to 1.5 mEq/L, calcium-1.5 mEq/L, magnesium-1.5 mEq/L, chloride-102 mEq/L and lactate 35 to 40 mEq/L. Dialysate is available in premixed, flexible, plastic bags, of 250 to 750 mL for children and 1 to 3 L for adults. Most adults tolerate 2 L volumes. Dextrose as an osmotic agent in PD has the advantages of being familiar, relatively safe and inexpensive and also is a source of calories. There is a concern however that it predisposes patient to hyperglycaemia, dyslipidaemia, obesity and long-term peritoneal damage. It is not very effective in high transporters. Alternate osmotic agents like icodextrin, aminoacids and gelatine are more expensive.

Peritoneal Dialysis Modalities

CAPD is the basic form of PD and is still in widespread use. A patient typically undergoes four manual exchanges per day (**Figure 2**). Three day-time exchanges of about 5 hours each and one overnight exchange of about 8 or 9 hours. By adjusting the dwell volume approximately most CAPD patients can achieve an adequate dose of dialysis. The simplicity of CAPD can be at home, freedom from machine, makes it most popular chronic peritoneal dialysis modality. It provides continuous therapy and steady physiologic state. The principal disadvantages of CAPD for many patients is the requirement of multiple procedure sessions each taking up 30 to 40 minutes and higher cost as compared to HD.

Automated peritoneal dialysis (APD) using cycler is now the fastest growing PD modality. APD is traditionally divided into

1. A 'Y' transfer set is connected to patient's PD catheter.
2. A bag full of fresh dialysis fluid is connected to one end of 'Y' transfer set and an empty bag is connected to the other end to drain used fluid.

1. A 'Drainage bag clamp' is closed when all the used fluid is drained into the bag
2. A 'Fresh dialysis fluid bag seal' is broken to drain fresh fluid into the peritoneal cavity.

1. When all the fresh dialysis fluid is inside the patient all the tubes are clamped.
2. All the bags are disconnected and patient is free from all equipments.

1. Paitent is ready with fresh dialysis fluid till next dialysis exchange is due.

Figure 2: Fluid exchange in continuous ambulatory peritoneal dialysis.

continuous cycling peritoneal dialysis (CCPD) and nocturnal intermittent peritoneal dialysis (NIPD). In CCPD, patient carries PD solutions in the abdominal cavity throughout the day but performs no exchanges and is not attached to a transfer set, at bed time patient hooks upto the cycler which drains and refills the abdomen with dialysate three or more times in the course of the night. In the morning, patient disconnects the cycler, the last dwell remaining in the abdomen. Patient is free to go about daily activities. In NIPD, the patient drains out fully at end of the cycling period and abdomen is 'dry' all day. Patient will perform cycler dialysis overnight. Because of the absence of a long day dwell, clearances are generally lower in NIPD than on CCPD. The main advantage of CCPD is ability to provide continuous therapy without need for on-off procedures during the day. All connections and preparations of equipment usually take place at bedtime in privacy of home, so psychological adjustment is facilitated and patient fatigue and 'burn out' may be reduced. It is also therapy of choice for most patients who require assistance in carrying out their dialysis like children, the dependent elderly and nursing home residents. The main disadvantage of CCPD is need for a cycler, the slightly greater complexity and cost.

Tidal peritoneal dialysis (TPD), a variant of APD was designed to optimise solute clearances by leaving a large volume of dialysis solution in the peritoneal cavity throughout dialysis session. It was thought that this would allow diffusive clearance to continue throughout cycling period. Initially peritoneal cavity is filled with a volume of solution selected to be as large as possible without causing discomfort. The volume used depends on patient size and habitus but is typically 2 to 3 litres. When TPD was introduced, 50% of tidal volume was common; for example if 2 L is being used, the next fill volume, the tidal volume, is 1 L, the next drain volume is about 1 L and so on. There is little evidence to suggest that TPD can provide clearance superior to that provided by cycler dialysis. However, it may decrease abdominal discomfort during inflow and outflow.

Choice and Assessment of Peritoneal Dialysis Adequacy

Inadequate dialysis and ultrafiltration failure cause patients to drop out from CAPD. Adequately dialysed patients feel well (absence of anorexia, nausea, vomiting, dysgeusia and insomnia) their BP is well controlled and they maintain a stable lean body mass. Their blood chemistry shows normal electrolytes. In order to provide adequate dialysis, total creatinine clearance (residual renal plus peritoneal) should be 50 to 60 L per week and kt/v for urea at least 2 per week. To achieve these goals, type of PD and prescription should be individualised according to residual renal function, body surface area and peritoneal membrane transport characteristic, as determined by peritoneal equilibrium test. High transporter will have poor ultrafiltration and adequate creatinine clearance, preferred mode would be multiple short dwells, like NIPD. High average transporters can be treated with standard-volume PD while low transporter will have adequate ultrafiltration but poor/inadequate solute clearance, appropriate mode will be high volume PD.

Complications of Peritoneal Dialysis

The complications observed during PD can be due to catheter malfunction; raised intra-abdominal pressure by continuous presence of dialysis solution in the peritoneal cavity; peritoneal response to unphysiologic solution and contamination; and systemic metabolic complications (**Table 3**) presents comprehensive list of problems encountered during CAPD.

Table 3: Complications during Peritoneal Dialysis

Technical complications: Catheter-related exit site infection, tunnel infection, peritonitis, pericatheter leakage, poor drainage, catheter migration rarely bowel perforation
Raised intra-abdominal pressure: Hernias, fluid leaks, rectal prolapse, vaginal prolapse, low back pain, scrotal oedema, and decrease in appetite
Unphysiologic solutions and contamination: All types of peritonitis, loss of ultrafiltration, sclerosing encapsulating peritonitis
Metabolic complications: Obesity, hypertriglyceridaemia, hyperglycaemia, hypoproteinaemia
Cardiopulmonary complications: Fluid overload, hypotension, hypertension atelectasis, hydrothorax, hypoxaemia

Peritonitis is one of the major risks of PD causing significant morbidity and mortality. It is one of the principle causes of drop out to HD. Peritonitis rates have fallen over the last 15 years from about one episode per 9 patient months (single bag system) to one episode per 24 patient months. Peritonitis is usually caused by single organism introduced by touch contamination. Peritonitis is suspected when returning fluid turns cloudy, white cell counts >100/mL with >50% polymorphonuclear leucocytes and symptoms like pain abdomen, cramps constipation or diarrhoea. Prompt empirical treatment should be started after sending fluid for Gram's stain, culture and antibiotics sensitivity. Infections with Gram-positive organism such as *Staphylococcus epidermidis*, *Staphylococcus aureus* and streptococcal species are common. Gram-negative organism causing peritonitis include *E. coli*, *Klebsiella* species, *Acinetobacter* species and *Pseudomonas* species, fungal, *Nocardia* and *Mycobacterium tuberculosis* cause peritonitis rarely. Management consists of abdominal lavage with three rapid in and out flushes of dialysate fluid. Followed by intra-peritoneal cefazolin, ceftazidime or aminoglycosides. Catheter removal is indicated if it is fungal infection or resistant, relapsing peritonitis.

Comparison of HD and PD

CAPD has a number of theoretical advantages compared with conventional haemodialysis, more independence, slow steady solute clearance, no cardiovascular instability and biochemistry destabilisation, salt and water control is generally easier, less dietary restrictions, higher haemoglobin, residual renal function is better preserved than HD. The rehabilitation rates and quality of life are better than observed in haemodialysis. Although maintenance dialysis prevents death from uraemia, patient survival remains an important issue. The survival on peritoneal dialysis is similar to that on haemodialysis. This value in older patients is slightly better than those with lung cancer and much worse than general population. CAPD is still underutilised in India because of high cost compared to haemodialysis. Major causes of death are cardiovascular disease infections and withdrawal from dialysis.

CONSERVATIVE AND PALLIATIVE CARE IN ESRF

In a country like India, cost of haemodialysis, transplant or CAPD is beyond the reach of many patients. Dialysis withdrawal is very common. Opting for conservative management is a passive suicide; patients will survive for few months. The goal of palliative conservative management is to achieve the best possible quality of life by relieving suffering,

controlling symptoms and restoring functional capability while maintaining sensitivity to personal cultural and spiritual belief and practices. Adequate calories with restricted protein, salt and water will prevent fluid overload and uraemic symptoms. Fluid overload treated with diuretics like furosemide or torsemide, treat acidosis with sodium bicarbonate to maintain HCO_3^- above 20 mEq/L. Maintain haemoglobin with iron and erythropoietin, control of hyperphosphataemia, secondary hyperparathyroidism with phosphate binders and vitamin D. The pain control may be done with simple paracetamol and tramadol. Strong opioids such as fentanyl and methadone may be used for pain control in severe cases. Constipation is treated with lactulose 15-30 mL orally or bisacodyl 30 mg orally or 10 mg rectal suppositories simple enema or glycerine rectal suppositories may also be effective. Phosphate-containing enemas should be avoided. Myoclonus, muscle twitching and seizure may be treated with clonazepam 0.5 to 2 mg orally. The terminal restlessness and agitation may be treated with midazolam 2.5 to 5 mg. For good symptom control, as required medication should be prescribed for likely symptoms in addition to regular medication for ongoing symptoms.

FUTURE HOPES

Our two kidneys work 24 hours a day, 7 days a week, so we filter 168 hours a week. It is very difficult to believe that 9 to 12 filtrations per week will do an adequate job. The kidney has synthetic, regulatory and excreting functions. Dialysis does only excretory and to some extent regulatory functions. Increasing data show that daily dialysis improves outcome, reduces anaemia and improves the QOL. Future hopes are a bionic artificial kidney, wearable human nephron filter and use of gastrointestinal tract for dialysis with oral sorbents, bio-encapsulated living cells and probiotics. Human nephron filter utilises a unique membrane-system created through applied nanotechnology. This is likely to mimic the function of a natural kidney. Animal studies using this technology are schedule to begin in the next 1 to 2 years with clinical trials to follow subsequently.

Bioartificial Kidney

The tubule assist device developed by H David Humes at the University of Michigan consists of a man made blood filter connecting a cartridge containing approximately one million human kidney cells. These proximal tubular cells can perform some of important kidney functions. Early experiments with dogs that had kidney failure demonstrated possible effectiveness of this device. Recently, phase II clinical trials with use of RAD device gave impressive results, but these need to be confirmed by a larger study.

CONCLUSION

Since the incidence of CKD is increasing, efforts should be directed to detect and treat renal failure early. Kidney failure is no longer an untreatable disease. Currently available treatment strategies, maintenance haemodialysis or PD, prolong useful life. Renal transplant is the treatment of choice. Haemodialysis and PD are prohibitively expensive and not enough donor organs are available for kidney transplantation. Therefore, it is necessary to develop affordable new approaches to replace renal function.

19.12 Renal Transplantation

George T John

The first successful renal transplant was reported from the United States of America between identical twins in 1956, while in India, it was done at Christian Medical College in Vellore in 1971. Currently about 3500 renal transplants are done annually in 150-odd centres all over India. This is the ideal form of treatment for chronic kidney disease—stage 5.

The issue of graft rejection is of primary concern in any transplantation. Therefore, understanding transplantation immunology is essential to be familiar with the measures taken to avoid/minimise the chance of such an occurrence. Pre-transplant evaluation selects the immunologically most suitable of the available donors. After transplantation, a balance of the immunity needs to be achieved, low enough to prevent graft rejection yet sufficiently high to protect the recipient from opportunistic infections and malignancies.

TRANSPLANTATION IMMUNOBIOLOGY

There are three phases of immune response to a transplanted allograft.

Recognition of Foreign Antigens

This occurs through the gene products (antigens) located on chromosome 6 at the major histocompatibility complex (MHC), which are called human leucocyte antigens (HLAs). When individuals differ in their histocompatibility antigens, the allografts are rejected. During maturation in the thymus, T cells that respond to self-antigens are deleted (negative selection) and those that respond to foreign peptides are selected (positive selection).

Activation of Antigen-Specific Lymphocytes

The recognition of alloantigen by T cells is the primary process that leads to activation, followed by proliferation, and then by differentiation of alloreactive T cells. This occurs by direct and indirect processes (**Figure 1**). The T-cell receptor (TCR) is a polypeptide heterodimer on the cell surface associated with the CD3 complex which is important for the expression of TCR and for the transmission of intracellular signalling. Antibody producing B lymphocytes mediate hyperacute rejection, which occurs within 24 hours in recipients with previous sensitisation to donor HLAs.

Effector Phase of Graft Rejection

Antigen presenting cells (APCs) present donor antigen on the MHC to T cells via TCR–CD3 complex. Antigen triggers T-cell receptors (TCRs) (**signal 1**). CD80 (B7-1) and CD86 (B7-2) on the APC bind to CD28 on the T-cell to provide **signal 2**. These signals activate three signal-transduction pathways—the calcium—calcineurin pathway, the mitogen-activated protein kinase pathway, and the protein kinase C–nuclear factor-κβ (NF-κβ) pathway—which activate transcription factors nuclear factor of activated T cells, activating protein 1 (AP-1), and NF-κβ, respectively. This results in the expression of interleukin (IL)-2

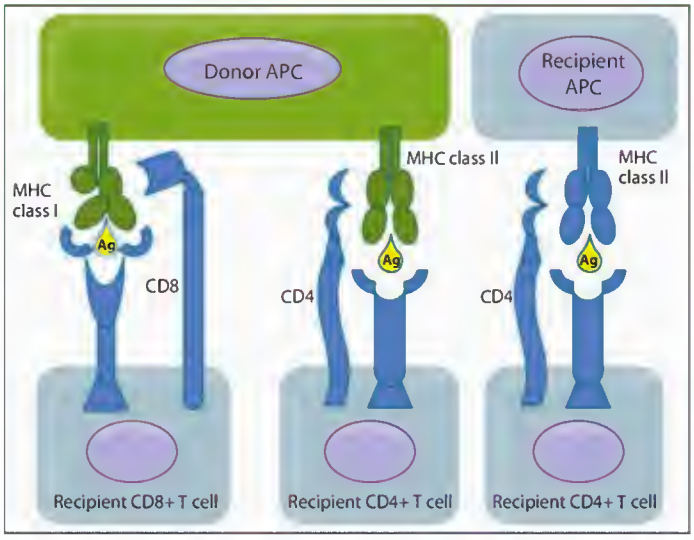

Figure 1: *Left panel:* Direct allorecognition. T-cell receptors (TCRs) on recipient T cells interact directly with intact donor major histocompatibility complex (MHC) antigens on antigen presenting cells (APCs) derived from the donor organ. CD8+ T cells preferentially interact with MHC class I antigens, whereas CD4+ T cells recognise MHC class II antigens. *Right panel:* Indirect allorecognition. Recipient T cells recognise peptides derived from donor MHC proteins that have been processed by recipient APCs and are presented in the context of self MHC expressed on APCs from the recipient.

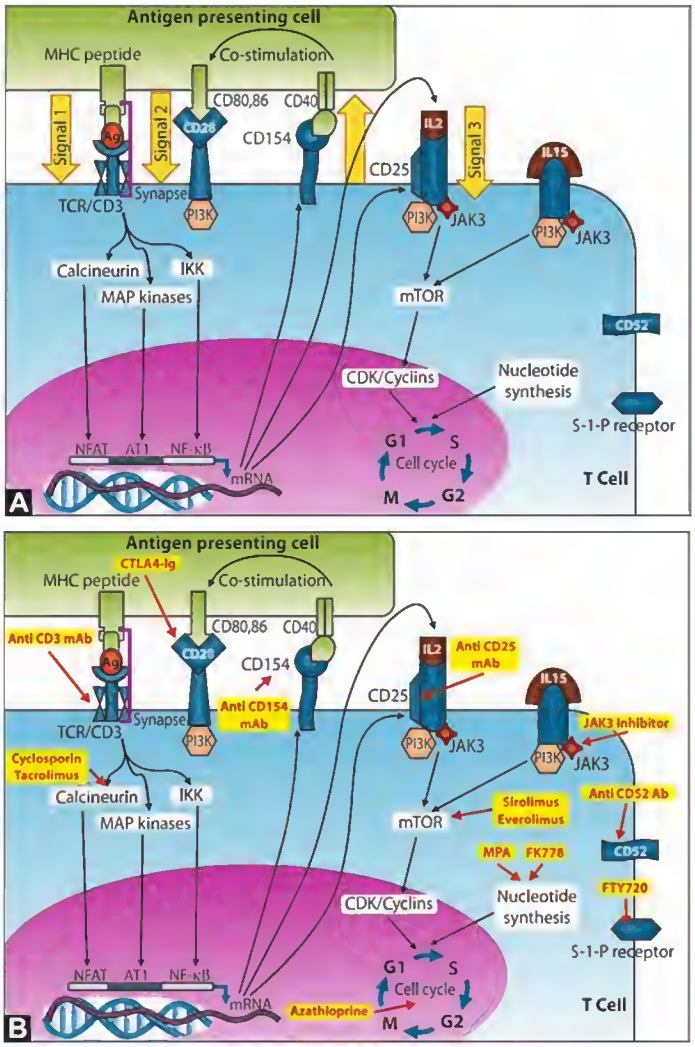

receptor α chain (CD25), IL-2 and CD154 (which further activates APCs). IL-2 and IL-15 provide growth signals (**signal 3**) through the phosphoinositide-3-kinase pathway and the mammalian-target-of-rapamycin pathway, which initiates the cell cycle. Lymphocytes require synthesis of purine and pyrimidine nucleotides for replication, regulated by inosine monophosphate dehydrogenase and dihydroorotate dehydrogenase, respectively. The CD8 cells kill with granzymes and perforins along with the engagement of Fas ligand to its target on the allograft causing apoptosis (**Figure 2A**).

Tolerance is the absence of destructive immunity against the allograft with otherwise preserved immunity. This has been achieved in experimental animal models while long-term induction of tolerance remains the holy grail of transplantation.

DRUGS OF CHOICE FOR IMMUNOSUPPRESSION

In India prednisolone and azathioprine were used in 1970s; cyclosporine and mycophenolate became available in 1990s and tacrolimus at the turn of the Century. Currently, most patients receive a triple drug regimen including tacrolimus, mycophenolate and prednisolone for maintenance immunosuppression. The sites of action of the various immunosuppressive agents are shown in **Figure 2B**.

Calcineurin inhibition with cyclosporin (CsA) and tacrolimus (FK 506; Tac) has improved results of renal transplantation remarkably. They form a complex with their specific cyto-

Figures 2A and B: (A) Shows the three-step signalling pathway for allorecognition to effector mechanisms; (B) shows sites of action of various immunosuppressive agents.

MHC = Major histocompatibility complex; TCR = T-cell receptor; JAK3 = Janus Kinase 3; MTOR = Mammalian-target-of-rapamycin; NFAT = Nuclear factor of activated T cells; MPA s = Mycophenalic acid; IKK = Inhibitor of nuclear factor-κβ kinase; CDK = Cyclin-dependent kinase.

plasmic proteins, cyclophilin and FK-binding protein respectively, which in turn bind to calcineurin. This protein which normally dephosphorylates nuclear regulatory proteins and promotes down-stream gene signalling is turned off when such a complex is formed. With therapeutic doses these drugs inhibit calcineurin by half, leaving just enough room for host defences against microbes and cancer; a delicate trade-off. For maintenance of immunosuppression, CsA or Tac are used in doses of 3 mg/kg and 0.1 mg/kg, respectively, targeting CsA trough levels of 100 to 250 ng/mL, C2 levels of 800 to 1,700 ng/mL; and tacrolimus trough of 3 to 9 ng/mL. Higher targets are achieved during the first 3 months of transplantation and lower targets are sufficient for later maintenance. Drug interactions with calcineurin inhibitors are similar; cytochrome P-450 inhibitors inhibit and augmenters increase metabolism of these drugs. Diltiazem or ketoconazole can be co-administered to reduce the dose and cost of CsA/Tac. CsA causes hirsutism and gum hypertrophy; tacrolimus causes tremor and hair loss while both drugs have nephrotoxicity. Although both drugs cause pancreatic β cell toxicity, tacrolimus is associated with a greater risk of diabetes mellitus.

Mycophenolic acid prodrugs, namely, mycophenolate mofetil (MMF) and mycophenolate sodium inhibit inosine monophosphate dehydrogenase resulting in blocking the *de novo* pathway of guanosine nucleotides producing a selective anti-proliferative action on lymphocytes which use this pathway more than other cell lines. MMF is usually dosed at 1.5-2.0 g per day in two divided doses although there is a large variation in the drug absorption and metabolism. These drugs are associated with better survival rates as compared to azathioprine-containing regimes.

Target of rapamycin (TOR) inhibitors (sirolimus, everolimus) bind to a regulatory kinase, after these form a ligand with FK-binding protein. This inhibits cytokine-dependent cellular proliferation. Sirolimus is used at a dose of 0.05 to 0.1 mg/kg per day in a single dose to achieve a target trough level of 3 to 7 ng/mL. TOR inhibitors are difficult drugs to use and have major side effects, especially when used in combination with full doses of CsA or tacrolimus. However, there is limited nephrotoxicity when TOR inhibitors are used without these agents.

Induction therapy at the time of transplantation with an IL-2 receptor blocker (basiliximab) or polyclonal antithymocyte globulin (thymoglobulin) is found to be beneficial in long-term survival of deceased donor allografts and perhaps in living donor transplant recipients.

PRE-TRANSPLANT EVALUATION FOR HISTOCOMPATIBILITY

Histocompatibility Testing and Cross-Matching

A cluster of genes on human chromosome 6 encodes for the HLAs which form the major barrier to transplantation of tissues and organs between individuals. Also, antibodies directed against HLAs as a result of repeated pregnancies, transfusions or transplantations, cause accelerated or hyperacute rejection following transplantation. The appearance of these antibodies after transplantation is associated with rejection episodes. HLAs are detected using microcytotoxicity tests or deoxyribonucleic acid-typing technology. The antibodies are detected using complement-dependent lymphocytotoxicity tests, enzyme-linked immunosorbent assay (ELISA) and fluorescence-activated flow-cytometry.

POST-TRANSPLANT MONITORING OF IMMUNE STATUS

Currently, monitoring of renal functions with urea and creatinine is the routine practice although decline in renal function is a downstream result in a cascade of events leading to rejection of the allograft. Monitoring of earlier immunological insurgencies of recipient T-cell and B-cell are possible with measurement of T-cell alloreactivity using ELISPOT test and with ELISA for donor-specific antibodies, respectively. However, these tests have not yet been shown to consistently correlate with alloreactivity. Expression of mRNA for perforin and granzyme B on histology samples correlate well with acute rejection. Frequent biopsies are difficult and mRNA for these cytotoxic mediators of cells passed into urine may become a valid non-invasive assay for rejection.

CURRENT PRACTICE

Renal transplantation is currently the best form of renal replacement therapy and is offered to children having 15 kg weight to adults up to the age of 65 years. Recipients have to be free of infection, malignancy and anti-donor-HLA antibodies.

They must have robust organ-systems to cope with the rigors of surgery and subsequent immunosuppression. Diabetics need detailed evaluation of cardiac, vascular and autonomic systems. The kidney donor source in India is still the living donor pool while in developed nations it is the brain-dead beating-heart donor. The living donors must be fully informed, consenting, medically fit, blood group compatible and without transmissible infective agents. HLA matching improves long-term survival, especially in India where profound immunosuppression needed with HLA mismatched transplantations leads to a high risk of infections. However, unmatched siblings, spouses, grandparents and paired kidney exchange donors are permitted to donate under 'The Transplantation of Human Organs Act' (THOA).

DECEASED DONOR TRANSPLANTATION

The THOA 1994 allows for deceased donor transplantations by defining the scope of brain-stem death in India. Non-governmental organisations in partnership with the state governments have expanded the deceased donor programme and a third of deceased donor organs have been made available by such initiatives. The deceased donor programme is hampered by poor awareness, lack of infrastructure to support critically ill patients and lack of co-ordinated teams for grief counselling, brain death certification, organ explantation and allocation. Until 2009, nearly 1400 deceased donor (brain-dead, beating-heart) organ transplantations have been done in India.

Altruistic donation is permitted according to the THOA but is used by some to foster paid donor transplants. The ethics of paid donor transplantation is hotly debated while the policy makers all over the world variably respond to the ever-increasing need for organs while patients remain on dialysis awaiting transplantation.

Pre-emptive transplantation (done before dialysis is initiated) from a living related donor of less than 50 years of age has the best survival advantage. It is, therefore, wise to have patients with renal failure referred to centres where a pre-emptive renal transplantation from a related donor can take place with benefits of better graft function and savings from avoiding dialysis related expenses.

Paired donor kidney exchange transplantation is being done when related donors are unsuitable for their respective recipients but suitable for a swap with an unrelated recipient, both pairs agreeing for a reciprocal donor kidney exchange. It is now possible to do renal transplantation across the ABO incompatibility barrier. Kidney donation after cardiac death is yet to be a routine practice in India. These strategies can increase the number of patients benefitting from transplantation.

TRANSPLANTATION

The donor nephrectomy can be done laparoscopically and this reduces the morbidity and the hospital stay. The recipient has the allograft implanted in the iliac fossa with anastomosis of the donor vessels to the iliac vessels and the ureter implanted into the recipient bladder using antireflux technique. Rarely, in those patients with type 1 diabetes mellitus, a deceased donor pancreas can be connected to the vascular system with the ducts usually draining into the urinary bladder simultaneously with kidney transplantation. Immunosuppression is often started 3 days prior to surgery in living donor transplants to build up drug levels. Immunosuppressive drug levels are monitored from within a week of the operation.

POST-TRANSPLANTATION COMPLICATIONS

Early surgical complications include wound infections, urinary catheter block, urinary leak and rarely vascular thrombosis. The early medical complications include acute tubular necrosis resulting in delayed graft function, acute rejection, bacterial infections of the wound, urinary tract and the lung.

Infections

The mortality and morbidity of patients in India are mainly due to infective complications. The chronological occurrence of various opportunistic infections is predictable for each environment and so it is for the tropics. The first month after transplantation shows complications of immunosuppression and surgery. The common infections are due to wound infections, lower respiratory tract infections following anaesthesia and cytomegalovirus (CMV) infections. Three to six months after transplantation is the period when tuberculosis, systemic fungal infections, CMV infections and other viral infections are seen. After six months of transplantation, nocardiosis and cryptococcal infections are also to be considered in a febrile patient. Post-transplant lympho-proliferative disorders are usually seen peaking in the first year of transplantation especially if induction therapy is used against lymphocytes and are usually a result of Epstein-Barr virus infection. Liver malignancies are generally caused by hepatitis C and B viruses. The presence of hepatotropic viruses, CMV, hyperglycaemia and polyclonal or monoclonal anti-lymphocyte antibody induction are risk factors for infections.

Rejection

Rejection processes of the renal allograft can occur from the time of surgery and for as long as the kidney remains *in situ*. The acute rejection episodes are clinically suspected if there is graft tenderness and decreased urine output and confirmed with a biopsy of the allograft. The laboratory features are more reliable and consist of decline in renal functions, leucocyturia and occasionally, haematuria. The types and severity of rejections are classified according to *Banff criteria*. Acute rejections are characterised by lymphocytic infiltration of interstitium and tubules (cellular rejection) and rarely with patchy infiltration of arterioles with or without necrosis and thrombosis (vascular rejection). Currently c4d immunostains and detection of donor-specific antibodies form the basis of diagnosing antibody-mediated rejections. Acute cellular rejections are treated with intravenous pulses of methyl-prednisolone or, if that fails, polyclonal/monoclonal antibodies are infused against lymphocytes. Vascular rejection is a more serious event adversely affecting graft survival and is usually treated with monoclonal (anti-CD3) or polyclonal anti-lymphocyte peptides.

Vascular Disorders

Vascular disorders rank high among the late complications. These are due to accelerated atherosclerosis brought about by hypertension, dyslipidaemia and renal dysfunction. These present as acute coronary syndromes, strokes, transplant artery stenosis and acral ischaemia. Transplant artery stenosis is usually seen in the context of severe hypertension and allograft

dysfunction; colour Doppler imaging is a good screening test and angiography with limited radio-contrast proves the diagnosis. Endovascular intervention with angioplasty and stenting is the current standard of care.

Recurrence of Glomerular Disorders

Recurrence of glomerular disorders is an important cause of allograft dysfunction. Focal and segmental glomerulosclerosis, mesangiocapillary glomerulonephritis (MCGN) type 1, MCGN type 2, IgA nephropathy recur in 35%, 50%, 100% and 30% of allografts, respectively. The type of immunosuppression does not alter this frequency although graft loss occurs only in a proportion of patients with recurrence. *De novo* glomerulo-nephritis is thought to be a rarer expression of rejection and is often morphologically similar to membranous nephropathy.

SURVIVAL AFTER TRANSPLANTATION

Survival after transplantation in India at 1, 5 and 10 years is about 97%, 80%, 60%, respectively. Most patients do not have the resources for further treatment if the allograft fails. So graft and patient survival are very similar in India. In developed nations with funding for transplantation, loss of an allograft would entail patient returning to the dialysis programme, waiting his turn for another deceased donor kidney.

FUTURE DIRECTIONS

Tolerance induction is the holy grail of transplantation; where specific tolerance to donor organ exists with robust immunity against other external antigens without the use of continuing immunosuppression. The underlying processes are vastly different among the different species of animals. In humans it has not been possible to consistently achieve tolerance with well-studied, non-hazardous protocols. However, the general direction has been to have a lymphocyte depleting strategy or a co-stimulatory blockade during the early phase of transplantation and calcineurin phosphatase-free immuno-suppression in the later phase. The use of stem cells in promoting tolerance pathways and in regenerating the damaged kidney is currently gaining attention.

CONCLUSION

Renal transplantation has progressed from an experimental endeavour to a highly effective therapy in the past six decades. With this success comes an increased demand for donor kidneys and a severe organ shortage. Long-term survival benefits have lagged behind the significant increments in short-term survival. Increasing the number of donor organs, improving anti-rejection therapy, tolerance induction and xenotransplantation are goals for the future.

20.1 Basic Considerations in Neurology

RS Wadia

The clinical evaluation of a patient with a neurological problem follows the standard practice of history-taking followed by physical examination and investigations as indicated by the clinical diagnosis.

THE IMPORTANCE OF HISTORY

It is important to note that in neurology the clinical examination is only useful to localise the site of lesion. The aetiology of the problem is made out by the history. In fact, at the end of history, one should be able to tentatively outline the anatomical and functional localisation as well as the pathological nature of the disease. Importantly, onset, duration and the time course of each symptom is helpful in delineating the same. Thus:

(a) Sudden onset with time of onset exactly located implies vascular aetiology,

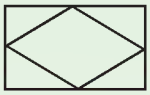
(b) Gradual progression implies space-occupying lesion (SOL),

(c) Gradual progress over months to years is a feature of degenerative disease,

(d) Recurrent attacks with recovery occurring 2 to 4 times a week or a month suggests transient ischaemic attack (TIA),

(e) Recurrent discrete episodes over months to years suggests demyelinating disease,

(f) A disease with sudden onset which then continues to slowly progress could well be an SOL with the sudden onset being due to haemorrhage within the tumour.



It is also to be noted that the three commonest complaints in neurology, viz. headache (all the primary headaches, migraine, tension headache, cluster headache, post exertional and coital headache), epilepsy and vertigo are very well analysed and diagnosed by history alone.

Of course while focusing on the present complaints in a neurologic examination, it cannot be over emphasised that a review of the other systems, a check on past history, a review of patient's social habits and hobbies and the family history play a vital role in neurologic diagnosis.

THE HIGHER FUNCTIONS

These include memory, orientation, intelligence, speech and abstract reasoning and are evaluated by the patient's response to examination. The mini-mental state examination (MMSE) is a rough measure of higher function, it gives a total of 32 points (**Table 1**). In disease of higher functions some terms need description. Dementia is a chronic disorder with overall reduction of higher function embracing at least two functions, e.g. memory, intelligence, orientation, speech, abstract reasoning and self-care. Although memory loss is first in cases of dementia, loss of memory alone is amnesia. In dementia memory is lost along with loss of orientation, speech and self-care. Dementia is suspected if there is a chronic disorder, MMSE score is 24 or less, and the person requires help in activities of daily living. Delirium is an acute change of higher function usually associated with fluctuating course and abnormal attention. There is usually motor restlessness, occasionally apathy. Mental retardation is the term used in children who are developing slower than normal. But these children can be noted to be developing. Mental regression is used when a child has developed some developmental milestones and then starts to lose them, stops walking and then cannot sit well, etc. Mental regression is the hallmark of metabolic disorder lipidosis, or leucodystrophy and may also be seen in chronic infections such as subacute sclerosing panencephalitis or HIV disease.

Table 1: The Folstein Mini-Mental State Examination (MMSE)

	Question	Scoring	Max. Score
1.	Where are you (state, country, city, hospital, clinic)	1 point for each	5
2.	What is the day, month, season, year, time	1 point for each	5
3.	Say these 3 words after me (yellow, apple, Ohio)	1 point for each	3
4.	Ask patient to begin with 100 and count backwards by 7's	Stop after 5, score no. correct or 1 point for each correct number	5
5.	Recall the three words given in question No. 3	1 point for each	3
6.	Ask the patient to name 'watch' then 'pencil'	1 point for each	2
7.	Ask the patient to repeat 'no, ifs, ands, or buts'	1 point if correct	1
8.	Three stage command: Take this paper in your right hand, fold it in half, and put it on the door	1 point for each correct	3
9.	Ask the patient to read silently and obey the command (print in block letters) - CLOSE YOUR EYES	1 point if correct	1
10.	Ask the patient to write a sentence	1 point if contains a subject and verb and makes sense (ignore spelling and grammar)	1
11.	Draw a clock with number and hands showing the time to be 8:20	1 points if correct numbers 1 if hands correct	2
12.	Have the patient copy this design 	1 point if all sides and angles are preserved and if intersecting sides form a quadrangle	1
		Total Score	**32**

Indian versions have been described and validated.

Minimal cognitive impairment is a new concept recently introduced. As people age they tend to be forgetful, cannot remember faces, people, and events as well as before. This is usually called benign forgetfulness. Those who have MMSE score between 25 and 27, and can otherwise look after themselves in activities of daily living are said to have minimal cognitive impairment (MCI) Patients with MCI have a six times greater risk of developing dementia and represent the early stages of dementia. Some cases of MCI may remain static and some may even improve if family circumstances improve. The importance of MCI lies in that it may represent the reversible state of dementia and a drug is likely to be more useful at this time rather than later.

LIMBIC SYSTEM

The limbic system represents the older parts of the brain and histologically does not have the six layers seen in the neocortex. It may be thought to consist of two adjoining rings: (a) Papez circuit of hippocampus going round in a ring below the corpus callosum including the fornix to the mamillary body and by the mamillothalamic tract to the anterior and dorso-medial nucleus of the thalamus; and (b) the associated areas which include amygdala, entorhinal cortex, parahippocampus and cingulate gyrus above the corpus callosum, septal area and preoptic nucleus of the hypothalamus. This limbic system subserves human emotions and is the seat of recent and short-term memory.

Memory is stored in this system with the most recent events in the hippocampal region and going backwards and round. Disruption of hippocampal fibres leads to loss of memory for a variable period as in retrograde amnesia (transient global amnesia) or transient ischaemic attack (TIA) of the limbic system or a post-ictal phenomenon or a migraine like event. Rarely a form of transient global amnesia may last beyond 48 hours, it is then invariably due to a metabolic encephalopathy.

The limbic system records immediate and short-term memory. Long-term memory is stored in the RNA of all the cells in the brain so that in very few and only advanced disorders can long-term memory be lost. Therefore, for early detection of dementia it is important to test recent memory and not past memory.

PYRAMIDAL SYSTEM

The motor movements are carried out by the upper motor neurons (UMN), i.e. the pyramidal system, and the lower motor neurons (LMN). Upper motor neurons are the descending fibre system with cells of origin in the cerebral cortex—predominantly precentral gyrus—that descends and innervates cranial nerve nuclei on the opposite side and the corticospinal tract decussates in the medulla and supplies the anterior horn cells (**Figure 1**) of the cord on the opposite side. Loss of function results in paralysis of movement and not of muscles. An acute insult causes atonic, areflexic paralysis, called neurogenic shock, which later manifests with classical signs of pyramidal dysfunction viz.:

1. A particular pattern of weakness with loss of movement
2. Increased tone with spasticity
3. Hyperreflexia of deep jerks
4. Clonus at knee or ankle
5. Absent superficial reflexes viz. abdominal and cremasteric reflexes
6. Extensor plantar (Babinski) response.

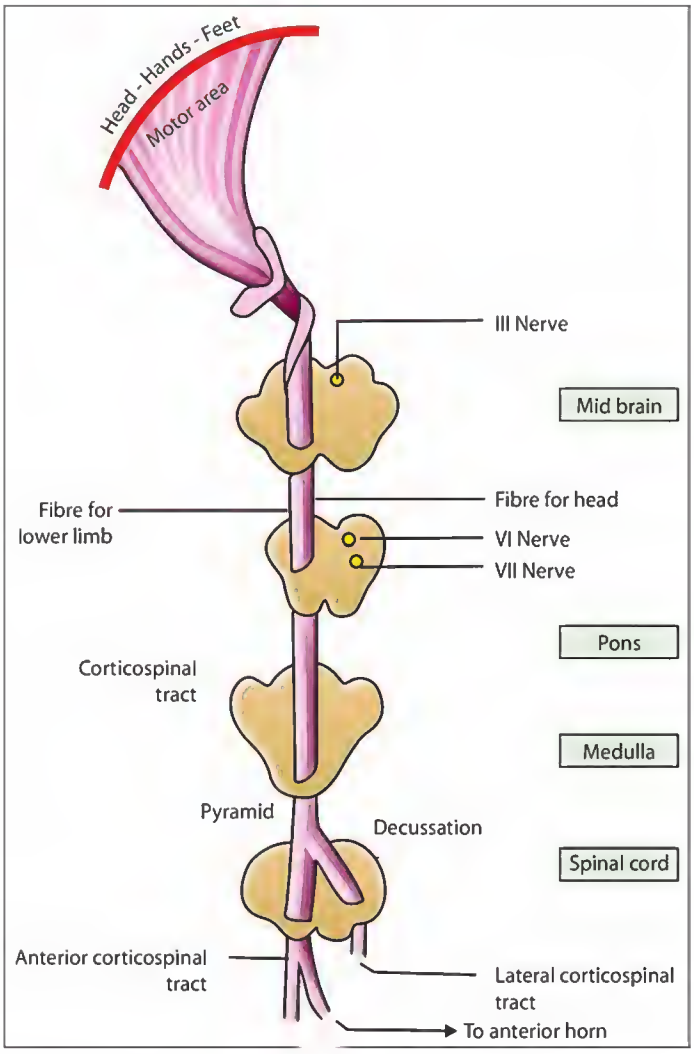


Figure 1: Schematic line diagram of motor pathways.

Generally, at least two of these signs are necessary to diagnose pyramidal disease. One alone pyramidal affection. Hyperreflexia alone, no matter how marked, should not be taken as evidence of corticospinal dysfunction. However, clonus alone is sufficient to make such a diagnosis.

The pattern of weakness is typical. In the upper limb the most affected muscles are the deltoid, triceps, and the hand muscles. In the lower limb the most affected muscles are hip flexors, knee flexors and dorsiflexors of the ankle. Hypertonia in pyramidal disease is called spasticity. It is different from that in extrapyramidal disease (rigidity) (**Table 2**).

Table 2: Differences Between Spasticity and Rigidity

	Spasticity (Pyramidal)	Rigidity (Extrapyramidal)
Muscles affected	Antigravity muscles	Agonists and antagonists equally
Nature	Clasp-knife, i.e. maximal at start of movement	Lead pipe or cogwheel
Velocity dependence	Considerable	Minor
Accompanying signs	Hyperreflexia, clonus, Babinski response	Tremors, bradykinesia, etc.

Pyramidal and extrapyramidal diseases are the main causes of hypertonia. However, there are other causes of hypertonia, viz. hysterical rigidity, gegenhalten (a plastic rigidity seen in frontal lobe disease, dementia or in some metabolic encephalopathies, e.g. hepatic) and diseases with muscle spasm, e.g. tetanus, strychnine poisoning and stiff-man syndrome.

EXTRAPYRAMIDAL DISORDERS

Extrapyramidal disorders may be divided into akinetic rigid syndrome of Parkinson's disease and allied disorders, and the dyskinesias; chorea (caudate nucleus lesion usually), athetosis (putamen lesion) and hemiballismus (subthalamic nucleus). The main lesion in the akinetic rigid syndrome is in the *substantia nigra*.

The important features of extrapyramidal lesions are shown in **Table 3**.

Table 3: Important Features of Extrapyramidal Lesions

Akinetic rigid forms

- Rigidity—Uniform increase in tone through entire range of movement (lead pipe)
- Tremor—At rest (pill-rolling type) combination of rigidity and tremor discharge causes cogwheel rigidity
- Bradykinesia (akinesia) as seen by mask face, infrequent blinking, and loss of associated arm swing while walking

Dyskinetic forms

- Chorea and choreiform movements and hypotonia
- Athetosis—Wriggling movements of fingers and hands
- Choreoathetoid movements
- Dystonia
- Hemiballismus—unilateral marked chorea

Chorea is a quasipurposive non-repetitive movement more marked at the larger joints. Dystonia is an abnormal limb position due to increased tone. It usually has a rotatory element and the limb is held in the abnormal position for some duration of time. In the akinetic rigid forms of extrapyramidal disorder unilateral affection at onset, and significant rest tremor favours idiopathic Parkinson's disease while early hallucination, early dementia and bilateral onset favours other akinetic rigid syndromes like multiple system atrophy or Lewy body disease.

CEREBELLAR DISEASE

The cerebellum and the extrapyramidal system modulate motor activity. The signs of cerebellar disease are basically three:

Ataxia

This gives rise to additional signs like dysdia-dochokinesia, past pointing, intention tremor, scanning speech and loss of balance to the same side.

Hypotonia

This causes two additional signs—the pendular knee jerk and rebound phenomenon. The jerk is said to be pendular when, on tapping the knee, it swings freely forward and backward. The number of swings is not important because a brisk pyramidal jerk will jump forward and may show 3 to 4 jerks before settling down. The cerebellar reflex swings to and fro without any jerk. Rebound phenomenon is said to be present when the patient is unable to slow his hand as we release it during power test and it goes on to strike the chest.

Inability to maintain a posture/position

This causes cerebellar tremor. The hand is held outstretched. It fails to hold a position so it goes down, then it is corrected and returns to normal, and the same cycle repeats. Cerebellar nystagmus is similar; when the eyes are looking laterally, the position cannot be held so it moves to midline and is jerked out again, and the same repeats. Its fast component is lateral whether looking left or right but is more marked on the side of the lesion. This is the hallmark of cerebellar nystagmus and is called gaze evoked nystagmus.

Acute cerebellar disease may have two more signs: skew deviation, i.e. a vertical separation of the eyes with one eye down and in, the other eye up and out. The lesion is on the side of the down and in eye. The cerebellar position of the head is with the occiput to the side of the lesion and spine concave towards the lesion. Both these signs regress after acute cerebellar injury is over.

Midline cerebellar disease is to be differentiated from lateral cerebellar disease. In midline disease, there is ataxia of stance and gait (tandem gait ataxia) without limb ataxia and tendency to fall forwards or backwards and not to one side. Midline disease frequently has no nystagmus. Cerebellar signs and symptoms are summarised in **Table 4**.

Table 4: Cerebellar Lesions—Signs and Symptoms

Head	Head tilted to affected side, rare head tremor
Eyes	Horizontal nystagmus fast component laterally more on looking to the side of lesion
Speech	Scanning or staccato (bombastic) speech
Gait	Broad based gait, drunken gait, leaning and swaying to affected side while walking in a straight line
Coordination	Intention tremors (more at end of voluntary act), past pointing, breaking of movement, dysdiadochokinesia
Muscles	Hypotonia, no wasting, no loss of motor power
Reflexes	Pendular knee jerk

MULTIPLE CRANIAL NERVE LESIONS (EXTRA-AXIAL AND INTRA-AXIAL DISEASE)

When it comes to brainstem and cranial nerve disease, the clinician often tries to recognise if the lesion is extra axial, i.e. outside the brain and catching cranial nerves, or within it, intra- axial, and causing cranial nerve palsies. Presence of long tract signs (pyramidal, spinothalamic, cerebellar) indicates an intra-axial lesion and absence suggests extra-axial lesion.

Three patterns of such multiple cranial nerve lesions are common:

(a) 2nd, 3rd, 4th, 5th and 6th cranial nerves on one side are involved in a lesion which is parasellar (by the sides of the sella) and involving the cavernous sinus, e.g. parasellar tumour, cavernous sinus thrombosis, or mucormycosis.

(b) 5th, 6th, 7th and 8th nerves on one side may be involved in a lesion at the cerebellopontine angle, e.g. acoustic neuroma or meningioma or arachnoid cyst or 5th nerve neurofibroma. To diagnose, if a cerebellopontine angle

tumour is an acoustic neuroma we go back to history. If the first symptom was hearing loss it is an acoustic. If it clearly was not, one of the other causes is more likely.

(c) 9th, 10th and 11th with or without the 12th nerve on one side are involved in a lesion near the jugular foramen.

A nasopharyngeal carcinoma entering the brain may involve any or all these three sites and may cause unilateral widespread cranial nerve palsy.

Meningitis can involve cranial nerves bilaterally and meningitides which do this are TB, syphilis, carcinomatous meningitis, sarcoidosis and some fungal meningitis.

CORD DISEASES

A cord lesion is recognised by the presence of bilateral limb signs, i.e. bilateral weakness, hypertonia, hyperreflexia or sensory loss. Of course this can occur also with brain disease, e.g. bilateral cerebrovascular disease so these signs with higher function involvement or cranial nerve disease imply brain disease. In the absence of higher function loss or cranial palsies bilateral upper motor neuron signs imply cord disease and this suspicion is increased if there is root pain, or sensory level on the trunk. When cord disease is diagnosed the first cord disease to consider is cord compression. Cord compression is diagnosed, if there is a chronic progressive disease of the cord and shows a level. The level may be a pain level—root pain—a motor level, e.g. biceps power normal, triceps weak (implying C6 lesion) or a reflex level biceps jerk absent, triceps jerk brisk (implying C5 lesion) or a sensory level. When there is a cord compression, the first tract to be involved is the pyramidal tract and next is the posterior column. So progressive pyramidal and posterior column signs without a level need also be investigated for cord compression. Spinal shock as a finding is the result of an acute cord lesion where all the reflex activity below the lesion is lost. So, though there is a cord lesion, the patient has hypotonia, areflexia, and retention of urine. One can suspect that it is spinal shock, and not a LMN nerve lesion, if the plantar is extensor or there is sensory level on the trunk.

A central cord syndrome is a lesion in the centre of the cord. It is seen in syringomyelia and intra-medullary tumour and is characterised by:

(a) Absence of root pain.

(b) Dissociated anaesthesia: Pain and temperature affected, and joint, vibration and touch sensations are preserved because pain and temperature cross the cord to go to the opposite side.

(c) Particular march of anaesthesia: In these cases first there is loss of sensation in one upper limb and adjacent trunk (half cape anaesthesia) as fibres from one side get caught; then there will be bilateral similar loss (cape anaesthesia); then jacket anaesthesia (upper limbs and trunk up to lower ribs), suspended jacket anaesthesia (sensory loss descends to umbilicus or so); and then sacral sparing. This last occurs because the spinothalamic tract is laminated so, as a central cord lesion expands, it catches first cervical, then thoracic, lumbar and sacral fibres in that order.

Root pain, i.e. pain along a nerve root often increased by coughing or sneezing is of course the hallmark of an extra-medullary cord compression.

Hesitancy (delay to initiate the act of micturition) and precipitancy (inability to hold back the act of micturition) are manifestations of cord involvement (See Chapter on Diseases of Spinal Cord).

DISORDERS OF SENSATION

Sensations in neurology are divided into superficial (touch, pain temperature) and deep (joint sense, vibration sense, sense of position, muscle sense, tendon sense and sense of deep pressure). Sensory disorders are positive or negative. Positive means paraesthesia, hyperaesthesia or allodynia. Hyperaesthesia implies a sensation, e.g. pinprick is felt more severe. Allodynia means a sensation, e.g. cold is felt as another sensation, e.g. pain.

Negative in sensation means loss of sensation and usually the superficial sensation are carried by the small nerve fibres and in the spinothalamic tract. The deep sensations are carried by large nerve fibres and in the posterior column of the cord. The patterns of sensory loss in neurology are multiple starting from peripheral nerve up, they include:

(a) Loss of sensation in a twig of nerve, e.g. in Hansen' disease in the patch of anaesthesia, or post-surgical incision, or in digital neuropathy.

(b) Mono-neuropathy means single nerve disease commonly seen in leprosy, diabetes or entrapment or pressure neuropathy.

(c) Radiculopathy shows a different distribution, e.g. an ulnar sensory loss is in the ulnar one and half fingers and the palm on that side and ending 1 inch proximal to the wrist roughly. Similarly the loss of median nerve lesion ends one inch proximal to the wrist. When the sensory loss includes ulnar hand and goes up the ulnar side of forearm it is a root lesion. Similarly a median territory hand loss extending on the forearm to the elbow or a dorsum of foot lesion extending up the leg is a radiculopathy not a neuropathy.

(d) Cord sensory losses are of various types. The sensory level of a transverse myelitis and the loss in a central cord lesion have been mentioned already. Other cord lesions are the unilateral cord lesion with touch, pain and temperature lost on one side and motor and joint vibration is lost on opposite side producing a Brown-Sequard syndrome. An anterior spinal artery occlusion causes sudden onset of major motor loss in both limbs and loss of touch, pain, temperature bilaterally but spares the posterior column as the anterior spinal artery does not supply that part of the cord. Other diseases affect the posterior column predominantly, e.g. subacute combined degeneration and may give rise additionally to a positive sign Lhermitte's sign when flexion of the neck causes a shooting pain going down the back and may be into the legs. Lhermitte's sign may be seen also in multiple sclerosis (plaque in posterior column) or radiation myelopathy or atlantoaxial dislocation.

(e) The brainstem sensory loss classically affects face on one side and spinothalamic sensory loss on the opposite side of body. This may be seen in a lesion from pons to medulla as the long sensory nucleus of the trigeminal extends from pons down to the medulla.

(f) Thalamic sensory loss is usually loss of all sensation on the opposite side of the body. This may be associated with a troublesome pain called thalamic pain on the entire

opposite body. This is central neuropathic pain and in a case of thalamic infarct may be a troublesome complaint for months or years after the infarct. Similar pain may occur with other lesions of the sensory pathways.

(g) Lastly parietal lobe lesions are characterised by mild loss of superficial sensation on the opposite side, major loss of joint sense and preservation of vibration sense. This is the only area in the body where joint sense may be lost and vibration preserved because in all other areas with deep sensation loss, e.g. peripheral neuropathy, or posterior column cord loss, or old age; vibration is lost before joint sense. Cortical sensory loss may also have astereognosis, two-point discrimination loss and may present as focal sensory epilepsy.

PERIPHERAL NEUROPATHY AND RADICULOPATHY

Peripheral nerves, i.e. the lower motor neuron extends from the anterior horn cell to the end of the nerve before the neuromuscular junction. The diagnosis of a radiculopathy is made by history of root pain and motor and sensory loss in root and not in nerve distribution (as discussed in sensory loss before). The differences between UMN and LMN lesions are given in **Table 5**.

Table 5: Comparison Between Signs of Upper Motor Neuron (UMN) and Lower Motor Neuron (LMN) Lesions

LMN	UMN
Paralysis of muscle	Paralysis of movement, especially fine movements
Weakness depending on nerve or root involved	Weakness of typical pattern in upper limb deltoid, elbow extension and, fingers. In lower limbs hip flexion, knee flexion, foot dorsiflexion
Hypotonia	Spasticity/clasp-knife rigidity
Wasting ++	Disuse atrophy at times but never severe wasting
Reflexes depressed or absent	Exaggerated reflexes ± clonus
Plantars flexors	Extensor plantar, absent abdominal reflexes

A peripheral neuropathy may be primarily due to axonal fibre degeneration or due to involvement of the nerve myelin. This is called segmental demyelination. **Table 6** shows the clinical differences in the two.

Table 6: Neuropathies—Axonal versus Demyelination

	Axonal Degeneration	Segmental Demyelination
Wasting	++	Often absent
Fasciculations	++	Nil
Site of affection	Predominant distal	Proximal and distal
Reflexes	Absent in severely affected muscles	Lost all over even in muscles not weak
Recovery	Slow, only after regeneration	Can be faster
Nerve conduction	Muscle action potential small Velocities remain near normal	Nerve conduction velocities and distal latencies slow >20% reduction

NEUROMUSCULAR JUNCTION

The clinical features to some extent depend on whether the lesion is post-synaptic, e.g. myasthenia, organophosphate poisoning, cobra bite; or pre-synaptic, e.g. Eaton-Lambert syndrome, botulism; or mixed, e.g. krait bite, antibiotic-induced myasthenia.

The common form as seen in myasthenia gravis is post-synaptic and classically causes weakness of ocular muscles (with sparing of pupils), bulbar muscles and proximal muscles of limb. The diagnosis is made partly by the distribution but mostly by the history of fatiguability, i.e. muscles get weaker with effort. Another feature is the variability of weakness from morning to evening. Classic pre-synaptic disease is often different (**Table 7**).

Table 7: Neuromuscular Junction Disease Localisation

	Post-synaptic	Pre-synaptic
Classic disorder	Myasthenia	Eaton-Lambert syndrome
Muscles affected	Ocular, bulbar and proximal limb	Limb muscles chiefly; eye, bulb spared
Reflexes	Good	Poor
Repeating reflex after exercise	Reflex reduced amplitude	Increased amplitude
Decrement test (nerve conduction)		
Slow rates (3 cps)	Decrement +	Decrement +
Fast rates (30 cps)	Decrement mild	Significant increment

Decrement implies that the amplitude of response reduces with repeated stimulation (usually only up to 4 to 5 stimuli). In increment, the response increases (and continues to increase up to 30 or more stimuli). **Figure 2** shows decrement in a case of myasthenia gravis.

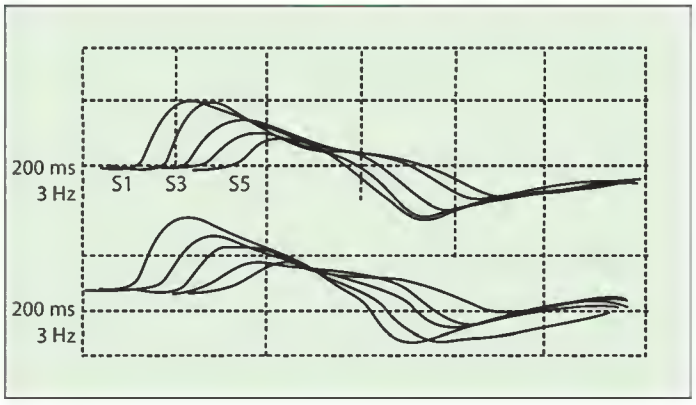

Figure 2: Decrement-reduced size of response with recurrent stimuli.

In testing decrement the ratio of response of S1 to S4 is usually calculated. A fall of 20% in S4 amplitude is considered significant for myoneural junction disease (10% for smaller muscles, e.g. face, orbicularis oculi).

MUSCLE DISEASE

Primary muscle diseases are characterised by weakness, hypotonia, preserved reflexes and normal sensations; wasting is a feature of muscle dystrophy. The weakness is usually symmetric and proximal in most cases, though hereditary distal myopathies are described, e.g. myotonic dystrophy. The acquired myopathies are all proximal.

Table 8 differentiation of causes of gradual-onset hypotonic weakness differentiates diseases of the three commonest sites of LMN-type lesion.

Table 8: Differentiation of Causes of Gradual-Onset Hypotonic Weakness

	Anterior Horn Cell Disease	Peripheral Nerves	Muscle Disease
Distribution	Proximal and distal	Distal	Proximal
Symmetry	May be absent	+ve	+ve
Fasciculation	Yes	Nil	Nil
Reflexes	Depressed equal to degree of Power loss	Depressed even with fair power	Depressed equal to degree of Power loss
Muscle percussion	+ve	+ve	Absent
Early contracture	Nil	Nil	Present
CPK and other muscle enzymes	Normal or may be elevated	Normal	Usually elevated
EMG	Neurogenic	Neurogenic	Myopathic
Nerve conduction studies	Small muscle action potential	Abnormal nerve conduction	Normal

Muscle percussion is performed by tapping a muscle directly when the deep tendon reflex is lost. Then if nerve or anterior horn cell is the cause of absent reflex the muscle contracts vigorously as reflex is lost due to nerve affection. When muscle disease is the cause, muscle percussion-induced contraction is also lost.

Weakness due to disease of muscle may be due to muscle degeneration or metabolic or inflammatory disease of muscle. **Table 9** gives features to differentiate inflammatory muscle disease from muscular dystrophy and metabolic myopathy.

Table 9: Differentiation of Inflammatory Muscle Disease from Mascular Dystrophy and Metabolic Myopathy

	Muscular Dystrophy	Inflammatory Muscle Disease	Metabolic Myopathy
Family H/o	+ve	–ve	–ve usually
Progress	Slow	Rapid	Rapid
Weakness/ wasting	Wasting more marked	Weakness > wasting	Weakness > wasting
Muscle tenderness	Absent	++	Nil
Fever, joint pain, rash	–ve	++	Nil
Reflexes	Depressed	May be increased	Depressed
Neck weakness	Rare (except myotonic dystrophy)	++	Rare
Swallowing defect	Rare	Common	Rare

20.2 Neurological Disorders—A Clinical Approach

MV Padma Srivastava

A thorough neurological evaluation is of paramount importance and is integral for correct diagnosis virtually in every clinical encounter. Relevant history and focused clinical examination are the keys to achieve the correct diagnosis. The standard practice is to record the patient's chief complaints, and take a history of the development of the symptoms, followed by the history of illnesses and surgeries, the family history, the personal and social history, and a review of any symptoms involving the main systems. A thorough neurological examination then follows and a differential diagnosis is constructed. What is unique to neurological examination is the extreme attention to 'localisation'. In general, the history provides the best clues for aetiology and the examination for localisation.

HISTORY

The chief complaint (or the several main complaints) is the usual starting point of the diagnostic process. An example might be, a patient presenting with the triad of complaints of headache, clumsiness and double vision. The complaints serve to focus attention on the questions to be addressed while taking the history and provide the first clue to the anatomy and aetiology of the disease underlying the complaints. In this case, it may suggest the presence of posterior fossa tumour affecting the cerebellum and the brainstem. The mode of onset is critically important in determining the aetiology. For example, a sudden onset usually indicates a vascular aetiology such as stroke. A course characterised by exacerbations and remissions may suggest multiple sclerosis, whereas a slowly progressive course may indicate a neoplasm or degenerative disorder. Paroxysmal episodes may suggest the possibility of seizures, migraines, periodic paralyses, etc.

Patient may provide a clear history or at times (especially in the elderly) may give tangential information not really required. Direct questioning is often required to keep the patient or health provider focused and also to clarify the symptoms. However, it is important not to lead the patient. Patients sometimes agree with everything that the physician may suggest even if it is incorrect. Reliability of patient's history is of paramount importance. Reliability depends on the patient's intelligence, memory, language function, educational and social status. Getting information from an observer other than the patient is important for diagnosing and characterising common neurological conditions such as epilepsy or dementia. In children, the history is always the composite perceptions of the child and the parent. Patients and physicians may use the same word to mean very different things. The word 'chakkar' may not really mean 'vertigo' but may mean, seizure, syncope, dizziness, fatigue, etc. Patients may describe a limb being 'numb' when what they actually mean 'paralysis'. 'Blurred' vision may mean decreased in vision or 'diplopia' which many a time is not 'complained' as double vision. The neurologist must understand the nature, onset, duration, and progression of each symptom and the temporal relationship of one symptom to another. One must ascertain if the symptoms are getting better, are constant or getting worse? What are the aggravating and relieving factors, if any. In infant and young children, the timing of developmental milestones will be of great relevance in many neurological illnesses.

In summary, the history of the presenting illness or chief complaint should include the following information:

1. Symptom onset (acute, subacute, chronic, or relapsing).
2. Duration.
3. Course of the condition (static, progressive, relapsing and remitting).
4. Associated symptoms such as pain, headache, vomiting, weakness and seizures).

Both the absence of expected features and the presence of unexpected features may assist in the diagnosis. A patient with numbness of the feet might have a peripheral neuropathy, but the presence of the backache and loss of sphincter control suggests that a spinal cord or cauda equina lesion is more likely.

The review of history should include the elements of nervous system function that did not surface in taking the primary complaints. The history should cover following fields of cognition, personality and mood change; hallucinations; seizures and other impairments of consciousness; orthostatic faintness; headaches, special senses, speech and language function, swallowing, limb movements, strength and sensation, pain, gait and balance and sphincter, bowel and sexual functions. A positive response may help clarify a diagnosis. For example, if a patient complaining of ataxia and hemiparesis admits to unilateral deafness, this may suggest a acoustic neuroma. Headaches in a patient with paraparesis suggest a parasagittal meningioma rather than a spinal cord lesion.

Personal History

The personal history in terms of occupation, marital status, and alcohol, tobacco and illicit drug use and the medical history of the parents, siblings and children looking for evidence of familial disease is essential. Many neurological disorders are hereditary. Hence a history of similar diseases in the family members or of consanguinity may be of diagnostic importance. However, an expression of a gene mutation may be quite different from one family member to another with respect not only to the severity of the neurological dysfunction but also to the organ systems involved. For instance, the mutations of the gene for Machado-Joseph disease (SCA-3) can cause several phenotypes. A patient with Charcot-Marie-Tooth disease (hereditary motor-sensory neuropathy) may have a severe peripheral neuropathy, whereas relatives may have only *pes cavus*.

Reported diagnoses may be inaccurate. Some clinical situations such as epilepsy and other neurological conditions presumed

to have a social 'stigma' may be kept secretive and patients may show great reluctance to divulge the correct information. The history of 'seizures' in the family members will invariably be 'negative' unless relentlessly and laboriously pursued. If there is a possibility that the disease is inherited, it is helpful to obtain information from parents and grandparents and to examine the relatives at risk. Minimum data for all first and second-degree relatives should include, age, cause of death and any significant neurological or systemic diseases.

History of Previous Illnesses

The record of history should include dates and details of all surgical procedures, significant injuries including head trauma and fractures, hospitalisations, and conditions requiring medical consultation and medications. For paediatric patients, information on the pregnancy and state of infant at birth should be recorded. Seizure and worsening headaches in a patient who previously had surgery for lung cancer suggests a brain metastasis. Chronic low-back pain in a patient complaining of numbness and weakness in the legs on walking half a mile suggests neurogenic claudication from lumbar canal stenosis.

Review of Symptoms in Non-Neurological Systems

Neurological function is adversely affected by dysfunction of many systemic disorders including that of the liver, kidney, gastrointestinal tract, and blood vessels. Several neurological diseases are characterised by multi-organ involvement such as vasculitis, sarcoidosis, mitochondrial disorders and storage diseases. History of gastric surgery may lead to vitamin B12 deficiency. Sarcoidosis may cause recurrent Bell's palsy, diabetes insipidus, ophthalmoplegia and peripheral neuropathy. Disorders of the liver, kidney and small bowel can be associated with a wide variety of neurological disorders. Systemic malignancy can cause direct and indirect (paraneoplastic) neurological problems. Medications are also often the cause of neurological disturbances, particularly, anti-epileptic agents, chemotherapeutic agents, etc. Isoniazid may cause a peripheral neuropathy. Lithium carbonate may produce tremor and ataxia. Neuroleptic agents can produce a parkinsonian syndrome or dyskinesias. Special emphasis needs to be given to intake of ayurvedic medications especially those that contain heavy metals and other over the counter drugs.

NEUROLOGIC EXAMINATION

The neurological examination is one of the most unique in all of clinical medicine. Unlike many other fields of medicine in which diseases are visible, or palpable, neurology is characterised by conditions that may be detected only be applying specific examination techniques and logical deduction, except when certain cutaneous markers or other stigmata suggest the diagnosis.

Steps in the Neurologic Examination

For the purpose of simplicity, the neurological examination is divided into several steps. When mastered these steps become second nature to the examiner. These steps include the following:

- Higher mental functions
- Speech and Language
- Cranial Nerves
- Motor System
- Sensory System
- Reflexes
- Cerebellum
- Meninges
- Spine
- Gait
- Systemic examination

Tools required will include an ophthalmoscope, a reflex hammer, and a tuning fork as minimum essentials for performing the examination.

Examination of the Higher Mental Functions

This includes testing of memory, orientation and intelligence besides other aspects of patients' psychic state. Any suspicion of disorder in higher mental functions will require a very detailed assessment including detailed lobe function tests which will be out of purview of this chapter.

Memory

It is the ability to register and recall prior sensory input. Recent and remote memory functions are differently affected depending on the disease process. Past memory is relatively preserved in chronic dementing processes, with major disturbances in the attention span and recent memory. On the contrary, all aspects of memory are impaired in acute encephalopathies.

Orientation

It is an individual's cognitive sense of his status in time, place and person. These functions are affected in the same order as they are in organic disease. In other words, the sense of time is first to be impaired in organic dysfunction and the sense of person is the last to be lost. However, the order may be disturbed in psychological dysfunction.

Intelligence

It is the ability to quickly and successfully apply previous knowledge to a new situation and to use reason in solving problems. Vocabulary, fund of knowledge, calculations, abstraction and judgment are good indicators of intelligence. Due regard and allowance is given to literacy state of the individual. A mini-mental state examination is given in annexure/echapter as examination of neurological disorder.

Mini-mental state examination (MMSE)

See previous chapter on Basic Considerations in Neurology

Speech and Language

Abnormalities include aphasia, or acquired language dysfunction; dysarthria or acquired dysfunction in articulation and dysphonia or acquired dysfunction in phonation.

Dysphasia or aphasia

In dysphasia the ability to process language is impaired, resulting in an inability to understand (i.e. receptive or sensory or Wernicke's aphasia), transfer signals from the Wernicke's are to the Broca's area (i.e. conduction aphasia), or properly execute speech (i.e. expressive, motor or Broca's aphasia). The combination of Broca's aphasia and Wernicke's aphasias is referred to as mixed aphasia.

Essential Elements of Common Aphasia

Type of aphasia	Fluency	Comprehension	Naming	Localisation
Broca's	Non-fluent	Intact	Impaired	Broca's area
Wernicke's	Fluent	Impaired	Impaired	Wernicke's area
Conduction	Fluent	Intact	Impaired	Fasciculus arcuate
Global	Non-fluent	Impaired	Impaired	Non localising

Transcortical aphasia

These are caused due to the involvement of the association cortices sparing the primary language areas. They are distinguished from primary aphasia by the preservation of repetition.

Dysarthria

It is the inability to articulate spoken words. The quality of the oration in impaired but the content remains intact (e.g. slurred speech). The patient's ability to understand and synthesise speech remains intact. It results from paralysis of pharyngeal, palatal, lingual or facial musculature. It is also observed with cerebellar lesions (staccato/scanning/explosive speech) or extrapyramidal disorders (monotonous and hypo-phonic as in Parkinson's disease) etc.

Dysphonia

Dysphonia is the impairment or inability to phonate. Neurologic causes include unilateral recurrent laryngeal nerve paralysis and lesions of the vagus nerve.

Examination of the Cranial Nerves

There are 12 cranial nerves; their anatomy and examination are given in chapter 7 section 20.

Examination of the Motor System

Trophic state

Assess the size, shape and symmetry of a muscle. Atrophy, hypertrophy or abnormal bulge or depression will be important diagnostic findings. Hypertrophy with weakness is seen commonly with Duchenne muscular dystrophy.

Tone

Muscle tone is the permanent state of partial contraction of a muscle and is assessed by passive movement. The muscle may be hypertonic and hypotonic. Hypotonia is defined as decreased tone and may be seen in lower motor neuron lesions, spinal shock and some cerebellar lesions. Hypertonia may manifest as spasticity or rigidity. Pyramidal lesions result in spasticity that may manifest as a clasp-knife phenomenon. Rigidity refers to increased tone associated with extrapyramidal lesions; it may result in a cogwheel (stepwise) or lead-pipe (uniform) resistance to passive movement.

An increase in tone is noted when there is an increase in the resistance to passive movements of the limbs. The movements are either flexing or extending the limbs, rotating the limbs or shaking the hands at the level of wrists. The increase in tone is classified as follows (Ashworth Scale):

0 – Normal to decrease (flaccidity)
1 – Normal
2 – Mild increase
3 – Moderate increase
4 – Severe increase
5 – Associated with spasms

Muscle strength

The MRC grading of muscle power is the standard method of testing for muscle power.

Score	Description
0	Absent voluntary contraction
1	Feeble contractions that are unable to move a joint
2	Movement with gravity eliminated
3	Movement against gravity
4	Movement against partial resistance
5	Movement against full resistance or normal power

A central lesion usually produces greater weakness in the extensors than in the flexors of the upper extremities and the reverse in the lower extremities.

Upper motor lesions are associated with weakness, spasticity (increased tone), hyperreflexia, primitive reflexes, and the Babinski sign. Primitive reflexes include the grasp, suck and snout reflexes. Lower motor neuron lesions are characterised by weakness, hypotonia (flaccidity), hyporeflexia, atrophy and fasciculations.

Fasciculations are involuntary movements which occur as fine rippling movements under the skin, at random intervals and distribution. They are indicative of a lower motor neuron disease. They are due to denervation of whole motor units. Atrophy of the muscle groups are usually associated with fasciculations as typically seen in motor neuron disease (MND). Fibrillations are spontaneous contractions of the individual muscle fibres and are therefore not visible to the naked eye.

Examination of individual muscled groups

- The deltoid muscle is innervated by the C5 nerve root via the axillary nerve.
- Ask the patient to abduct both the arms or each arm separately to 90° and raise them above against resistance. Compare the strength of each arm. Alternately, ask the patient to raise both their arms in front of them simultaneously as strongly as they can.
- Ask the patient to extend and raise both arms in front of them. Ask the patient to keep their arms in place while they close their eyes. If there is an upper motor weakness, there will be a positive pronator drift, in which the affected arm will pronate and fall. In upper motor neuron weakness, supination is weaker than pronation in the upper extremity, leading to a pronation of the affected arm.
- The biceps muscle is innervated by the C5 and C6 nerve roots via the musculocutaneous nerve.
- Test the strength of lower arm flexion by holding the patient's wrist from above and instructing them to 'flex their hand up to their shoulder'. Provide resistance at the wrist. Repeat and compare to the opposite arm.

- The triceps muscle is innervated by the C6 and C7 nerve roots via the radial nerve.
- Have the patient extend their forearm against the examiner's resistance. Make certain that the patient begins their extension form a fully flexed position because this part of the movement is most sensitive to a loss in strength. Note any asymmetry in the other arm.
- The wrist extensors are innervated by C6 and C7 nerve roots via the radial nerve. The radial nerve is responsible for all the extensor muscles in the upper and lower arm.
- Test the strength of wrist extension by asking the patient to extend their wrist while the examiner resists the movement. This tests the forearm extensors. Repeat with the other arm.
- Finger flexion is innervated by the C8 nerve root via the median nerve. Observe for intrinsic hand, thenar and hypothenar muscle wasting. Test the patient's grip by having the patient hold the examiner's fingers tightly and instructing them not to let go while the examiner attempts to remove them. Normally, the examiner cannot remove their fingers. Note for any asymmetry in both the hands.
- Finger abduction is innervated by the T1 nerve root via the ulnar nerve.
- Test the intrinsic hand muscles by having the patient abduct and 'fan out' all of their fingers. Instruct the patient to not to allow the examiner to compress them back in. Normally, one can resist the examiner from replacing the fingers.
- Thumb opposition in innervated by the C8 and T1 nerve roots via the median nerve.
- Test the strength of the thumb opposition by asking the patient to touch the tip of their thumb with their little finger. Apply resistance to the thumb with the examiner's index finger. Repeat with the other thumb and compare.
- The hamstrings are innervated by the L5 and S1 nerve roots via the sciatic nerve.
- Test the flexion of the hip by asking the patient to lie down and raise each leg separately while the examiner resists. Repeat and compare the test flexion at the knee by holding the knee from the side and applying resistance under the ankle and instructing the patient to pull the lower leg towards their buttock as hard as possible. Repeat with the other leg.
- Ankle dorsiflexion is innervated by the L4 and L5 nerve roots via the peroneal nerve. Test dorsiflexion of the ankle by holding the top of the ankle and have the patient pull their foot towards the body as strongly as possible. Repeat with the other foot. This tests the muscles in the anterior compartment of the lower leg.
- Ankle plantar flexion is innervated by the S1 and S2 nerve roots via the tibial nerve.
- Ask the patient to 'press down' as hard as possible. Repeat with the other foot and compare. This tests the gastrocnemius and soleus muscles in the posterior compartment of the lower leg.
- The extensor hallucis longus muscle is almost completely innervated by the L5 nerve root. Ask the patient to move the large toe against the examiner's resistance towards the body. This test the extensor hallucis longus.

Involuntary movements

Involuntary movements include fibrillations, fasciculations, asterixis, tics, myoclonus, chorea, dystonia, athetosis, hemiballismus, seizures, etc. and will be described in detail in respective chapters.

Sensory System

Non-cortical sensory system

Light touch, pain, heat, cold and vibration sensations can be included in this group. Light touch is tested by touching the skin with a wisp of cotton or tissue. Pain is tested by using a sharp object such as an open safety pin. Temperature can be tested by touching the patient's skin with two test tubes, one with warm water and the other with cold water. Vibration is tested with a 128 Hz or 256 Hz tuning fork. Compare findings on the two sides, and also with corresponding areas on the examiner.

Pain and light touch sensation

The corresponding nerve root for each area tested is indicated in parenthesis:

1. Posterior aspect of the shoulders (C4)
2. Lateral aspect of the upper arms (C5)
3. Medial aspect of the lower arms (T1)
4. Tip of the thumb (C6)
5. Tip of the middle finger (C7)
6. Tip of the little finger (C8)
7. Thorax, nipple level (T5)
8. Thorax, umbilical level (T10)
9. Upper part of the upper leg (L2)
10. Lower-part of the upper leg (L3)
11. Medial lower leg (L4)
12. Lateral lower leg (L5)
13. Sole of foot (S1)
14. Peri-anal area (saddle area) (S2, S3, S4)

Alternating between pinprick and light touch, touch the patient in the above 14 areas. Touch one body part followed by the corresponding body part on the other side with the same instrument. This allows the patient to compare the sensations and note asymmetry.

Position sense is tested by asking the patient with eyes closed to report if his/her large tow is 'up' or 'down' when the examiner manually moves the patient's toe in the respective direction. Repeat on the opposite foot and compare.

Fine touch, position sense (proprioception) and vibration sense are conducted together in the dorsal column system. Rough touch, temperature and pain sensation are conducted via the spinothalamic tract.

Cortical sensory system

The cortical sensory system includes the somatosensory cortex and its central connections. This system enables the detection of the position and movement of the extremities in space (kinaesthetic sensation), size and shape of objects

(stereognosis), tactile sensations of written patterns on the skin (graphaesthesia) and tactile localisation and tactile discrimination on the same side or both sides of the body.

Stereognosia

Test stereognosis by asking the patient to close his/her eyes and identify the object that is placed in their hand. Place a key, or pen or coin in the hand. Repeat this test with the other hand using a different object.

Astereognosis refers to the inability to recognise objects placed in the hand with eyes closed. Without a corresponding dorsal column system lesion, these abnormalities suggest a lesion in the sensory cortex of the parietal lobe.

Graphaesthesia

Ask the patient to close his/her eyes and identify the number or letter that the examiner writes with the finger or back of the pen on his/her palm. Repeat on the other hand and compare.

Apraxias are problems with executing movements despite intact strength, coordination, position sense and comprehension. This finding is associated with cortical damage.

Extinction or simultagnosia

Patient must sit with eyes closed. Touch the patient on the trunk or legs in one place and then tell the patient to open their eyes and point to the location where they noted the sensation. Repeat the manoeuvre a second time, touching the patient in two places on opposite sides of their body simultaneously. Then ask the patient to point to where they felt sensation. Normally they should point to both areas. If not, sensory extinction is present.

Examination of Reflexes

The different reflex responses may be divided into three categories on the basis of their clinical significance.

Primitive reflexes

These include the glabellar tap, rooting, sucking, and palmomental reflexes. As a rule, these signs are generally absent in adults. When present, these signs signify diffuse cerebral damage, particularly the fontal lobes.

Superficial reflexes

These are segmental reflex responses that indicate the integrity of cutaneous innervation and the corresponding motor outflow. These include the corneal, conjunctival, abdominal, cremasteric, anal wink and the plantar (Babinski) reflexes. The corneal and conjunctival reflexes may be elicited by gently touching the appropriate structure with a sterile wisp of cotton. The normal response is bilateral winking. The abdominal reflex can be elicited by drawing a line away from the umbilicus along the diagnals of the four abdominal quadrants. A normal reflex draws the umbilicus toward the direction of the line that is drawn. The best known amongst these group of reflexes is the plantar reflex. The most commonly performed manoeuvre is stroking the lateral aspect of the sole with sharp object (but not noxious). The normal response is plantar flexion of the great toe. Dorsiflexion of great tow with and without fanning of toes describes the Babinski's response.

Deep tendon reflexes

These are mono-synaptic spinal segmental reflexes. When they are intact, integrity of the following is confirmed: cutaneous innervation, motor supply and cortical input to the corresponding spinal segment. These reflexes include the biceps, brachioradialis, triceps, patellar or knee and ankle jerks. The spinal roots that subserve these reflexes are:

Muscle	Spinal Roots
Biceps	C5, C6
Brachioradialis	C6
Triceps	C7
Knee	L2 to L4
Ankle	S1

Grading of Reflexes

Score	Reflexes
0	Absent
1	Hypoactive or present only with re-enforcement
2	Readily elicited with a normal response
3	Brisk with or without evidence of spread to neighbouring roots
4	Associated with a few beats of unsustained clonus
5	Sustained clonus

Individual reflexes

The biceps and brachioradialis reflexes are mediated by the C5 and C6 nerve roots. The biceps reflex is elicited by placing the examiner's thumb on the biceps tendon and striking the thumb with reflex hammer and observing the arm movement. Repeat and compare with the other arm. The brachioradialis reflex is observed by striking the brachioradialis tendon directly with the hammer when the patient's arm is resting. Note the reflex supination. Repeat and compare with the other arm.

The triceps reflex is mediated by the C6 and C7 nerve roots, predominantly by C7. The triceps reflex is measured by striking the triceps tendon directly with the hammer while holding the patient's arm with the other hand. Repeat and compare with the other arm.

The knee jerk is mediated by the L3 and L4 nerve roots, mainly by L4.

With the patient supine, lift the knee and stroke the quadriceps tendon directly with the reflex hammer. Or, with the lower leg hanging freely off the edge of the examination table, stroke the tendon. Repeat and compare to the other leg.

The ankle jerk is mediated by the S1 root. The ankle reflex is elicited by holding the relaxed foot with one hand and striking the Achilles tendon wit the hammer and noting plantar flexion. Compare with the other foot.

There are certain reflexes which are elicited when there is a suspicion of pyramidal involvement indicating heightened reflexes. These include:

Jaw jerk: Elicited by asking the patient to partially open his mouth, placing the thumb over the patient's chin and striking the thumb with the hammer. Closing movement of the jaw indicates lesion above the midbrain.

Finger flexion: Elicited by tapping the balls of the fingers with hammer.

Hoffman's response: This is elicited by holding the patient's middle finger between the examiner's thumb and index finger and using the thumb nail, press down on the patient's finger nail. A positive Hoffman's response is when the other fingers flex transiently after the click.

Wartenburg: Pull the flexed fingers of the patient outward with the examiner's hand. The thumb should extend outward.

The above three reflexes indicate upper motor neuron lesion affecting the upper extremity.

Cerebellar Signs

The cerebellum provides an important feedback loop for coordination of muscle activity by integrating the functions of the cortex, basal ganglia, vestibular apparatus and spinal cord. Midline cerebellar dysfunction results in ataxia of gait, difficulty in maintenance of upright posture and truncal ataxia. Acute neocerebellar hemispheric lesions result in additional signs. The following are the various cerebellar signs:

1. Ataxia, atonia
2. Intention tremor
3. Dyssynergia
4. Dysmetria
5. Dysrhythmia
6. Dysdiadochokinesia
7. Dysarthria
8. Nystagmus and various other eye signs
9. Pendular knee jerks
10. Rebound phenomenon

Meningeal Signs

Signs of meningeal irritation indicate inflammation of the dura, these signs are described below:

1. Nuchal rigidity or neck stiffness is tested by placing the examiner's hand under the patient's head and gently trying to flex the neck. Undue resistance implies diffuse irritation of the cervical nerve roots from meningeal inflammation.
2. Brudzinski's sign is flexion of both knees during the manoeuvre to test nuchal rigidity. This indicates diffuse meningeal irritation in the spinal nerve roots.
3. Kernig's sign is elicited by flexing the hip and knee on one side while the patient is supine, then extending the knee with the hip still flexed. Hamstring spasm results in the posterior thigh muscle and difficulty with knee extension. With severe meningeal inflammation, the opposite knee may flex during the test.

Gait and Spine

Neurological examination will be incomplete without watching the patient stand and walk. In certain situations, abnormality of gait will be the only sign. Different gait disorders can be the hemiparetic gait, the ataxic gait, the shuffling gait, the steppage gait, the spastic or scissor gait and antalgic gait. Spine must be checked for any abnormalities such as scoliosis, gibbus and also finally look for neurocutaneous markers including *pes cavus*.

Gait is evaluated by having the patient walk across the room under observation. Gross gait abnormalities should be noted. Ask the patient to walk heel to toe across the room, then on their toes only, and finally on their heels only. Normally, these manoeuvres are possible without too much difficulty. Also note the arm swing while walking. Any slowing or decrease in arm swing would indicate a subtle extrapyramidal involvement or mild weakness of upper motor neuron type.

Walking on heels is the most sensitive way to test for foot dorsiflexion weakness and walking on toes is the best way to test early foot plantar flexion weakness.

Abnormalities in heel to toe walking (tandem gait) may be due to weakness, incoordination, vertigo, sensory ataxia (poor position sense), and leg tremors.

Rhomberg's test

Perform the Romberg's test by having the patient stand still with their heels together. Ask the patient to remain still and close their eyes. If the patient loses their balance, the test is positive.

To achieve balance, a person requires the following inputs to the cortex.

1. Visual confirmation of position
2. Non-visual confirmation of position (including proprioceptive and vestibular input)
3. A normally functioning cerebellum.

If the patient loses their balance after standing still with eyes closed, and is able to maintain balance with their eyes open, then there is likely to be lesion in the cerebellum.

The full neurological examination is too lengthy to perform in practice. Instead, the experienced neurologist uses the focused neurological examination to examine in detail the neurological functions that are relevant to the history, and performs a screening neurological examination to check the remaining parts of the nervous system. This approach should confirm, refute or modify the initial hypotheses of disease location and causation derived from the history. The standard neurological examination is less effective when used to monitor the course of a disease or its temporal response to treatment. Special quantitative functional tests and rating scales are needed to measure change in neurological function over time.

General physical examination

The nervous system is damaged in numerous medical disease and a general examination is an integral part of the examination of patients with neurological disorders. For instance, atrial fibrillation, valvular heart disease, or an atrial septal defect may cause embolic strokes. Hypertension increases the risk of all types of stroke. Signs of malignancy raise the possibility of metastatic lesions of the nervous system or paraneoplastic syndromes. Some diseases, such as vasculitis and sarcoidosis, affect both the brain and other organs.

The skills of a neurologist are learned. Seeing many cases of disease teaches the neurologist which symptoms and signs should be present, and just as important, which should not be present. However, there is no substitute for experience and pattern recognition. The diagnosis of a neurological disease is a combination of science and experience and the management of neurological disease is an art.

20.3 Clinical Neurophysiology

J Kalita, UK Misra

Neurophysiological techniques help in understanding the functional aspect of central and peripheral nervous system. It involves the recording, display, measurement and interpretation of action potentials arising from the central nervous system (CNS) [electroencephalography (EEG) and evoked potentials], peripheral nerves (nerve conduction studies), neuromuscular junction (repetitive nerve stimulation) and muscles (electromyography). Knowledge about the generation of waveforms or potentials is essential for proper conduct and interpretation of the electrodiagnostic test.

ELECTROENCEPHALOGRAPHY

The EEG rhythms depend on the spontaneous intrinsic activity, which is modulated by the afferent inputs from thalamus and brainstem. The EEG abnormality, therefore, may occur either due to disruption of cortical network or sub-cortical inputs to cortical neurons. On scalp recorded EEG, the voltage of EEG signals are attenuated due to impedance of CSF, meninges, skull and scalp. The amplitude of the cortical EEG ranges between 500 to 1,500 μV whereas in the scalp it is 10 to 100 μV.

EEG Recording and Reporting

For routine EEG, electrodes are placed using '10-20' system of electrode placement (**Figure 1**). The recording electrodes interconnect into chains and the potential difference between pairs of electrodes is recorded. Electrode pairs are interconnected in different arrangements to comprehensively evaluate the whole brain activity which are known as montages. Routine EEG is recorded for 30 to 45 minutes including two activation procedures; hyperventilation and intermittent photic stimulation. Sometimes, EEG during sleep or in sleep deprived state is useful.

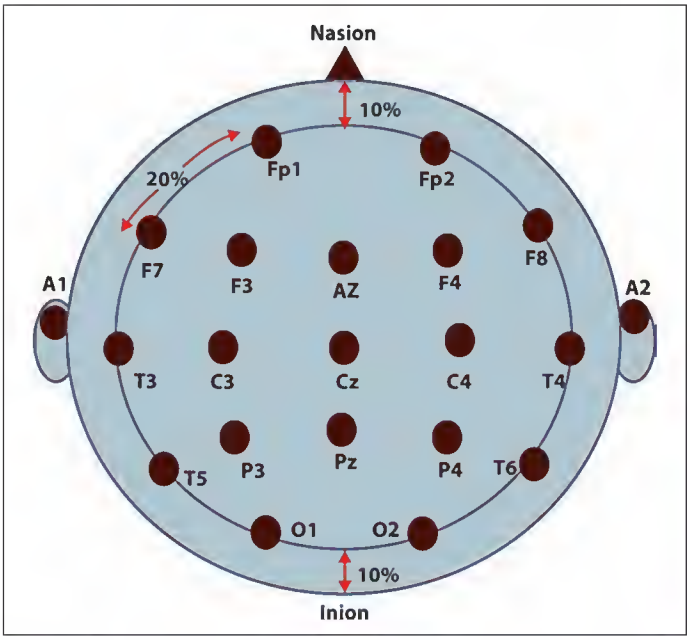

Figure 1: Schematic diagram shows '10-20' system of electrode placement for electroencephalography recording.

The EEG reporting needs knowledge of age, artifacts, sleep transient, normal variants and epileptiform and non-epileptiform abnormal discharges. The EEG report should include description of waveforms, interhemispheric coherence, reactivity and abnormal discharges (**Table 1**).

Table 1: Important Points in Electroencephalography Reporting

Waveforms: frequency, voltage, morphology, spatial distribution, modulation of frequency and voltage
Interhemispheric coherence
Symmetry: voltage and frequency
Synchrony: voltage and frequency
Reactivity: eye opening, pain, touch, sound, mental activity
Abnormal discharge: epileptiform, non-epileptiform and others

Basic EEG Rhythm

The basic EEG rhythms are named on the basis of their frequency into alpha, beta, theta and delta (**Table 2**). In normal adults, the awake pattern of EEG rhythm is of alpha range which is dominant in the occipital area. Alpha waves are sinusoidal waveform whose amplitude is reduced on eye opening (**Figure 2; Table 3**). Beta activity (10 to 20 μV) is normally present in the frontocentral area and is more marked in tense individual and those on barbiturate or diazepam.

Table 2: Electroencephalography Rhythms

Alpha: 8 Hz to 13 Hz
Beta: 14 Hz to 40 Hz
Theta: 4 Hz to 7.5 Hz
Delta: 0.1 Hz to 3.5 Hz

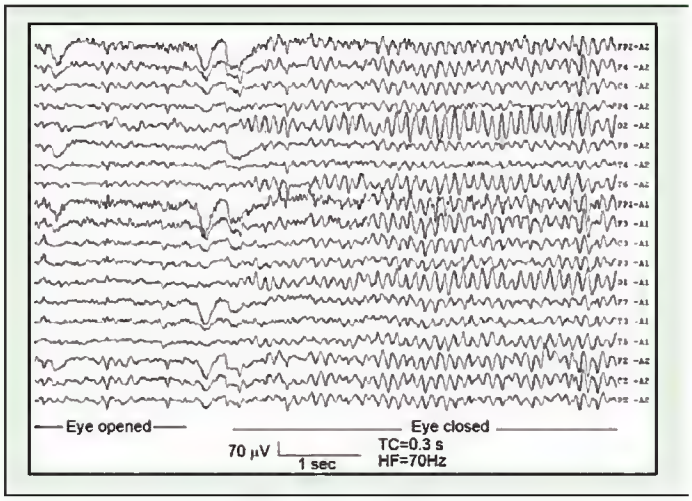

Figure 2: Electroencephalography of a normal adult individual shows posterior alpha activities. The amplitude of alpha activities is augmented when the eyes are closed.

Table 3: Characteristics of Alpha Rhythm

8 Hz to 13 Hz, 50 μV in amplitude
Maximum in posterior head region
Increased voltage in occipital, wax and wanes, varies at different time in the same individuals
Best seen in closed eyes and mentally relaxed state
Blocked by open eyes and mental effort

In normal adults, temporal theta activity may be seen. Delta activity is absent in normal adults during awake state but seen during sleep. Slow activities (delta and theta) are predominant waveforms in newborn but these are replaced by alpha and beta with the maturation of EEG; 8 Hz posterior rhythm develops by 3 years, 10 Hz by 10 years and alpha remains same till the age of 90 years.

Sleep EEG

During non-rapid eye movement (NREM) sleep, EEG tends to synchronise and during rapid eye movement (REM) sleep, it is desynchronised. The sleep spindles are 12 Hz to 14 Hz activity, which wax and wane in amplitude and are prominent in frontocentral region. It appears by 2 months of age. Vertex sharp waves are positive followed by large negative deflection of 70 ms to 200 ms duration, maximum in vertex and appear by 5 months of age. K-complexes are characterised by initial biphasic (100 ms) followed by fast activities (**Figure 3**). It appears by the age of 5 months and is prominent in frontocentral area. The EEG and clinical correlates of different stages of sleep are presented in **Table 4**.

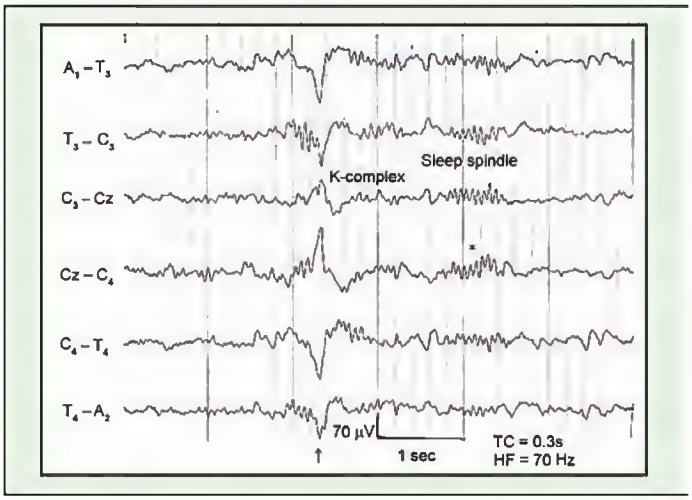

Figure 3: Electroencephalography recording during sleep shows K-complexes and sleep spindles.

Utility of EEG

EEG is crucial for the diagnosis and classification of epilepsy. Certain patterns of EEG are disease specific such as Creutzfeldt Jakob disease and subacute sclerosing panencephalitis. EEG also helps in prognostication of the patients. However, EEG is not a screening test and is not a replacement for proper history and clinical examination. While ordering EEG requisition, a precise clinical description is helpful in interpretation of the EEG.

Limitation of EEG

EEG although helps to understand the underlying brain function, but its limitations should also be appreciated which are summarised in **Table 5**.

Table 4: Clinical and Electroencephalography Correlates of Sleep

Stages of Sleep	Clinical	EEG
Non-rapid eye movement sleep		
Stage I	Drowsiness	Alpha drop out, POSTS, vertex sharp waves (VS)
Stage II	Light sleep	4 Hz, with fast waves, VS, sleep spindle, K-complex
Stage III	Deep sleep	Slowing, K-complex, some spindle and VS
Stage IV	Very deep sleep	Fast activity
Rapid eye movement sleep		Desynchronisation of EEG activity

EEG = Electroencephalography; POSTS = Posterior occipital sharp transient of sleep.

Table 5: Limitations of Electroencephalography

Surface EEG does not unambiguously determine the synaptic events contributing to EEG waveforms
EEG changes are rarely disease specific
Many focal brain dysfunctions may not be recorded by EEG, especially if deep seated or in the sulci

Abnormal EEG

The abnormal EEG may be categorised broadly into three types: (i) epileptiform discharges; (ii) periodic or quasi-periodic discharges; and (iii) non-epileptiform paroxysmal EEG abnormalities.

Epileptiform discharges

The inter-ictal epileptiform discharges are spike, sharp waves, poly or multiple spikes, runs of rapid spikes, small sharp spike and spike and slow wave complex. Ictal EEG discharges include 3 Hz spike and slow waves (absence/generalised epilepsy; **Figure 4**), generalised theta/delta (tonic seizure), periodic generalised theta or delta (myoclonic seizures), generalised electrodecremental (infantile spasm), focal periodic or dysrhythmic slow waves (*epilepsia partialis continua*), temporal, fronto-temporal or temporal low voltage wave (complex partial seizure) and localised beta (neonatal seizure).

Spike and sharp wave

Spikes are mono-, bi- or tri-phasic waveform of 20 ms to 70 ms duration whereas the duration of sharp waves is 70 ms to 200 ms.

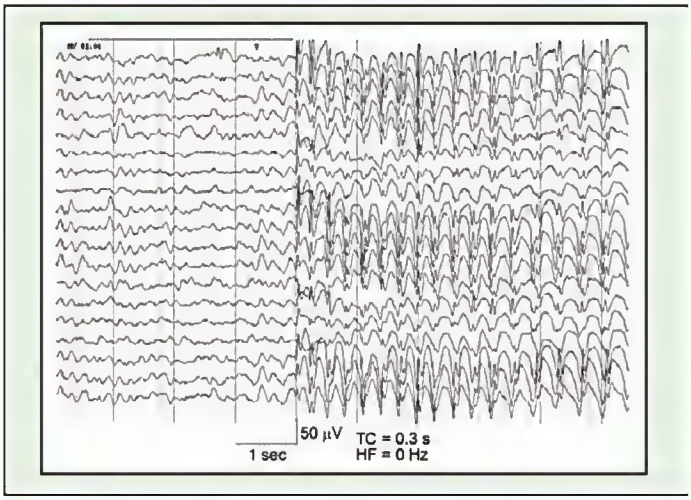

Figure 4: Electroencephalography record of a 6-year-old boy with absence seizure shows generalised 3 Hz spike and slow wave discharges during hyperventilation.

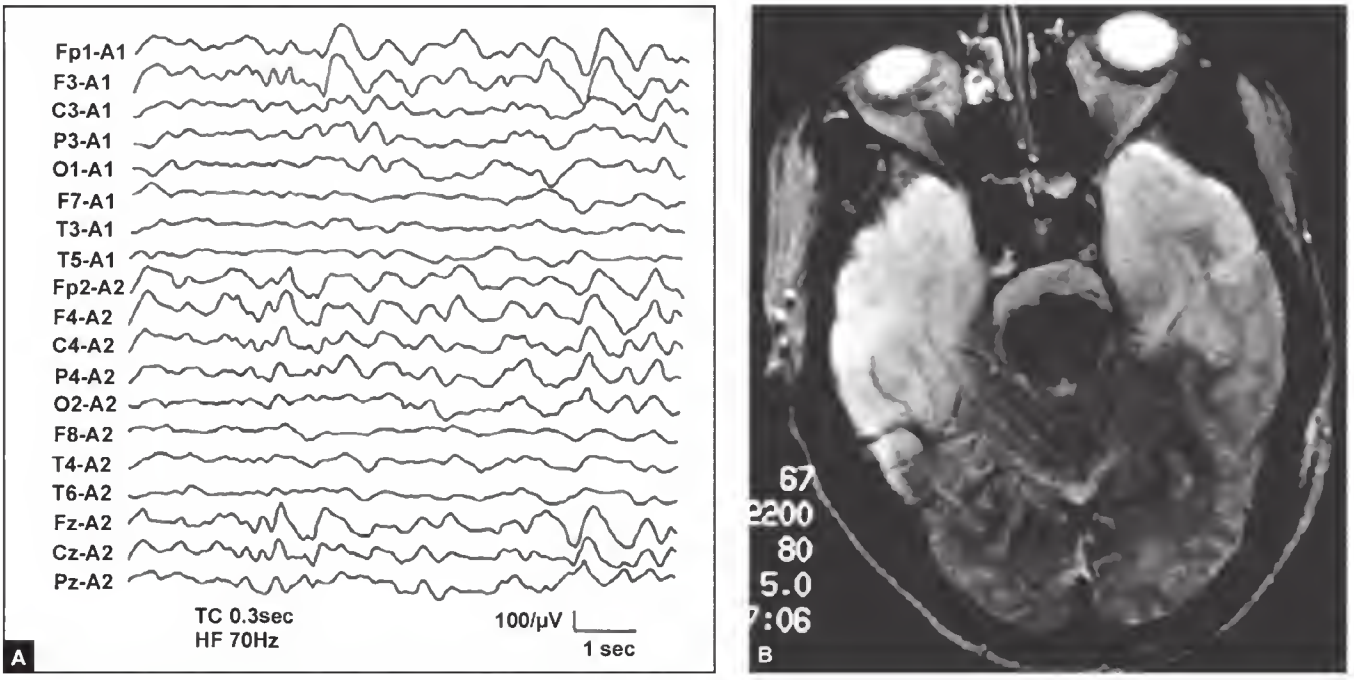
Spike and sharp waves both stand out of background. The location of spike or sharp waves suggests the possible seizure focus.

Periodic or quasiperiodic discharges

Periodic discharges are sharp or long duration (up to 150 ms), high amplitude (100 μV to 300 μV) waveforms occurring at periodic interval. These may be focal, widely scattered or generalised. Various patterns of periodic/quasiperiodic discharges are described which include: (1) burst suppression in hypoxic encephalopathy, barbiturate, nitrous oxide and cyclopropane poisoning; (2) generalised repetitive sharp transient in Creutzfeldt Jakob disease and anoxic encephalopathy; (3) periodic lateralised epileptiform discharges in herpes simplex encephalitis (**Figure 5**), temporal lobe abscess and syphilis; (4) generalised tri-phasic waves in metabolic encephalopathy; and (5) generalised periodic slow wave complexes in Lennox-Gastaut syndrome (**Figure 6**) and subacute sclerosing panencephalitis (**Figure 7**).



Non-epileptiform paroxysmal EEG abnormalities

Non-epileptiform paroxysmal EEG abnormalities are as follows:

1. Widespread intermittent slow activity associated with active or diffuse brain dysfunction.
2. Bilateral persistent EEG slowing associated with impaired consciousness (**Figures 8A and B**).
3. Focal persistent EEG slowing associated with focal cerebral dysfunction.

EVOKED POTENTIALS

Evoked potentials (EPs) are electrical signals generated in the nervous system in response to sensory stimuli except motor evoked potential which is recorded from the target muscle by

Figures 5A and B: (A) EEG record shows periodic lateralised epileptiform discharges (frontal predominance) with background delta slowing in a patient with febrile encephalopathy with seizure; (B) Cranial MRI of the same patient shows bilateral temporal T2 hyperintensity suggestive of herpes simplex encephalitis.

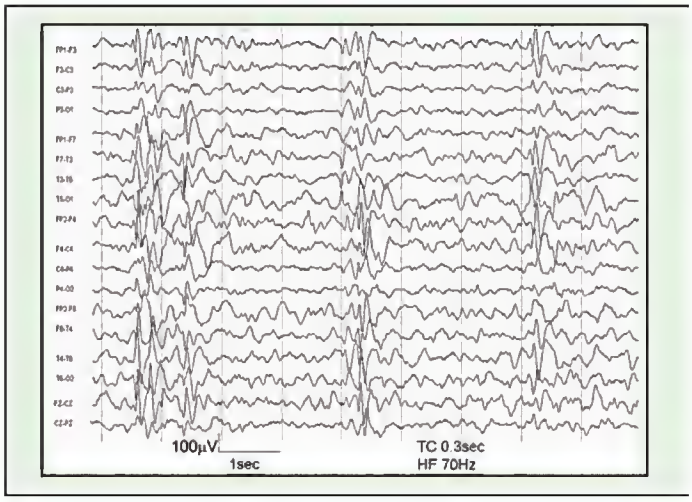


Figure 6: EEG record of a 4-year-old boy with Lennox-Gastaut syndrome shows generalised slow spike and slow wave discharges with some periodicity during sleep.

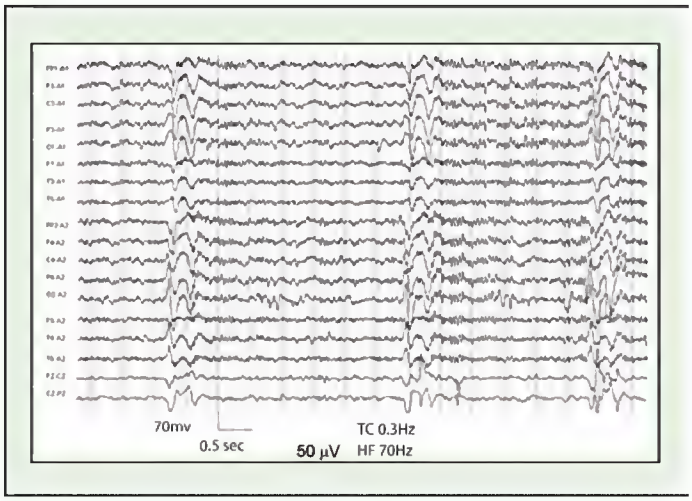

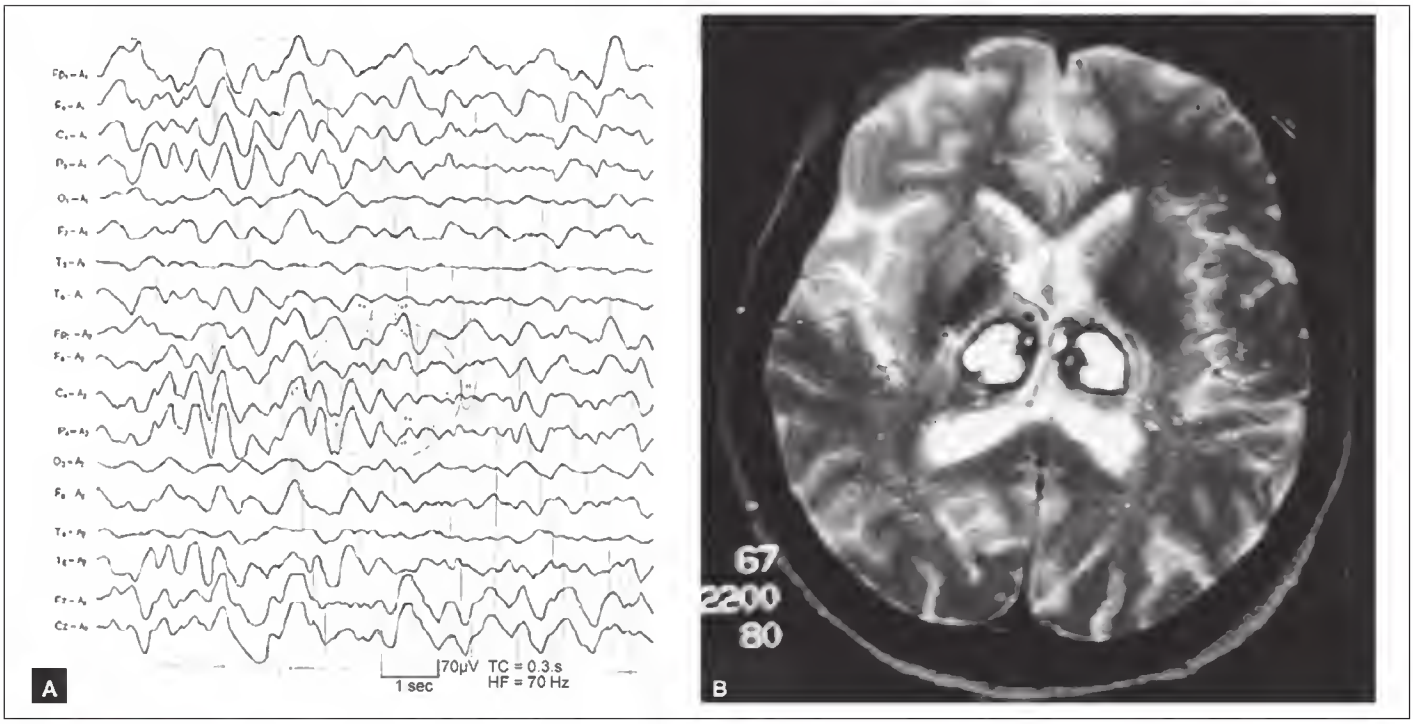

Figure 7: EEG record of an 8-year-old boy with subacute sclerosing panencephalitis shows pseudoperiodic discharges on EEG. The R complexes are coming at a rate of 2.5 to 3 interval.

Figures 8A and B: (A) EEG record of a 23-years-old lady with viral encephalitis shows delta slowing; (B) MRI of the same patient shows bilateral thalamic T2 hyperintensity with a hypointense rim suggestive of Japanese encephalitis.

applying magnetic or electrical stimuli over the motor cortex. Commonly used evoked potentials are visual evoked potential, brainstem auditory evoked potential, somatosensory evoked potential and motor evoked potentials. Cognitive and other event related potentials are yet to establish its role in the clinical practice.

Visual Evoked Potential (VEP)

VEP is obtained by averaging the responses from occipital scalp electrode in response to more than 100 sequential visual stimuli. Pattern reversal stimuli are more sensitive than flash (stroboscope) as the flash evoked VEP has great variability, insensitive to clinical lesions and provide limited information about the visual pathway. The interpretation of VEP is based on P100 latency which is an electropositive wave appearing at about 100 ms in the normal individual (**Figure 9**). Uniocular prolongation of P100 latency after full field mono-ocular stimulation suggests an abnormality anterior to the optic chiasma on that side. Bilateral P100 latency prolongation may be due to involvement of both the optic nerves, chiasma or posterior to the chiasmal lesion. Unilateral visual cortical lesion does not alter the P100 latency. VEP is abnormal in 70% to 80% patients with definite multiple sclerosis without visual symptoms (**Figures 10A and B**). VEP is abnormal in leucodystrophy, subacute combined degeneration, optic nerve tumour or tumour compressing the optic nerves and Leber's hereditary optic atrophy. VEP is normal in psychogenic blindness.

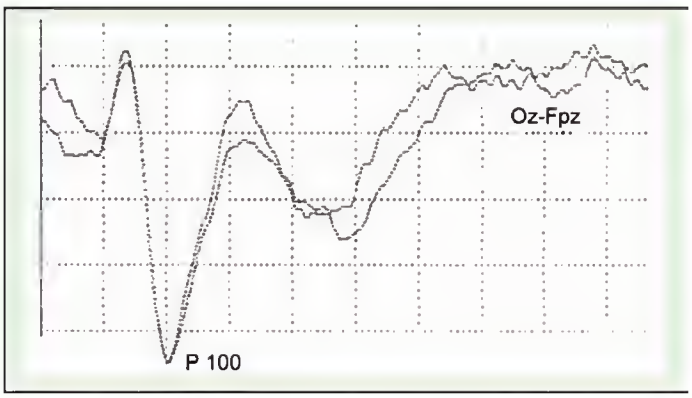

Figure 9: Pattern shift visual evoked potential in a normal individual, Sweep speed 50 ms/div, sensitivity 2μV/div.

Brainstem Auditory Evoked Potentials (BAEPs)

BAEPs refer to the series of signals generated in the auditory nerve and brainstem in response to auditory stimuli. BAEPs are recorded from the ipsilateral and contralateral mastoids or ear referred to vertex (Cz). There are 5 major waveforms (wave I, II, III, IV and V) and their absolute peak latency, peak to trough amplitudes and inter-peak latencies (IPL) of I-III, I-V and III-V are measured (**Figure 11**). BAEPs are resistant to various metabolic encephalopathies and deep anaesthesia. The generators of various waveforms of BAEPs are summarised in **Table 6**. BAEPs are abnormal in acoustic neuroma, cerebellopontine angle tumours, pontine lesion, multiple sclerosis and other demyelinating diseases.

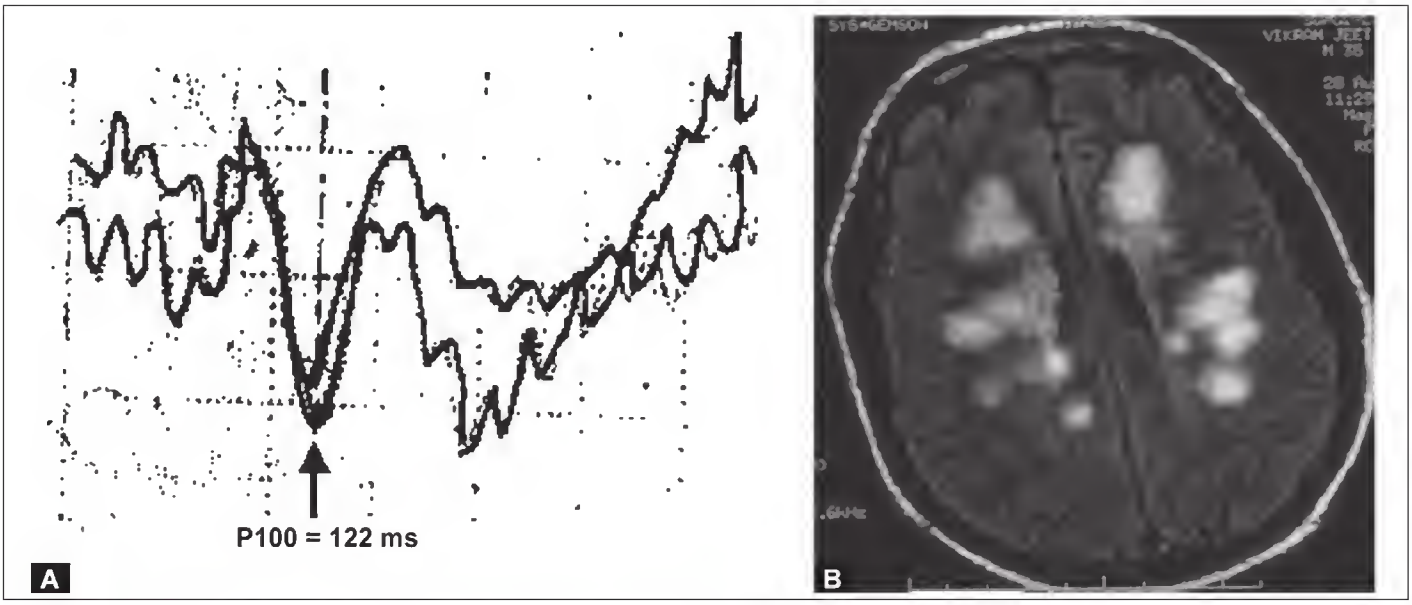

Table 6: Generators of Brainstem Evoked Potential

Waveforms	Generators
I	VIII nerve
II	Cochlear nucleus
III	Superior olivary nucleus
IV	Lateral lemniscus
V	Inferior colliculi

Somatosensory Evoked Potential (SSEP)

SSEP evaluates the integrity of sensory pathway from peripheral nerves to the cortex. Usually median, posterior tibial and or peroneal SSEPs are carried out (**Figures 12 and 13**).

Central sensory conduction time is prolonged or unrecordable in various conditions affecting the sensory pathway in the spinal cord (posterior column) and brainstem (lemniscus), thalamus

Figures 10A and B: (A) Pattern shift visual evoked potential in a 32-year-old lady with multiple sclerosis shows prolongation of P100 latency (122 ms). Sweep speed 50 ms/div, sensitivity 2μV/div; (B) Cranial MRI reveals multiple periventricular hyperintense lesions on FLAIR sequence suggestive of multiple sclerosis.

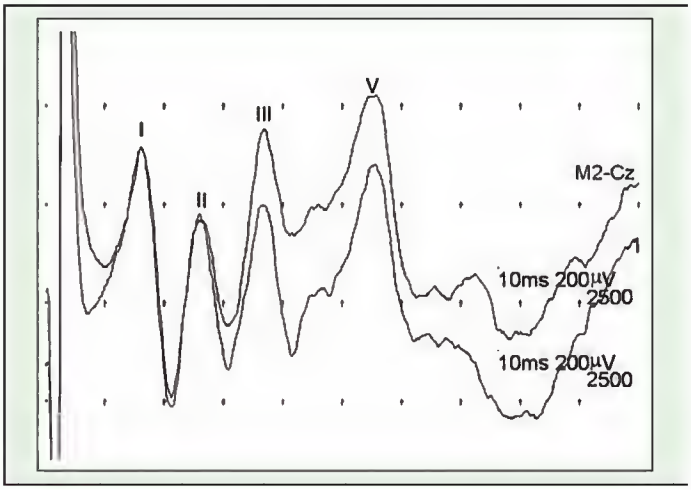

Figure 11: Normal brain auditory evoked potential.

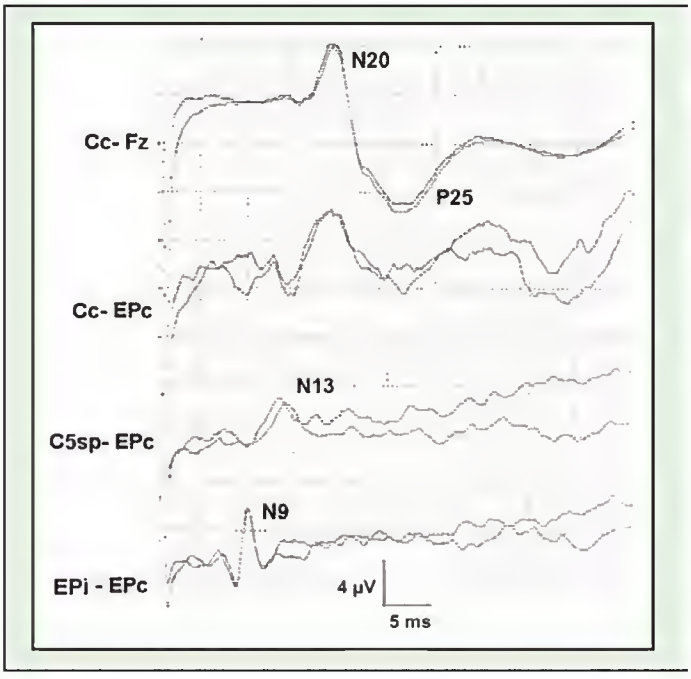

Figure 12: Normal median somatosensory evoked potential.

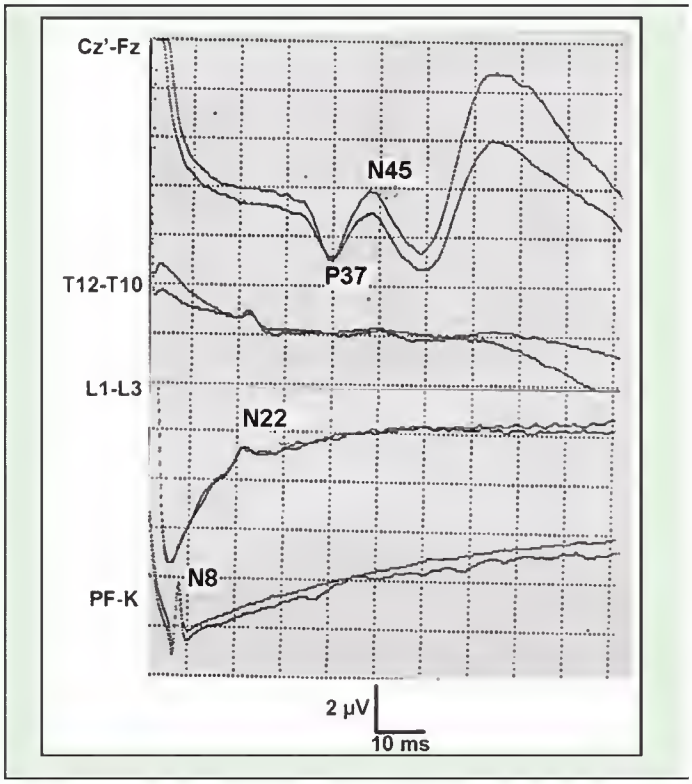

Figure 13: Normal tibial somatosensory evoked potential.

and thalamocortical pathway. 90% patients with multiple sclerosis have SSEP abnormalities. The other conditions such as hereditary ataxia, subacute combined degeneration, vitamin E deficiency, leucodystrophies, spinal sand brainstem tumours, stroke and cervical spondylosis may also result in SSEP abnormality.

Motor Evoked Potential (MEP)

MEP assesses the fast conducting motor pathways and is performed by stimulating the motor cortex using a magnetic or electrical stimulator and recorded from the target muscles (abductor digiti minimi in the upper limb and tibialis anterior in the lower limbs).

Central motor conduction time is abnormal in patients having involvement of motor pathway due to stroke, trauma, tumour, demyelinating and dysmyelinating conditions.

Repetitive transcranial magnetic stimulation has also been used for therapeutic purposes such as movement disorder and depression. Evoked potentials are also used for intra-operative monitoring and EEG for carotid endarterectomy.

NERVE CONDUCTION AND ELECTROMYOGRAPHY

Nerve conduction studies (NCS), electromyography and repetitive nerve stimulation (RNS) evaluate the functional integrity of peripheral nerves, muscles and neuromuscular junction, respectively.

Nerve Conduction Studies

Electrical stimulation of the nerve fibres results in impulses that travel along the motor, sensory or mixed nerves and produce a compound action potential. Most of the peripheral nerves can be evaluated which are accessible for stimulation.

Motor NCS

The motor NCS is done by supramaximal stimulation of the motor/mixed nerve at two points and recording from the target muscle (**Figure 14**).

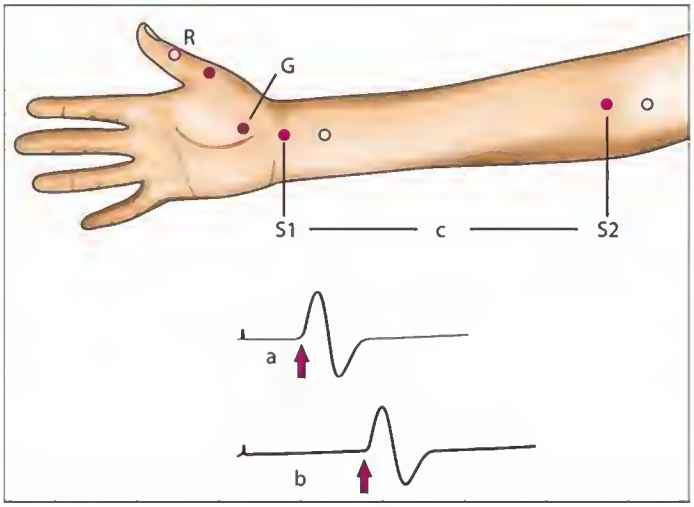

Figure 14: Schematic diagram shows method of motor nerve conduction study. The nerve conduction velocity is 'c/(b–a)' m/sec, where 'c' is the distance between proximal and distal stimulation in mm, 'a' is the distal latency in ms and 'b' is the proximal latency in ms.

R = Recording electrode; S = Stimulating electrode; G = Ground electrode.

Sensory NCS

Sensory NCS is either recorded orthodromically or antidromically. The antidromic sensory NCS is done by stimulating the sensory nerve 20% to 30% above the sensory threshold and recording from the sensory receptors, i.e. sensory innervated areas by the nerves. The reverse is done in orthodromic recording. The latency (onset/peak), amplitude (base to peak or peak to peak) and NCV are measured (**Figure 15**).

$$\text{Sensory NCV} = \frac{\text{Distance between stimulating and recording electrode in mm}}{\text{Latency in ms}} \text{ m/s}$$

The parameters of NCS should by compared with the normal laboratory values. For localising focal nerve lesion such as the carpal tunnel syndrome or other entrapment neuropathies,

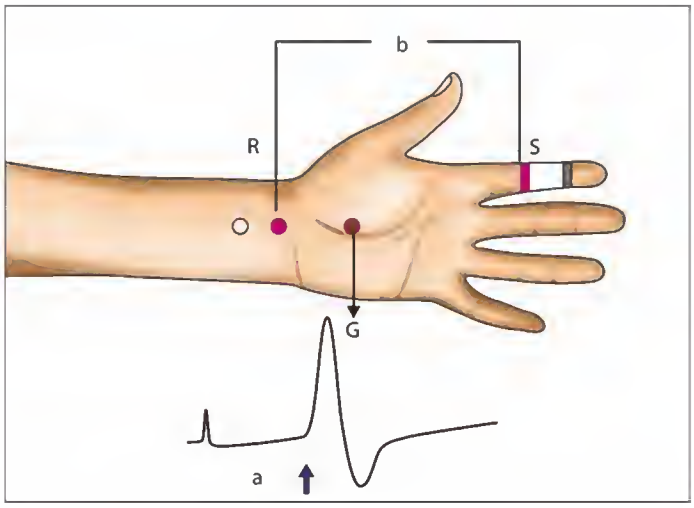

Figure 15: Schematic diagram shows method of orthodromic sensory nerve conduction. The sensory nerve conduction velocity is 'b/a' m/sec; where 'b' is the distance between the stimulating and recording electrodes in mm and 'a' is the onset latency of sensory potential.

stimulations may be applied along the nerve at a distance of 1 cm and the CMAP or SNAP is recorded (inching technique).

NCS may be affected by age, height, anomalous innervation, temperature, stimulus artefacts, electrode noise, submaximal stimulation, co-stimulation of adjacent nerves, misplacement of recording or reference electrode and error in the measurement of nerve length. In full term neonate, the NCV is half the adult value and one-third in premature baby due to incomplete myelination. NCV reaches adult value by 3 years to 5 years. Mean NCV declines by 10% by 60 years of age.

Late responses (F wave, H reflex and axon reflex)

Late responses are the potentials appearing after the motor response (M wave) following mixed nerve stimulation. There are three important late responses—H reflex, F wave and axon reflex; of these F wave is clinically more useful.

F wave: F wave is a late response resulting from the antidromic stimulation of motor neuron involving conduction to and from the spinal cord. It is elicited by supramaximal stimulation of peripheral mixed or motor nerves and recorded from the distal muscles. For clinical practice 10 to 20 F waves are adequate. The F wave parameters used in clinical practice are minimal F latency, chronodispersion, persistence, amplitude and repeated waves. Markedly prolonged F wave latency is highly suggestive of demyelinating neuropathy (**Figure 16**). It may also be prolonged in radiculopathy.

Electromyography

Electromyography (EMG) is the study of the electrical activity of resting muscle and muscle in action. Teflon coated concentric and monopolar needles are equally satisfactory. The needle is inserted slightly away from the neuromuscular junction to avoid endplate noise as well as pain. Electromyographer should know the anatomical landmark and the method of activation and relaxation of the sampled muscle. The principles used during EMG are: (a) during insertion or movement of the needle, insertional activity is produced due to injury of muscle fibres which is short lasting; (b) moving the needle for a short distance and pausing for a few seconds helps in the evaluation of spontaneous activity with the single cutaneous insertion. Relocating the needle in four quadrants of the muscle

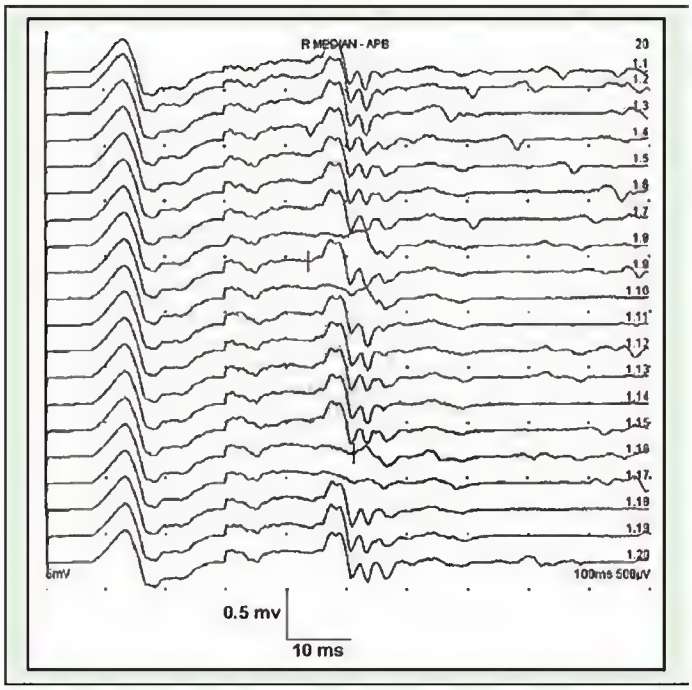

Figure 16: Median F wave study in a patient with acute inflammatory demyelinating neuropathy showing prolonged minimal latency (43.8 ms) and increased chronodispersion (8 ms).

completes the evaluation; (c) motor unit potential (MUP) is evaluated when the muscle is minimally contracted. The needle should be pushed deep or pulled out to get a sharp MUP; and (d) increasing intensity of contraction of sampled muscle shows the recruitment pattern and at the maximal contraction, interference pattern is seen.

The characteristic of insertional, various spontaneous activities and MUPs are shown in **Table 7**. The normal MUPs are usually bi- or tri-phasic and vary from 0.3 mV to 5 mV in amplitude and 3 to 13 ms in duration. The number of phases equals the number of negative and positive peaks extending to and from the baseline or the number of baseline crossings plus one. Normal MUPs have 4 or less phases and approximately 5% to 15% of MUP may have ≥5 phases which may increase to 25% in the proximal muscles. Two patterns of abnormal MUPs are found: (a) 'neurogenic—long duration, high amplitude, polyphasic with poor recruitment'; and (b) 'myopathic—short duration, low amplitude, polyphasic with early recruitment'.

Table 7: Characteristics of Spontaneous Activities on Electromyography

Potential	Morphology	Firing Rate	Firing Pattern
End plate spike	Biphasic, initial negative	5 Hz to 50 Hz	Irregular
Fibrillations	Bi/triphasic, initial positive	0.5 Hz to 10 Hz	Regular
Positive sharp waves	Biphasic, initial positive and slow negative wave	0.5 Hz to 10 Hz	Regular
Myotonia	Brief spike, positive	20 Hz to 150 Hz	Wax and waning amplitude
Complex repetitive discharges	Brief spike, positive	5 Hz to 100 Hz	Stable
Fasciculations	Like MUP	0.1 Hz to 10 Hz	Irregular
Neuromyotonia	Like MUP	150 Hz to 250 Hz	Waning

MUP = Motor unit potential.

Repetitive Nerve Stimulation

RNS helps to evaluate the diseases of neuromuscular junction (NMJ), such as myasthenia gravis, Lambert-Eaton myasthenic syndrome, botulism and congenital myasthenia. RNS is done by applying supramaximal stimulation of motor or mixed nerve and recording from the muscle supplied by that nerve. The rate of stimulation depends on the type of NMJ disorder. Low rate stimulation (2 to 3 Hz, 3 to 5 impulses) is used to evaluate the post-synaptic defect *(myasthenia gravis)* and high rate stimulation (20 to 50 Hz) for 2 to 10 seconds to evaluate the pre-synaptic defect (Lambert-Eaton myasthenic syndrome).

In low rate RNS, decrement is calculated by the baseline CMAP amplitude to that of lowest CMAP, i.e. 3rd on 4th CMAP; using the following equation:

$$\text{Decrement (\%)} = \frac{\text{Baseline CMAP amplitude} - \text{lowest CMAP amplitude}}{\text{Baseline CMAP amplitude}} \times 100$$

More than 10% decrement in any muscle is suggestive of post-synaptic NMJ disorder.

In high rate RNS, incremental response is measured as follows:

$$\text{Increment (\%)} = \frac{\text{Amplitude of highest response (last)} - \text{amplitude of 1st response}}{\text{Amplitude of 1st response}} \times 100$$

High rate RNS is painful and usually carried out in distal muscles such as abductor digiti minimi or tibialis anterior by stimulating ulnar nerve at wrist and peroneal nerve at fibular head, respectively. More than 50% incremental response in any muscle is suggestive of Lambert-Eaton myasthenic syndrome. Incremental response suggests pre-synaptic NMJ disorder. The classical findings on RNS in pre-synaptic and post-synaptic disorders are summarised in **Table 8**.

Table 8: Classical Repetitive Nerve Stimulation (RNS) Findings in Pre-synaptic and Post-synaptic Disorders

	Pre-synaptic	Post-synaptic
CMAP amplitude	Normal	Low
Low rate RNS	Decrement	Decrement
High rate RNS	Normal/decrement	Increment

CMAP = Compound muscle action potential.

Single fibre EMG may be done in patients with myasthenia gravis whose RNS test is negative.

Electrodiagnostic tests are important tools in the evaluation of neurological disorders. It is important to decide the appropriate test for appropriate clinical setting to get its highest yield.

RECOMMENDED READINGS

20.4 Neuroimaging

Rakesh K Gupta, Sunil Kumar

Neuroimaging has evolved into a super-speciality of Radiology and has found a place as a separate subject leading to degree. It is essential for the budding physicians to have at least basic knowledge of this subject. We are introducing the subject with a view to give a bird's eye view of Neuroimaging.

PLAIN RADIOGRAPHY

This is often the first imaging modality to be used for skull and spine. However, skull radiography has lost most of the indications as the changes are seen late and are indirect in nature. Computed tomography (CT) has overtaken skull radiograms in trauma, due to its superior contrast and spatial resolution. In addition, the underlying brain can also be assessed on CT. In spine, lateral and frontal radiographs of cervical, dorsal or lumbar spine are still in clinical use as it provides gross information about presence of degenerative changes, assessment of bone density and allows dynamic radiography to evaluate atlantoaxial dislocation, and spondylolisthesis. In trauma, the radiography has been superceded by CT.

MYELOGRAPHY/CT MYELOGRAPHY

Myelography, once a useful technique to evaluate intraspinal pathology, is now seldom performed, as the spinal imaging has been taken over by MRI. Myelography, if at all performed, is combined with CT to evaluate the desired region. It is helpful in patients in whom MRI is contraindicated and in some cases to demonstrate the site of a cerebrospinal fluid (CSF) leak or for diagnostic evaluation of spinal or skull base where there is poor correlation of physical findings with MRI studies. The procedure for myelography/CT myelography consists of performing a lumbar puncture and injecting water soluble, non ionic iodinated contrast medium in the strength of 180 mg I/mL for lumbar region and higher concentration up to 300 mg I/mL for cervical region if myelography is performed first. There is a waiting period of about 20 minutes to 30 minutes when a higher concentration is used.

DIAGNOSTIC ANGIOGRAPHY

Invasive diagnostic angiography has been mostly replaced by CT angiography and MR angiography for the evaluation of the blood vessels in the brain and neck. The basic reason is that it is invasive and thus associated with a small but definite incidence of complications. Special equipment, digital subtraction angiography system, is needed for these studies, which allows online visualisation of injected blood vessels. Presently, it is most often used for interventional procedures. Diagnostic angiography is reserved for cases where these studies are equivocal or where intra-cranial cross circulation is to be studied pre-operatively. It is also performed for post-operative evaluation of aneurysms, and arteriovenous malformations. In spine, it still finds a primary role in the proper evaluation of vascular malformations. The procedure is performed via transfemoral route under local anaesthesia and selective cannulation of the desired artery is done under fluoroscopic guidance. This is followed by injection of iodinated contrast medium and fast acquisition as the contrast flows through the vessel.

COMPUTED TOMOGRAPHY

The hardware of CT consists of a gantry that houses the X-ray tube and a detector assembly which typically contains 4, 16, or more rows of detectors along with a patient table which synchronises with the gantry for its movement. For usual brain studies the patient lies supine on the table that moves during scanning either incrementally or continuously while the X-rays are being emitted. The scan time is usually in seconds. The slice thickness varies from sub millimetre to 5 mm depending upon the clinical indication. The X-rays pass through the patient's head or spine and the exiting X-ray photons are detected by the detector assembly. The signals produced are processed and finally cross sectional images are reconstructed which can be viewed on a monitor. In the volume CT scanners, the data sets can be used to create three-dimensional (3D) images those can be viewed from any angle. This is very useful in analysing vascular structures such as arterial or venous systems, known as CT angiography. Different tissues in the body absorb different amount of X-rays and thus these can be differentiated, e.g. bone, brain parenchyma, CSF or water, fat and air. These have fairly constant attenuation values, called as Hounsfield units. Tissues with high Hounsfield units, such as bone, calcification, acute blood in parenchyma (haematoma), appear bright at the windows and level customised for brain parenchyma to appear greyish. At this window and level settings, fluids such as CSF, fat, and air appear dark. Hounsfield unit of water is zero. If in doubt, Hounsfield units can be quantified for tissue characterisation. Iodinated contrast media can be administered to enhance abnormal tissue with abnormal blood brain barrier. Thus a comparison with non enhanced images can help in delineating intra-cranial space occupying lesions such as tumours, granulomas, abscesses, or abnormal meninges.

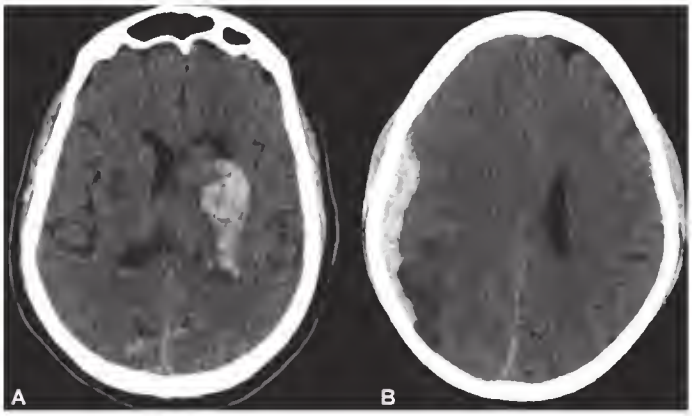
Indications

Due to its high speed of scanning, wide gantry, no restrictions for the anaesthesia equipment and the monitoring systems, and its ability to show acute blood unequivocally, CT brain is most useful in patients with suspected intra-cranial bleed, and cases of trauma where a quick scan is enough to evaluate the bones, parenchyma and epidural space. Very fast contrast enhanced studies with 3D reconstruction are useful for analysing arteries or veins of the brain at a high spatial and contrast resolution obviating the need for a conventional or digital subtraction intra-cranial angiogram. This fast imaging has also been utilised to study first passage of contrast medium through the brain, i.e. perfusion imaging and analysed for parameters such as volume, regional cerebral blood flow, mean transit time and

permeability. These parameters have been found to be useful in grading of brain tumours and stroke management.

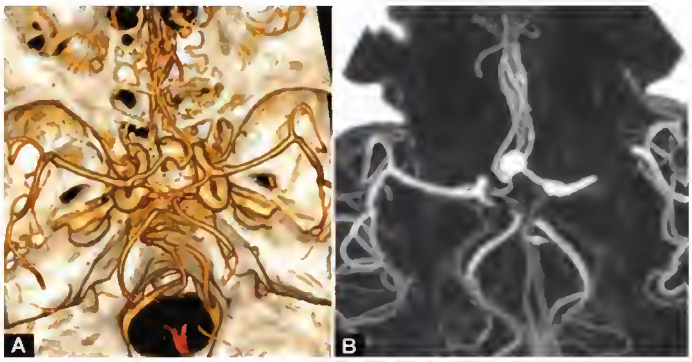
Contraindications

Patient population at risk such as pregnant women, small children, should be examined with caution. Iodinated contrast medium should also be injected with caution as it may cause renal dysfunction. Hence, it is contraindicated in patients with deranged renal function, diabetes, multiple myeloma, thyroid toxicity, dehydration, etc.



Brain

Normal appearance



Normal brain can be easily distinguished into parenchyma, ventricular system containing the CSF, other CSF spaces such as cisterns and sulci, bony calvarium, and normally aerated paranasal sinuses. At times, certain areas of brain show physiological calcification such as pineal gland, globus pallidi, falx, etc. Grey and white matter may be distinguished on proper window settings.

Abnormal appearance

Non-enhanced CT is extremely useful in the evaluation of brain trauma, where it can show the bone injury, extradural/subdural haematoma, parenchymal haematoma (**Figures 1A and B**), and brain contusion. It can also suggest brain swelling in the form of effacement of sulci. Herniation of brain secondary to mass effect can also be detected. CT is also useful in detecting acute blood, hence it is often the first imaging modality where haematoma is to be excluded, for example, in a hypertensive patient with sudden alteration in sensorium, to confirm or exclude subarachnoid haemorrhage in a patient with sudden and severe headache, in the post-operative period after brain surgery, and similar clinical situations. CT angiography has replaced diagnostic angiography in the workup of patients with subarachnoid haemorrhage. The vascular abnormalities such as aneurysms (**Figures 2A and B**), arteriovenous malformations etc are well-delineated on CTA. Brain tumours can also be detected on CT but with inferior resolution compared to MRI especially in the posterior fossa. Presence of a mass can be inferred on a non enhanced CT by the mass effect caused by it which displaces the normal brain structures and the brain symmetry is lost. In severe cases, there is herniation of vital parts of brain through the spaces bound by rigid dural structures, which may cause irreparable damage. Non contrast studies also detect the presence of calcium in the lesion which may help in tissue characterisation. In addition, erosion or thickening of adjacent bones is also a useful indicator of the aetiology. After contrast administration, most of the tumours enhance thereby making its detection evident. The degree of enhancement may depend upon the histological grade of the tumour or its composition. The enhancement occurs due to a disruption of the blood brain barrier which allows leakage of contrast in the interstitium. Similarly, CT can detect all the non-neoplastic lesions that disrupt the blood brain barrier and enhance, thereby confirming the location and number of the lesions. Anatomical localisation is helpful as certain lesions tend to manifest in certain sites. The pattern of enhancement also helps in improved tissue characterisation as some lesions enhance homogenously, e.g. meningiomas, primary lymphomas, etc. CT is also useful in post shunt evaluation in cases of hydrocephalus. Certain congenital lesions have fatty elements which are detected easily on non-contrast study like lipomas. However, complete evaluation of a space occupying lesion is usually done with both non-enhanced and enhanced studies.

Figures 1A and B: Axial non-enhanced CT scan (A) showing a hyperdense area in left basal ganglia, suggestive of intraparenchymal haemorrhage with mass effect compressing the left lateral ventricle. Haemorrhage into subarachnoid spaces is also noted posteriorly. Axial CT scan (B) of another patient showing cresentic hyperdensity along the right fronto-parietal convexity suggesting subdural haematoma.

Figures 2A and B: Axial CT angiographic volume rendered (A) and maximum intensity projection (B) images demonstrated an anterior communicating artery aneurysm.

Spine

CT is the imaging modality of choice in spinal trauma where bony evaluation is needed for management planning. Imaging is performed in axial plane with the patient supine. As the images can be post processed for 3D models, evaluation becomes easier. Similarly CT is advocated in bony craniovertebral anomalies, in some cases of disc herniation, and in the assessment of ossified or calcified lesions. For evaluation of intradural conditions, CT myelography is performed. CT is also indicated for image-guided biopsies of the bony lesions.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is an imaging technique based on the interaction of radiofrequency induced proton shifts in a strong magnetic environment. Signal intensity is directly proportional to the field strength of the magnet used. However, in view of human safety and problems in maintaining a high degree of field homogeneity, clinical scanners currently do not exceed 3 T. Magnetic resonance (MR) scanner designed for optimal clinical study consists of a superconducting magnet of 1.5 T or 3 T (1 Tesla=10,000 Gauss) along with a moving table on which patient lies supine (although smaller strengths of 0.2 T to 0.4 T systems of permanent magnet are commercially

available, these have certain limitations). This is housed in a specially shielded room. Other cabinets and operator's console are placed separately. For imaging, radiofrequency waves are introduced after the patient lies within a coil which is matched to the region of interest to be imaged. These waves are switched on and off and the resulting signals are processed in the presence of locally varying fields which are known as gradients to form images that can be acquired in any desired plane. During the off phase, the excited protons relax and this is measured either as T2 (spin-spin or horizontal relaxation) and T1 (spin-lattice or longitudinal relaxation) relaxation. These are used to create T2 and T1 weighted images. In the normal brain, cortex, white matter, CSF, fat, air have all different appearances on T2 and T1 images. The radiofrequency waves and gradients can be combined in different ways that are known as sequences. Most commonly the sequences are used to form anatomical images but the signals can also be acquired and processed to obtain metabolite (MR spectroscopy), functional MRI (fMRI), water diffusion (diffusion weighted imaging and diffusion tensor imaging) and tissue perfusion information. Sequences can also be designed to detect the blood flow and present the information as angiograms (MR angiography). MR angiography can also be obtained after injection of a MR detectable contrast agent combined with fast imaging. These contrast agents are usually based on gadolinium compounds which shorten T1 relaxivity (enhancing lesions appear brighter). Lately, iron oxide particles based contrast agents have been introduced that work on reducing T2 relaxivity and have found uses in liver, etc. Study times typically for a MR examination vary between 15 minutes and 45 minutes depending upon the clinical protocol.

Indications

T2 and its derivatives such as fluid attenuated inversion recovery (FLAIR) are the mainstay of any imaging protocol as these bring out most of the abnormalities separately from normal brain. Usually the accompanying oedema appears bright and lesion itself may vary from hyperintense, isointense to hypointense. This is supported by a T1 weighted image which gives excellent anatomical details. Further depending upon the clinical indication protocols may consist of diffusion weighted sequences that highlight acute stroke due to restriction of water movement, MR angiography to study blood vessels in the neck or brain, contrast enhanced studies for further characterisation of the lesion, and advanced studies such as perfusion or functional imaging. Currently, MR is the investigation of choice for the evaluation all neurological disorders.

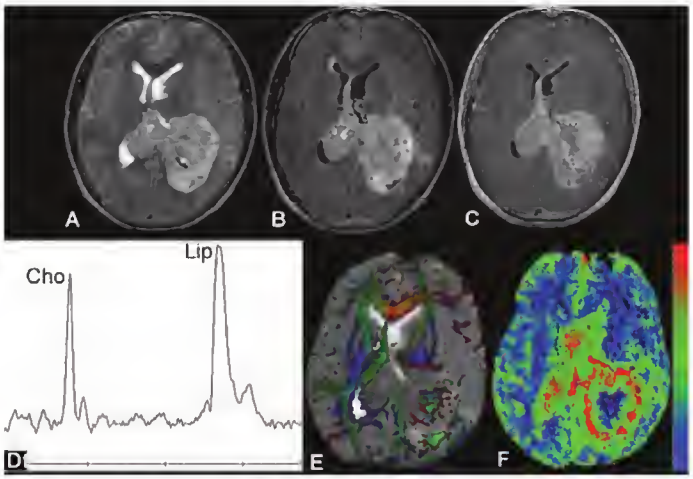
Contraindications and Safety Issues

There are three main reasons to be cautious before subjecting a patient with an implanted device for MR study. The object may move if iron is present. This may cause injury which can be quite severe depending upon its proximity to vital organs. Second problem is of heating of the device by the deposition of radiofrequency waves and cause thermal injury to surrounding areas. Lastly, the devices may be affected by the presence of varying electromagnetic fields and may stop functioning or may malfunction. Patients with implanted pacemakers, or electromagnetically activated devices such as cochlear implants etc. cannot undergo MR examination as it causes device malfunction due to the presence of a strong magnetic field and varying gradients. Similarly, objects such as bullets, pellets or other iron foreign bodies may move in the presence of a strong magnetic field. Some of devices may move just after their implantation in the patient's body and need 6 weeks to 8 weeks for local stability due to fibrosis before they are safe for MR imaging. Most of the other devices are considered safe. They may, however, produce artefacts if the scanning is done in their location. Devices made of titanium produce less obscuring of the area compared to stainless steel or other metals. Children and disoriented adults require some form of sedation to make them lie quietly without moving for the duration of the study. This needs constant monitoring and oxygenation for which specially designed MR compatible anaesthesia trolleys, laryngoscope and monitoring devices are a must. About 0.5% to 2% of patients may be claustrophobic and may not be able to undergo MRI.

Brain

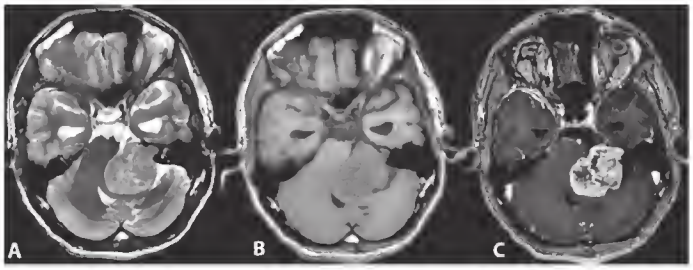
Normal appearance

Normal grey matter appears slightly brighter on T2 compared to white matter and darker than white matter on T1 images. Fat appears brightest and CSF appears darkest on T1. Fat shows intermediate to bright intensity and CSF also appears brightest on T2 images. Air and bony cortex remains dark on both T1 and T2 sequences. Blood vessels with fast flow show 'flow void' or appear dark on both the T1 and T2 images whereas slow flow such as seen in some veins appears brighter. MR shows exquisite anatomical details that far surpass those seen on CT. Metallic devices have susceptibility effect and appear dark on both T1 and T2 images accompanied by a bright area. Imaging can be done in any plane without changing patient's position. In addition 3D imaging can be performed that allows thin slices and reformatting. MR spectroscopy of normal brain demonstrates three main peaks those of N-acetyl aspartate (NAA), creatine (Cr) and choline (cho). Normal brain does not show lactate or lipid peaks. These peaks are displayed on a scale based on chemical shifts and are constant in position along x-axis irrespective of the strength of the magnet. The higher field systems have better spectral demonstration due to improvement in resolution.



Abnormal appearance

The abnormalities are detected on MR directly accompanied by their mass effect or oedema, if any.



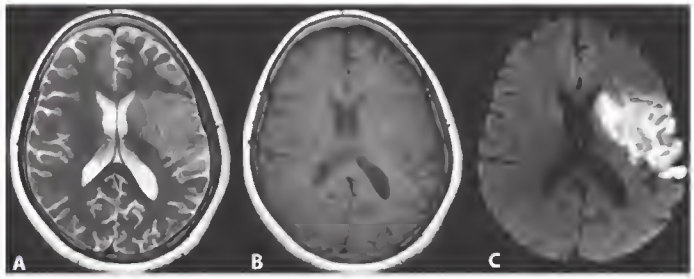
Neoplasm

Most of the tumours appear hyperintense on T2 and FLAIR and iso to hypointense on T1 images (**Figures 3A to F and 4A to C**). Accompanying oedema and necrosis within the tumour appears brighter on T2 (but less bright than CSF) and darker on T1 images (less dark than CSF). Cystic changes parallel CSF intensities on T1 and T2 images. MR can directly show the mass effect and herniation, if present. In neoplastic lesions, the contrast studies are a part of the imaging protocol which assesses the enhancement of the lesions. Contrast studies also delineate the tumour in its entire extent, and also show dural invasion, if present, as thick focal dural enhancement. The multiplicity such as those of metastases is also better evaluated on contrast studies as small cortical lesions without significant oedema may be isointense and thus not apparent on non-contrast studies. Neoplasms, especially high grade, are associated with more necrotic areas and significant mass effect whereas low grade gliomas are homogenous and usually

exhibit minimal mass effect. Further characterisation can be done by MR spectroscopy which shows elevated peak of choline and reduced peak of NAA. Lipid peak may be present in glioblastomas. High grade neoplasms also have high rCBV in comparison with low grade gliomas. fMRI may be required by the neurosurgeons to identify known functional areas in the vicinity of the lesion, as due to mass effect, these areas may be shifted. Identification of calcification is difficult on routine MR imaging sequences, however, newer sequences are being developed that can overcome this disadvantage.

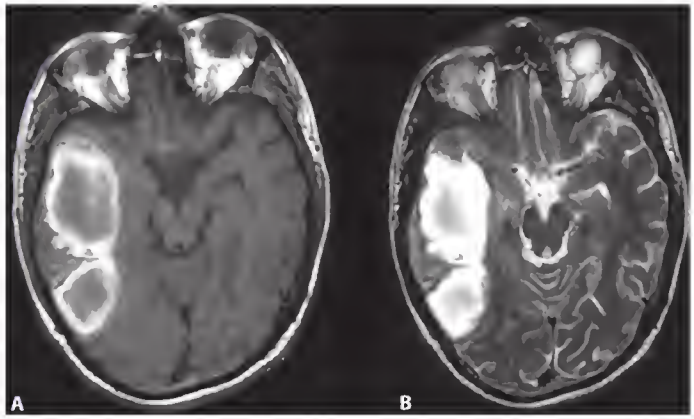
Figures 3A to F: (A) Axial T2, (B) FLAIR, (C) Post-contrast, (D) H-MR Spectroscopy, (E) Diffusion tractography and (F) Perfusion weighted scans in a patient with a large left temporal lobe Glioblastoma Multiforme. T2, FLAIR and post-contrast scans show a mixed signal, heterogeneously enhancing mass in the left temporal region. MR spectroscopy shows increased choline and lipid peaks, DTI shows entrapment of normal white matter fibres by the tumour and perfusion weighted image, and reveals increased relative cerebral blood volume in the periphery of the lesion.

Figures 4A to C: (A) Axial T2, (B) T1 and (C) post-contrast T1-weighted MR images show 'ice cream cone' appearance of schwannoma that consists of a large mixed signal, heterogeneously enhancing left CP angle mass and a smaller intra-canalicular component. The ipsilateral CP angle cistern is enlarged.



Because of its multiplanar capability, the lesions in the base of skull region including sella can be aptly demonstrated.

Trauma

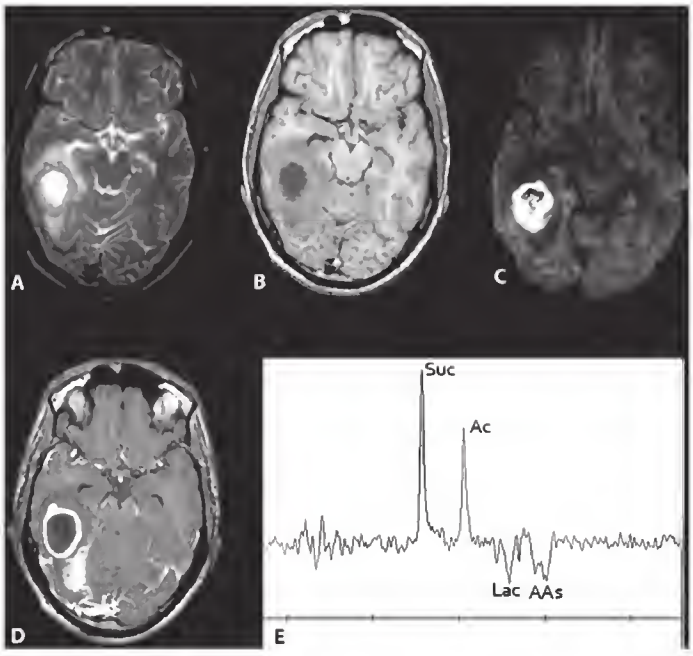


In trauma, even as CT is the primary investigation of choice, MR does have the capability to show bleed in different stages, whereas CT demonstrates it only in the acute stage. MR can additionally show small contusions or shear injury to deeper structures with clarity.

Vascular

MR is the earliest to confirm the presence of acute stroke within 2 hours on diffusion weighted images where the affected site becomes bright (**Figures 5A to C**). Other MR sequences may a take a day or more to show similar changes, though oedema or mass effect may manifest earlier. MR angiogram may show occluded intra-cranial blood vessels in the affected territory in case of a large vessel disease. In cases of embolic stroke MR angiogram of brain and neck can demonstrate the culprit plaque in the origin of internal carotid artery in the neck. Combined with perfusion imaging, diffusion imaging can show the penumbra or the region at risk if ischaemia continues. Treatment options can be chosen and initiated early based on MR imaging to maximise the recovery of the patient. Haematomas secondary to hypertension can also be documented and can be reasonably differentiated from other pathological bleeds on the basis of its appearance. Bleeds can also be categorised into acute, subacute and chronic stages based on imaging findings (**Figures 6A and B**). Other vascular conditions such as arteriovenous malformations, and aneurysms larger than 3 to 4 mm can be easily diagnosed on MRI. MR venography (MRV) can also be performed which depicts only the larger veins and venous sinuses with consistency. Diagnosis of cerebral venous sinus thrombosis can be confirmed or excluded based on MRV appearances.

Figures 5A to C: Axial T2, T1 and Diffusion weighted MR sequences show an area of (A) T2 hyperintensity, (B) hypointense on T1 weighted image and (C) with restricted diffusion in the left MCA territory suggesting acute nonhaemorrhagic infarct.

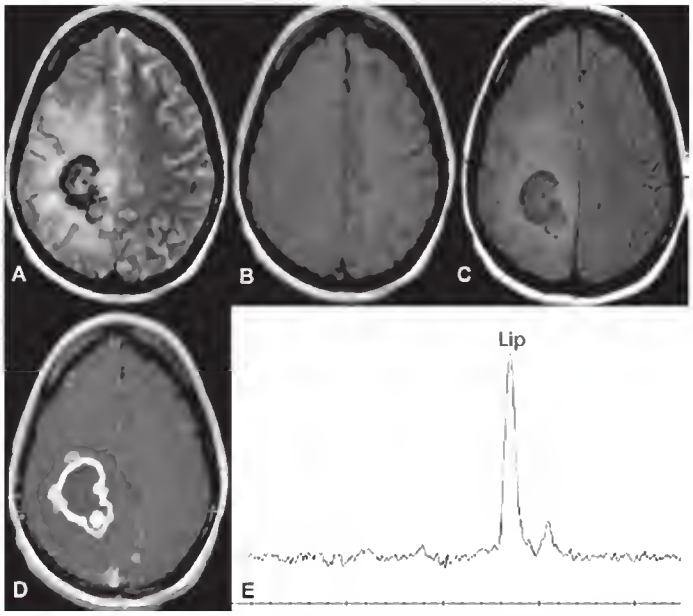


Figures 6A and B: Axial MR images show an area of hyperintensity on both (A) T1 and (B) T2 weighted sequences in the right temporal lobe suggesting subacute intraparenchymal haemorrhage.

Infections

Central nervous system Infections are common in our part of the world. If recognised, most of them are fully treatable after initiation of correct therapy, else complications ensue which can be life-threatening. In acute viral encephalitis, characteristic bilateral asymmetric signal intensity changes in inferior frontal or in temporal lobe suggest herpes encephalitis. Other viral encephalitis can have non-specific imaging features, but changes are usually bilateral and may be multifocal. In other infections, MRI can document the presence and location of the lesions which usually display ring enhancement. MR can characterise brain abscesses

by demonstrating high signal intensity on diffusion-weighted imaging (DWI) (**Figures 7A to E**). MR spectroscopy shows peaks of amino acids in addition to acetate and succinate. Common causes of seizures in this part of the world include granulomas secondary to neurocysticercosis (NCC) and tuberculomas. Both may exhibit similar MR imaging pattern, though presence of a scolex is diagnostic of neurocysticercosis. At times T2 and T1 images show a scolex; more frequently thin slice imaging is needed for its demonstration. Further characterisation may be done on MR spectroscopy where NCC shows peaks of succinate and acetate without amino acids. Tuberculosis occupies a special place in developing nations. Its common CNS manifestations include tubercular meningitis and tubercular granulomas also known as tuberculomas. Tuberculomas share the imaging features with other granulomas. However, these may be differentiated on a special imaging sequence, magnetisation transfer, on which the wall of the tuberculomas appear bright and on quantification, shows a lower magnetisation transfer ratio compared to lesions with similar MR appearance (**Figures 8A to E**). On MR spectroscopy, tuberculomas display prominent lipid peak amidst absence of normal brain peaks. Meningitis of any aetiology will show diffuse linear meningeal enhancement and may show evidence of its complications such as hydrocephalus and infarcts.



Figures 7A to E: Pyogenic abscess in the right temporal lobe of a 32-year-old man. (A) Axial T2 WI image shows a large well-defined T2 hyperintense lesion with thin hypointense rim, perifocal oedema and mass effect. (B) T1 weighted image shows isointense rim of the lesion. (C) Diffusion restriction noted on diffusion weighted image. (D) Post-contrast T1 weighted image shows rim enhancement of the lesion. (E) In vivo proton MR spectroscopy from the cystic cavity shows presence of cytosolic amino acids (Cy), lactate (L), acetate (Ac) and succinate (Suc) characteristic of an abscess.

MR is also helpful in the recognition of osmotic demyelination secondary to rapid correction of hyponatraemia which causes central pontine T2 hyperintensity. Similarly certain other encephalopathies such as hypertensive encephalopthy, ADEM may be suggested on the basis of imaging findings in the presence of appropriate clinical scenario.

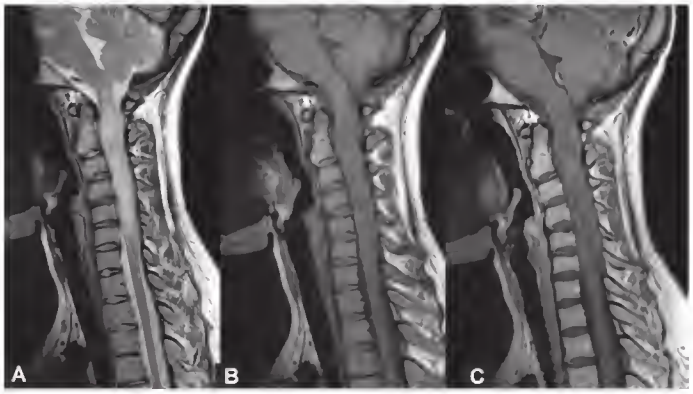
Congenital

Developmental brain lesions can be in the form of structural anomalies such as holoprosencephaly, heterotopia, Dandy Walker

Figures 8A to E: (A) Axial T2, (B) T1. (C) MT-T1, (D) post-contrast and (E) MR spectroscopy scans in a patient with right parietal tuberculoma. The lesion appears hypointense on T2, hypo to isointense on T1 with a peripheral bright rim on MT-T1 sequence which enhances on post-contrast image. MR spectroscopy shows prominent lipid peak.

syndrome, abnormalities of delayed myelination or abnormal myelination, herniation of brain through bone defects—cephaloceles, changes secondary to perinatal insults, and many other conditions. Usually non-enhanced MR imaging in axial and sagittal plane will delineate all these disorders in their entirety.

Degenerative neurodegenerative diseases can also be studied by MRI and show a variety of changes. These include changes in signal intensities, or changes in volume as in dementias.

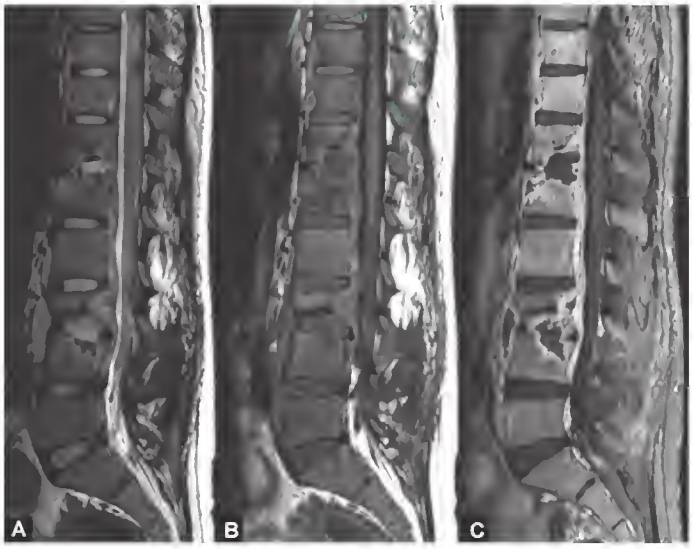


Spine

MR has revolutionised the imaging of spine and its constituents. It offers assessment of the spinal cord, intradural CSF space and epidural tissues directly in any desired plane. Usually sagittal and axial planes form the mainstay of spinal imaging. Spinal cord and nerve roots appear grey on both T2 and T1 images, and the CSF bright on T2 and dark on T1 images. The vertebrae appear relatively brighter compared to adjacent muscles on both T1 and T2 imaging. The vertebral bodies have a thin hypointensity of cortex all round. The normal dura mater may be directly seen especially in the presence of intra-canalicular fat. MR also demonstrates the normal and abnormal intervertebral discs.

Abnormal appearance

Neoplasm: MR can show marrow changes much before any bony destruction takes place. Most abnormalities of the vertebral bodies appear hyperintense on T2 and hypointense on T1 and enhance on contrast-enhanced T1 studies. These changes may occur in a single vertebra or multiple vertebrae which may be contiguous or far apart. Neoplastic conditions such as metastases and multiple myeloma may also have associated pre or paravertebral soft tissue but this is not large, usually does not exceed 8 mm in thickness, and enhances homogenously, unlike peripheral enhancement in abscess formation. Other bony tumours are less frequent in spine and usually involve posterior elements. MR can identify the tumour and define its



extent. Lesions extending to epidural space can also be easily delineated. Similarly intradural extramedullary lesions like meningiomas, neurofibromas, etc. and intramedullary tumours such as astrocytomas, ependymomas, etc. can be delineated in their entirety for the surgical excision (**Figures 9A to C**). Drop metastases from intra-cranial tumours such as medulloblastomas, glioblastomas, etc. are seen as small nodular enhancing areas within the CSF space.

Figures 9A to C: (A) Sagittal T2, (B) T1 and (C) post-contrast T1 weighted MR images in a patient with cervical cord astrocytoma show diffusely expanded cervical spinal cord which is hyperintense on T2 and hypointense on T1 weighted sequences with patchy enhancement following contrast administration.

Infection

In infections, solitary or more frequently two or more contiguous vertebrae are involved with hyperintensity on T2 and hypointensity changes on T1 images. Intervening disc is often involved, but this involvement may be late in tuberculosis. Infective conditions frequently cause abscess formation in the adjacent soft tissues which can be easily appreciated on T2 (these show almost fluid intensity) and post-contrast T1 imaging (abnormal soft tissue shows peripheral enhancement) (**Figures 10A to C**). On DWI, these show low AIDS-dementia complex values.

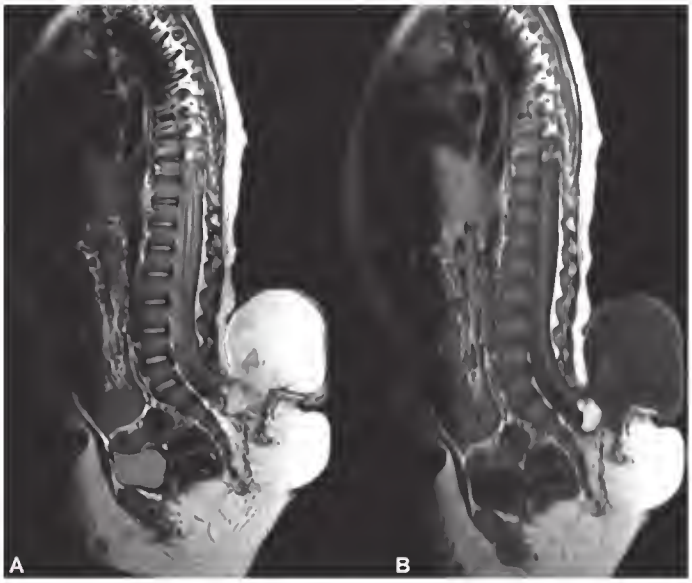
Figures 10A to C: (A) T2 weighted sagittal image shows hyperintense destructive process involving the D12-L1 and L3-L4 vertebrae and the intervening disc. There is evidence of a hyperintense pre-vertebral collection and intra-canalicular collection causing extradural compression. (B) The vertebrae and collection appear hypointense on T1 weighted image. (C) Post-contrast T1 weighted sagittal images show enhancement of the abnormal tissue along with rim enhancement of the pre-vertebral collection.

MR can also demonstrate the nerve roots along their course within the CSF space as well as through the neural canal. Root changes in arachnoiditis such as thickening, clumping, and abnormal enhancement are all documented well on MRI. In addition, CSF loculation and abnormal meningeal enhancement can also be seen in arachnoiditis.

Vascular

In spinal AVMs, MR shows serpiginous, long channels of flow void within the CSF space posterior or occasionally anterior to the cord.

Trauma



In trauma, MR is useful in the assessment of the spinal cord and informs about its integrity and presence of haematoma.

Degenerative

Normal disc can be identified by its typical appearance of hyperintensity with a thin central hypointensity on T2 images. Disc desiccation causes the entire disc to become hypointense. Disc bulges, and herniations can be differentiated on MR. MR can also show far lateral disc herniations directly that cause root compression as these exit the canal. Similarly, abnormalities of alignment are clearly shown.

Congenital

MR is especially useful in the evaluation of congenital malformations. Meningocoeles can be fully evaluated for their contents, presence of neural placode (**Figures 11A and B**) and associated Chairi II malformation or syringomyelia can be established along with intra-cranial ventricular assessment. MR is especially useful in skin covered malformations and in cases with suspected tethering where it can show low lying cord, or thick filum terminale. Any associated intradural tumours such as dermoid, epidermoids can also be seen. Diastematomyelia can be diagnosed on delineation of two cords within the same dural sheath or in different sheaths. Bone spur, if present, is easily seen.

Figures 11A and B: (A) Sagittal T2 and (B) T1 weighted MR scan in an infant with meningomyelocele. The spinal cord is tethered into a CSF filled dural sac that protrudes dorsally through a dysraphic lumbosacral spine. A small lipoma is also noted within the sac.

INTERVENTIONAL PROCEDURES

Interventional procedures have become accepted in clinical management in certain diseases as they offer much less invasion compared to operative procedures, thereby reducing complications. These procedures are frequently performed under local anaesthesia and via a percutaneous route. The most common interventional procedures are embolisation of intra-cranial and spinal arteriovenous malformations including fistulas, coiling of intra-cranial aneurysms, stenting of internal carotid plaques in the neck, and recanalisation in some cases of acute intra-cranial thrombosis. Pre-operative embolisation is also performed to reduce vascularity in some tumours such as meningiomas, glomus tumours. In the spine, vertebroplasty is performed in cases of painful benign collapse of vertebrae. This consists of injecting bone cement through percutaneous route into the affected vertebral body which seals the micro-fractures responsible for pain in these cases.

20.5 Epilepsy

Sanjeev V Thomas

INTRODUCTION

Epilepsy is one of the oldest diseases known to mankind.The word seizure is derived from the sixth century Latin word 'seiz' that means to 'take possession of'.The word epilepsy is derived, from the Greek word '*Epilepsia*' which means to 'seiz'.

EPIDEMIOLOGY

Worldwide, there are about 50 million people with epilepsy and 90% of them live in developing countries. The prevalence of epilepsy ranges from 5 to 10 per 1000 in most countries, but it is likely to be higher in developing countries than in developed countries.The incidence of epilepsy in developed countries ranges from 24 to 53 per 100,000 population.The age specific incidence is highest at extremes of age. In developed countries it had probably reduced in young people and had increased in those aged more than 60 years.The natural history of untreated epilepsy is not readily available. It is possible that about 20% to 30% of patients are likely to have spontaneous remission while about 35% of patients may continue to get seizures in spite of treatment with two or more anti-epileptic drugs (AED). Persons with epilepsy carry 2 to 3 times increased risk (standardised mortality ratio) of death when compared to others. Sudden unexplained deaths in epilepsy (SUDEP) account for 2% to 18% of all deaths while status epilepticus accounts for 12.5% deaths.

Treatment Gap

The proportion of persons that fail to receive treatment, expressed as a percentage of those who require treatment, is termed as treatment gap.Treatment gap for epilepsy varies widely between countries and within countries. The treatment gap is highest in low income countries such as India (75%) moderate in medium income countries (~50%) and least in high income countries (<10%).Treatment gap in rural areas is twice that in urban areas.

EPILEPTOGENESIS

The term epileptogenesis refers to a long standing state in which recurrent seizures occur without any immediate provocation. It involves genetic and acquired mechanisms with several stages, the details of which are not sufficiently understood. Several genetic traits and genes associated with epilepsy have been described. Maturation of a localised lesion in the brain in to an epileptic focus involves complex synaptogenesis, neurogenesis and establishment of reverberating circuitry.

DEFINITION

An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Epilepsy is a disorder of the brain characterised by an enduring predisposition to generate epileptic seizures and by the neurobiological, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least two epileptic seizure.

CLASSIFICATION

The classifications of seizures and epilepsy syndromes have undergone several changes since the first attempt to classify them in 1960.The present classification of seizures (approved in 1981) and epilepsy syndromes (approved in 1989) were prepared before much of the knowledge on advanced imaging and molecular genetics of epilepsy had evolved.

Epileptic seizures are classified according to the ictal semiology and electroencephalographic (EEG) findings. The classification currently approved by the International League Against Epilepsy was introduced in 1981.

Partial Seizures

International classification divides seizures broadly into partial and generalised seizures with several subtypes under each category. Partial seizures have a demonstrable focal onset in clinical semiology or in EEG. In simple partial seizures, there is no loss or alteration of consciousness.They are further classified according to the phenomenology (**Table 1**).

Complex partial seizures that come as the second category under partial seizures are characterised by impairment of consciousness either from the onset or later on as the seizure progresses. Partial seizures may become secondarily generalised with typical tonic

Table 1: International Classification of Epileptic Seizures

I. Partial (focal, local) seizures
- Simple partial seizures (consciousness not impaired)
  - With motor signs
  - With sensory symptoms
  - With autonomic symptoms or signs
  - With psychic symptoms
- Complex partial seizures (Temporal lobe or psychomotor seizures; consciousness impaired)
  - Simple partial onset followed by impairment of consciousness
    - With simple partial onset (A.1 to A.4) followed by impaired consciousness
    - With automatisms
  - With impairment of consciousness at onset
    - With impairment of consciousness only
    - With automatisms
- Partial seizures evolving to secondarily generalised seizures (tonic-clonic, tonic or clonic)
  - Simple partial seizures (A) evolving to generalised seizures
  - Complex partial seizures (B) evolving to generalised seizures
  - Simple partial seizures evolving to complex partial seizures evolving to generalised seizures

II. Generalised seizures (Convulsive or Nonconvulsive)
- Absence (Petit mal) seizures
- Myoclonic seizures
- Tonic seizures
- Atonic seizures
- Clonic seizures
- Tonic clonic (grand mal) seizures

clonic convulsions and less often with either tonic or clonic convulsions. Partial onset may occasionally reveal the precise origin of the seizures in anatomical terms. Occasionally, partial motor seizures may be followed by post-ictal paresis that may last several hours. Certain specific signs or symptoms that occur during a seizure may reveal the lateralisation or localisation of the seizures. Ictal and post-ictal aphasia indicates a dominant hemispheric origin while ictal speech would favour a non-dominant hemispheric origin of seizures. Complex automatisms involving oro-alimentary structures (epigastric rising sensation, nausea and vomiting may suggest a temporal lobe origin. Experiential phenomenology such as distortion of memory, dreamy state, *déjà vu* (a feeling that a particular experience has occurred earlier) *jamais vu* (a sensation that a familiar experience is new) are some of the characteristic temporal lobe ictal semiology. While an unnatural laughing (gelastic seizures) may indicate hypothalamic origin of seizures. Seizures originating in occipital lobe often present with visual phenomenology. The common automatisms (coordinated involuntary and often semi purposive complex activities) are movements such as lip smacking, chewing, swallowing movements, scratching, picking on clothes, trying to ease oneself from the bed or surroundings. Often these movements are confined to the limbs on the side of the ictal onset. In contrast to this, posturing is involuntary tonic spasms of the muscles leading to abnormal posturing of certain body parts such as hands, legs, etc. and manifest on the contralateral side of ictal origin. Occasionally, the semiological features of a seizure may be due to selective propagation of the electrical discharges to certain areas of the brain rather than due to the focus itself. This may lead to false localisation of seizure origin.

Generalised Seizures

They are broadly categorised into convulsive and non-convulsive (absence) seizures.

Absence Seizures

Absence seizure is characterised by abrupt onset loss of consciousness, a vacant look and behavioural arrest. The person is able to maintain posture, but may have 3 per second eyelid myoclonia. Each seizure may last a few seconds and ceases abruptly when the child returns to the previously engaged activity. The EEG signature of absence is 3 per second generalised spike and wave discharges over a normal background. The EEG spikes and seizures are characteristically provoked by hyperventilation. An alteration in the T type of calcium channels in thalamus is responsible for these seizures. Childhood absence epilepsy is characterised by absence seizures that tend to start around three years of age in children who normal development. These seizures tend to respond well to ethosuximide, sodium valproate and lamotrigine.

Generalised Tonic Clonic Seizures

A typical tonic clonic seizure begins with a tonic phase characterised by loss of consciousness and tonic contraction of facial, axial and limb muscles leading to a loud cry, rolling up of eyes, rigid posturing of the extremities and apnoea. The clonic phase that follows the tonic phase is characterised by rhythmic jerking of the limbs (due to intermittent contraction and relaxation of the muscles) as in a clonus. Tongue may be bitten during the latter part of the tonic phase or during the clonic phase. There may be pupillary constriction or incontinence during this phase.

Myoclonic Seizures

Myoclonic seizures are characterised by sudden, brief shock-like contractions of agonist and antagonist group of muscles leading to a brief jerk (often less than 500 milliseconds). Myoclonus can involve any group of muscles and can occur in isolation or in a train, when it may resemble tremor or *epilepsia partialis continua*.

Tonic Seizures

Tonic seizures are usually very brief (lasting a few seconds) but longer than myoclonic seizures. They are characterised by sudden spasm of the muscles particularly the axial muscles that literally throw the subject forcibly down to the floor, resulting in deep cuts on the head or face. EMG shows a dramatic increase in muscle activity during a tonic seizure.

Atonic Seizures

Atonic seizures are characterised by sudden lapses in muscle tone resulting in lapses in posture or falls. Atonic seizures are usually very brief and occur in combination with other types of seizures as in the case of Lennox-Gastaut Syndrome.

EPILEPSY CLASSIFICATION

In contrast to the classification of seizures, classification of epilepsy attempts to classify specific epilepsies and syndromes according to their clinical presentation, seizure type, accompanying neurological deficits and EEG or imaging characteristics. Age of onset, course of illness, anatomical localisation of the epileptogenic zone and underlying pathology are taken into consideration while classifying epilepsy syndromes. The currently accepted classification of epilepsies and epileptic syndromes was approved by the ILAE in 1989 (**Table 2**).

Infantile Spasm (West Syndrome)

This syndrome manifests between 4 months and 6 months of age. A specific etiological factor can be identified in only half of the patients. Tuberous sclerosis, malformations of cortical development, trisomy 21, birth asphyxia, central nervous system (CNS) infections and inborn errors of metabolism are the common etiological factors for infantile spasm. Seizures are similar to myoclonus, but are slower in evolution. It can be flexor type, extensor type or mixed type. Flexor spasms occur as sudden contraction of the shoulder flexors, elbow flexors and flexion movement of axial muscles. The EEG in infantile spasm has typical findings—hypsarrhythmia—characterised by high amplitude slow wave (1 Hz to 3 Hz) background activity and multifocal polyspike discharges. One of the recommended treatment for infantile spasm is ACTH (150 units/m^2 for one week followed by gradual tapering and withdrawal by four weeks). Infantile spasm particularly that associated with tuberous sclerosis responds very well to vigabatrin, but the potential risk to vision has limited its use.

Lennox-Gastaut Syndrome

Lennox-Gastaut syndrome (LGS) is an epileptic encephalopathy that typically starts around three years of age. It characterised by multiple seizures types (tonic seizures, atonic seizures, myoclonus, generalised seizures and partial seizures) that are often refractory to AED therapy and developmental regression. The EEG shows characteristic slow spike wave discharges (1.5 to 2.5 Hz) and abnormal background activity (**Figure 1**). Sodium valproate, topiramate, lamotrigine, and clonazepam have been found to be

Table 2: International Classification of Epilepsies and Epileptic Syndromes

Localisation related epilepsies and syndromes

- Idiopathic (with age related onset)
  - Benign childhood epilepsy with centro-temporal spikes (BECT)
  - Childhood epilepsies with occipital paroxysms
  - Primary reading epilepsy
- Symptomatic epilepsy
- Chronic progressive *epilepsia partialis continua* of childhood (Kojewnikow's Syndrome)
  - Syndromes characterised by specific modes of precipitation
  - Temporal lobe epilepsies
  - Frontal lobe epilepsies
  - Parietal lobe epilepsies
  - Occipital lobe epilepsies
- Cryptogenic epilepsies

Generalised epilepsies and syndromes

- Idiopathic (with age-related onset-listed in order of age)
  - Benign neonatal familial convulsions
  - Benign neonatal convulsions
  - Benign myoclonic epilepsy in infancy
  - Childhood absence epilepsy (pyknolepsy)
  - Juvenile absence epilepsy
  - Juvenile myoclonic epilepsy (impulsive petit mal)
  - Epilepsy with grand mal (GTCS) seizures on awakening

Contd...

Contd...

  - Other generalised idiopathic epilepsies not defined above
  - Epilepsies with seizures precipitated by specific modes of activation
- Cryptogenic or symptomatic (in order of age)
  - West Syndrome (Infantile spasms)
  - Lennox-Gastaut syndrome
  - Epilepsy with myoclonic-astatic seizures
  - Epilepsy with myoclonic absences
- Symptomatic
  - Non-specific aetiology
  - Early myoclonic encephalopathy
  - Early infantile epileptic encephalopathy with suppression burst
  - Other symptomatic generalised epilepsies not defined above
- Specific syndromes

Epilepsies and syndromes undetermined whether focal or generalised

- With both generalised and focal seizures
  - Neonatal seizures
  - Severe myoclonic epilepsy in infancy
  - Epilepsy with continuous spike-waves
  - Acquired epileptic aphasia (Landau-Kleffner syndrome)
  - Other undetermined epilepsies not defined above
- Without unequivocal generalised or focal features

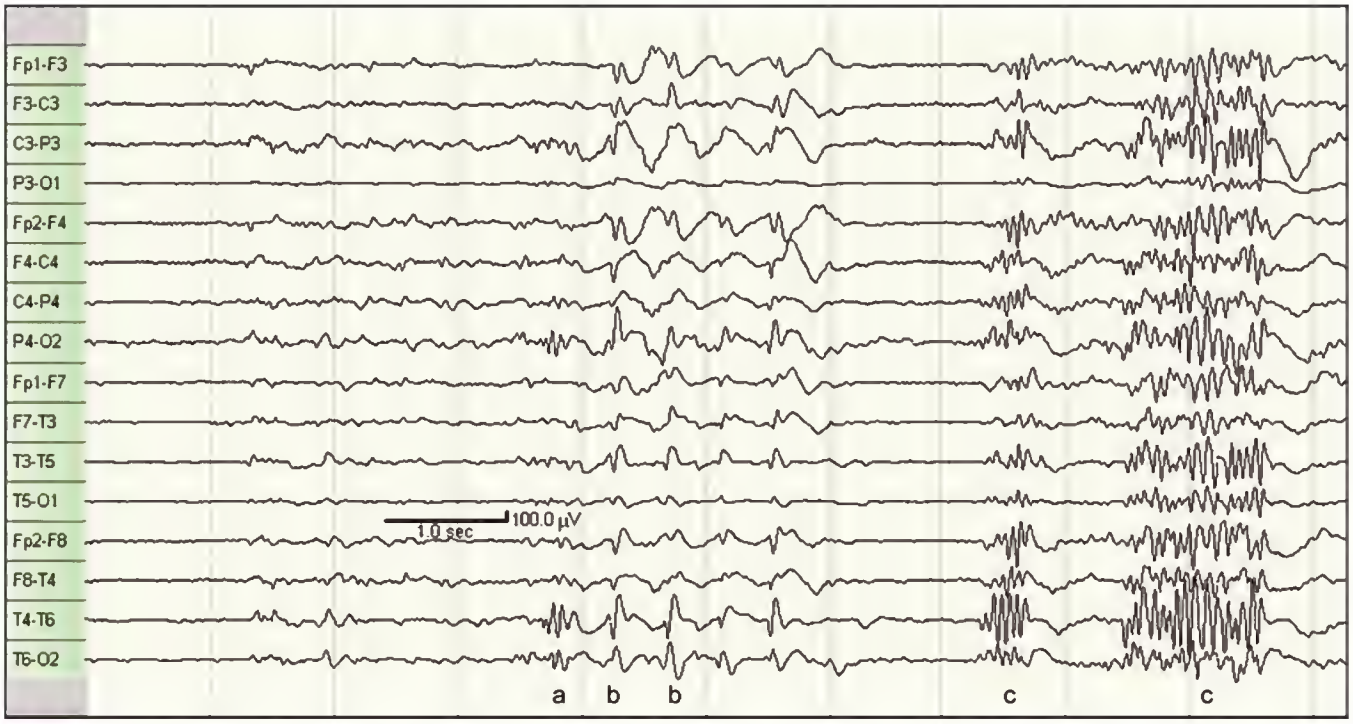

Figure 1: Lennox-Gastaut syndrome. EEG in longitudinal bipolar montage in a child (sleep state) showing (a) focal spikes (T4-T6), (b) generalised slow spike and wave discharges (2 Hz), (c) bursts of generalised paroxysmal fast activity.

effective in the management of LGS. Medically refractory cases may benefit from callosotomy, vagus nerve stimulation (VNS) or ketogenic diet. Patients tend to have a poor prognosis with persistent seizures and neurocognitive impairment.

Benign Epilepsy with Centrotemporal Spikes (BECT)

This is the most common epilepsy in childhood. It starts after three years of age and the seizures remit by adolescence. The partial seizures typical of this syndrome involve focal twitching of facial muscles, speech arrest and sialorrhoea that occur during sleep. Rarely, children can have generalised seizures during sleep. The EEG features of BECT include normal background, biphasic spike and wave discharges over centro-temporal location. These spikes have a tangential dipole with electropositivity over frontal region and electronegativity posteriorly (**Figure 2**). Most children

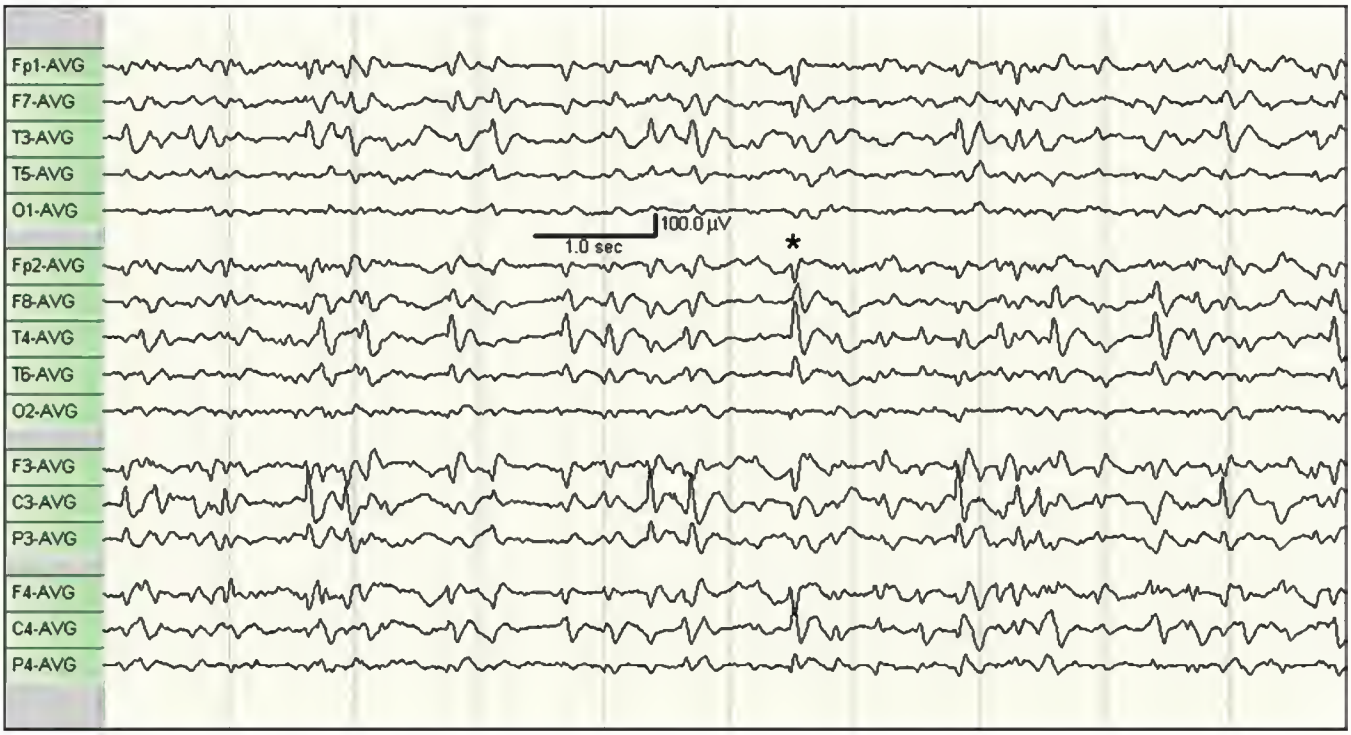

Figure 2: BECT. EEG in referential montage in drowsy state in a child showing generalised slowing of the background activity, consistent with light sleep. Spike and slow waves are profusely activated independently over both hemispheres. These spikes demonstrate typical tangential dipole with frontal electropositivity (see star in FP2-AVG derivation and electronegativity posteriorly in T4-AVG derivation). Centrotemporal spikes with extensive activation during sleep, tangential dipole and bilateral discharges are characteristic of benign childhood epilepsy with centrotemporal spikes.

respond to carbamazepine, but some may experience paradoxical worsening or an encephalopathy state. The latter group would require change of AEDs, when valproate could be an alternate AED.

Hot Water Epilepsy

Hot water epilepsy is one of the reflex epilepsies characterised by provocation of seizures by pouring hot water over head during bathing. The condition is frequently reported from Karanataka state where it accounts for 6.9% of all epilepsies.

Juvenile Myoclonic Epilepsy (JME)

This is one of the most common epilepsy syndromes in young adults. It is characterised by adolescent onset of myoclonus and generalised tonic clonic seizures without any aura. A third of affected persons give history of absence seizures in childhood. The myoclonus tends to cluster in the morning on awakening. Seizures are specifically provoked by sleep deprivation. Affected persons have normal birth, development and scholastic achievements. The EEG shows normal background activity and generalised fast (5 Hz to 6 Hz) spike wave discharges with higher amplitude frontally (**Figure 3**). Record may show photoparoxysmal response (**Figure 4**) and increased activation of spikes during sleep. JME responds well to AED therapy. JME can be distinguished from secondary generalised epilepsies and progressive myoclonic epilepsy syndromes by the normal neurological examination, normal brain imaging and typical EEG characteristics. Sodium valproate, lamotrigine, levetiracetam and phenobarbitone have been found to be effective in JME. The dosage of medications can be reduced considerably in most patients who are in remission. Nevertheless, seizures tend to relapse in about 90% patients when AEDs are withdrawn completely. Hence treatment for an indefinite period is recommended for most patients.

Temporal Lobe Epilepsy

Temporal lobe epilepsy (TLE) is the most common localisation related epilepsy in adults. Typically, the patients give a past history of atypical febrile seizures and thereafter several years of normalcy. By adolescence or young adult life, they manifest complex partial seizures characterised by aura (epigastric rising sensation, fear, formed visual hallucinations, etc.) behavioural arrest, posturing of extremities contralateral to the epileptic focus and automatisms ipsilateral to the epileptic focus. The seizures evolve gradually over several seconds to one or two minutes. TLE can be due to pathology in the mesial temporal structures such as amygdala, hippocampus or parahippocampal gyrus or due to pathology in the temporal neocortical structures when the seizures may simulate extratemporal origin. Magnetic resonance imaging (MRI) of the brain typically shows mesial temporal atrophy with gliosis (**Figure 5**). Developmental tumours, gliosis and arteriovenous malformations are some of the other causes of temporal lobe epilepsy. Inter-ictal EEG typically shows focal spike and wave discharges over the anterior temporal region (**Figures 6A and B**). Anti-epileptic drugs, such as carbamazepine and phenytoin are effective in controlling the seizures in a substantial proportion of patients. Nevertheless, others (particularly those with mesial temporal sclerosis) prove resistant to medical management. Those who have failed more than one appropriate AED therapy require presurgical evaluation to decide whether anterior temporal lobectomy would bring about remission. Those who demonstrate good electroclinical correlation and concordant imaging findings are likely to benefit most from surgery.

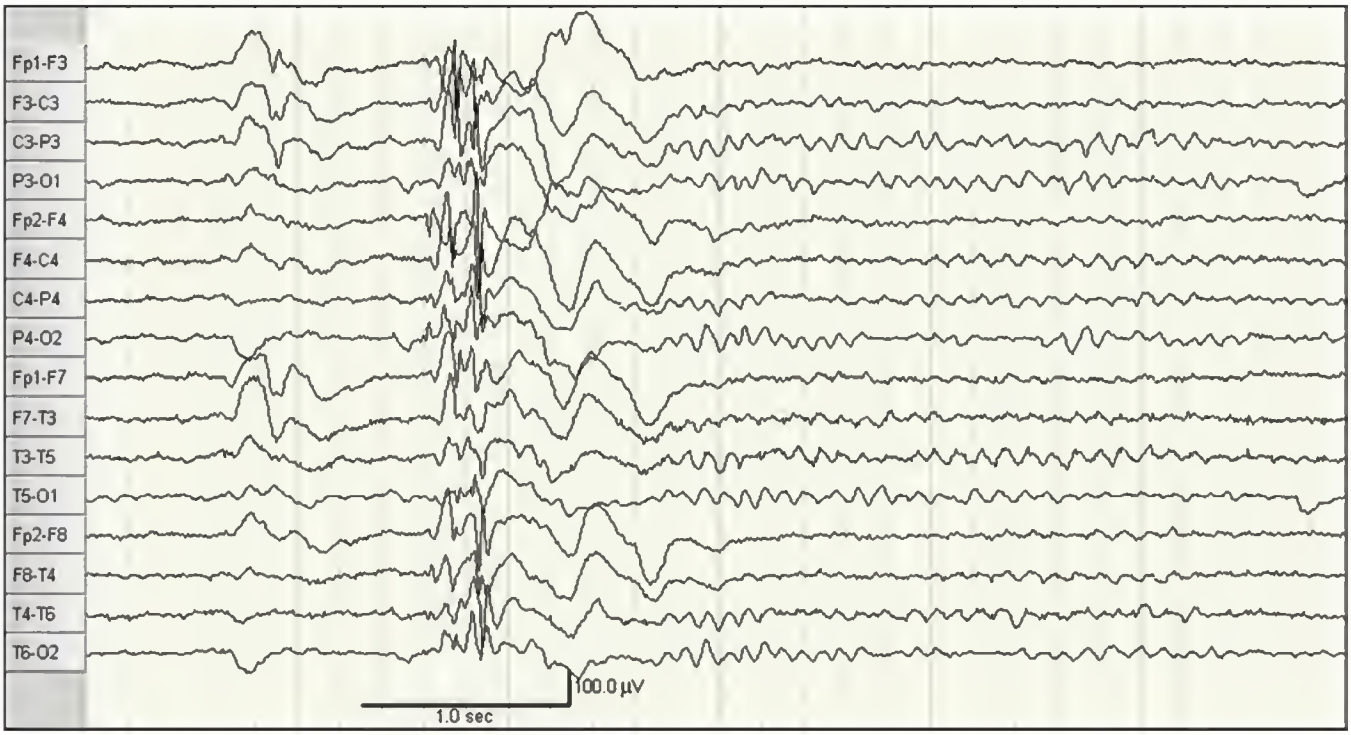

Figure 3: JME polyspike. EEG in longitudinal bipolar montage in a young adult showing generalised polyspike and slow wave activity followed by normal alpha rhythm. Generalised fast spike wave discharges (4 Hz to 6 Hz).

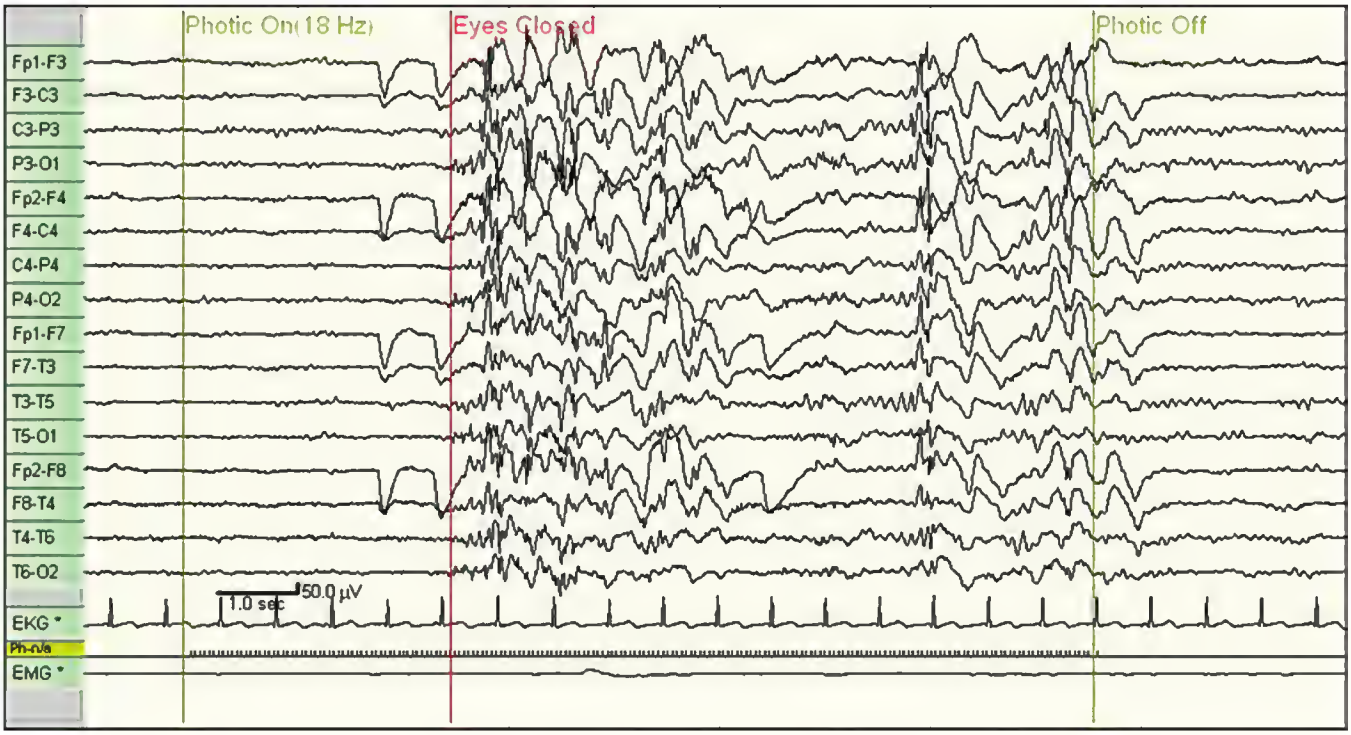

Figure 4: JME photoparoxysmal response. Continuation of previous EEG showing polyspike wave discharges with photoparoxysmal discharges at fast frequencies are typical of juvenile myoclonic epilepsy.

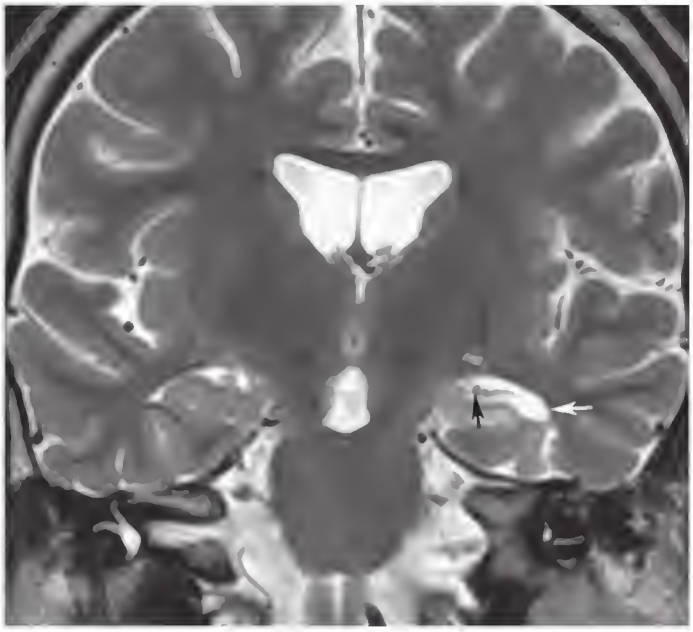
AETIOLOGY

Genetics

Genetic factors had been identified as aetiological factor in several types of epilepsies. Persons with epilepsy have 2 to 3 times higher family history for epilepsy when compared to persons without epilepsy. The molecular genetic basis of some of the paediatric epilepsy syndromes has been identified (**Table 3**). Mutations involving sodium, potassium, chloride channels, acetylcholine and GABA receptors have been identified in some of the epilepsy syndromes. Certain chromosomal disorders are associated with epilepsy and malformation of cortical development (**Table 4**).



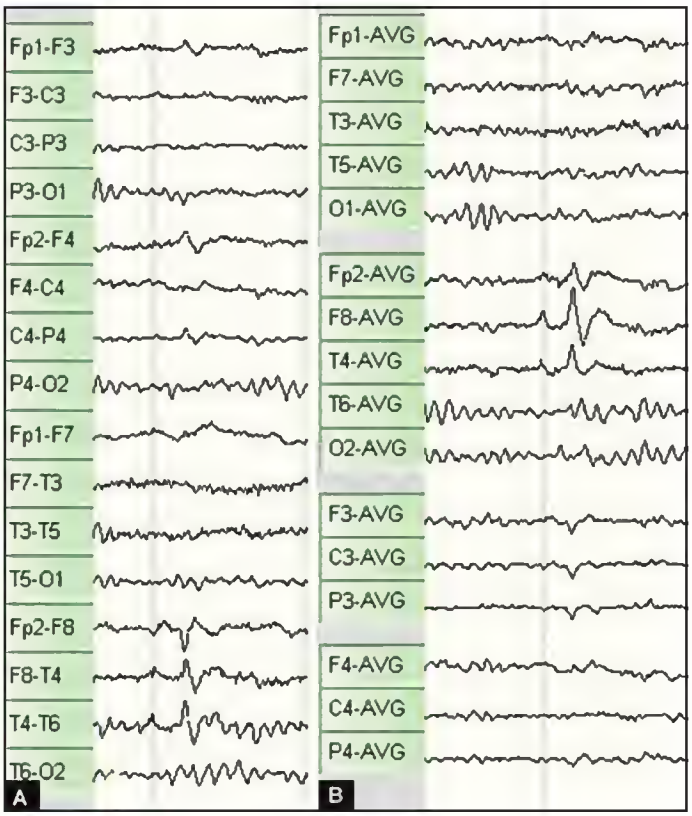


Figure 5: MTS. MRI brain T2 weighted image showing left mesial temporal sclerosis as hyperintense atrophied hippocampus (black arrow) and dilated temporal horn (white arrow).

Figures 6A and B: TLE. (A) EEG in a young adult in awake state shows spike and slow wave discharge with phase reversal across F8 electrode in the longitudinal bipolar montage. (B) The same spike when displayed in referential montage shows highest amplitude in F8-AVG derivation. These spikes are typical of temporal lobe epilepsy.

Trauma

A global survey by WHO had shown that trauma is the most frequently reported aetiology of epilepsy in more than 92% countries and it accounts for about 10% of all cases of epilepsy. Head trauma characterised by missile injury, prolonged coma, post-traumatic amnesia, depressed skull fracture or intra-cranial bleed carry higher risk of post-traumatic epilepsy.

Table 3: Selected Epilepsy Syndromes where Gene Loci have been Identified

Epilepsy Syndrome	Locus
Idiopathic generalised epilepsy	3q26; 14q23; 2q36
Adolescent onset idiopathic generalised epilepsy	8p12; 18q12; 5p
Childhood absence epilepsy	1p; 8q24
Juvenile myoclonic epilepsy	6p21; 15q14
Familial adult myoclonic epilepsy	8q23.3
Familial idiopathic myoclonic epilepsy	16p13
Benign familial infantile convulsions	19q
Benign Rolandic epilepsy	15q24
Partial epilepsy with pericentral spikes	4p15
Autosomal dominant nocturnal frontal lobe epilepsy	15q24; 3p22; 8q11.2

Miller-Dieker syndrome (del 17p13.3)
Angelman syndrome
Inversion duplication 15 syndrome
Terminal deletion chromosome 1q
Terminal deletion chromosome 1p
Ring 14 syndrome
Ring 20 syndrome

Neurocysticercosis

Epilepsy can occur due to a number of parasitic diseases such as malaria, cysticercosis, schistosomiasis and paragonimiasis. Computed tomography (CT) scan or MRI brain shows typical cysts with invaginated scolex as ring enhancing lesions or small plaques or calcifications. The control of seizures with AEDs is easier after cysticidal treatment than when left untreated.

INVESTIGATIONS

The diagnosis of seizures is made largely on the basis of detailed history obtained from an observant bystander. Nevertheless, several investigations are helpful in establishing a diagnosis of epilepsy, for certain.

Electroencephalography

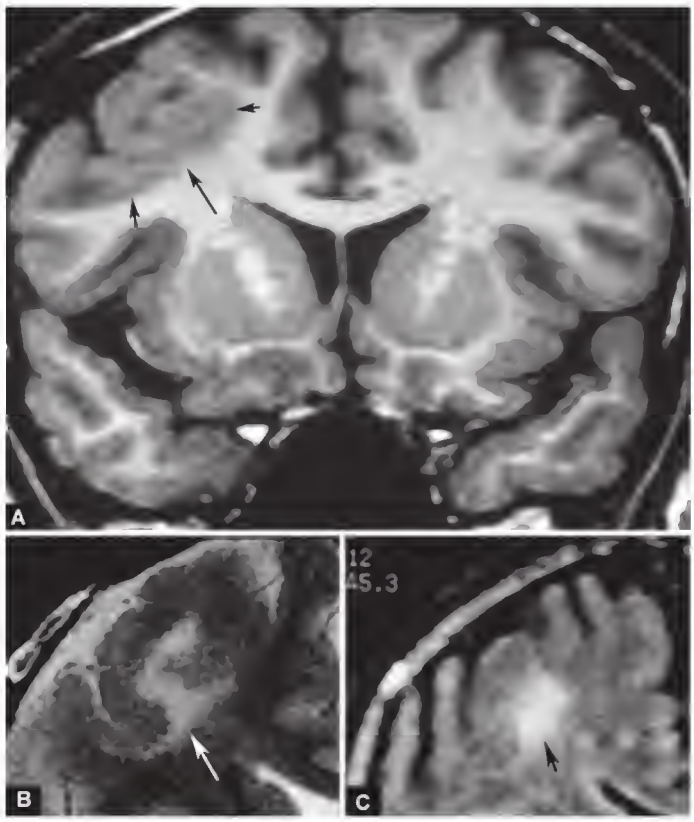
Electroencephalography (EEG) is the key investigation in a suspected case of seizures. A series of electrodes are applied to the scalp according to a standard format and the electrical potentials thus gathered are amplified and displayed as an array of traces. Electrodes on left side of scalp are odd numbered while corresponding ones on right side are numbered even. The normal background activity of a subject varies according to the age and behavioural state (awake versus sleep) and the hallmark of seizures in the EEG is the occurrence of random, high amplitude spike and slow wave discharges that stand out from the background. The frequency and distribution of the spike and wave discharges are useful in making precise classification of epilepsy syndromes. These inter-ictal spike and wave discharges may occur synchronously all over the scalp in

generalised discharges. It may be confined to focal areas in the case of localisation related epilepsy. EEG may fail to reveal the spike wave discharges in some patients with epilepsy. The yield of a single EEG (presence of epileptiform discharges) is approximately 50% which increases 92% in the fourth EEG. Hence, it is important to repeat EEGs if necessary but probably is unrewarding beyond four EEGs. The yield from any single EEG can be increased by recording it after the patient has been sleep deprived. An optimal recording in the setting of epilepsy should be for 30 minutes of awake time and 20 minutes of sleep. It is important to include activation procedures such as hyperventilation, photic stimulation and mental activation. Use of special electrodes such as sphenoidal electrodes and anterior temporal electrodes (T1 and T2) are useful when the electrical focus is suspected to be in the temporal lobes. The characteristic EEG patterns for different epileptic syndromes are described in the respective sections.

Video EEG

Video EEG is a refinement on EEG, wherein a person's EEG is recorded simultaneous with videography of physical state continuously for several hours to days. The time synchronisation between EEG and video helps one to correlate the physical state of the patient precisely with the EEG activity. Video EEG recording can help physicians to make electro-clinical correlations of various types of seizures, particularly in patients evaluated for potential surgical syndromes. Video EEG is helpful to distinguish non-epileptic psychogenic seizures from genuine seizures. Video EEG is indicated when the seizure semiology is not clear from the history or when detailed seizure semiology is necessary, as in the case of potential candidates for epilepsy surgery.

Neuroimaging



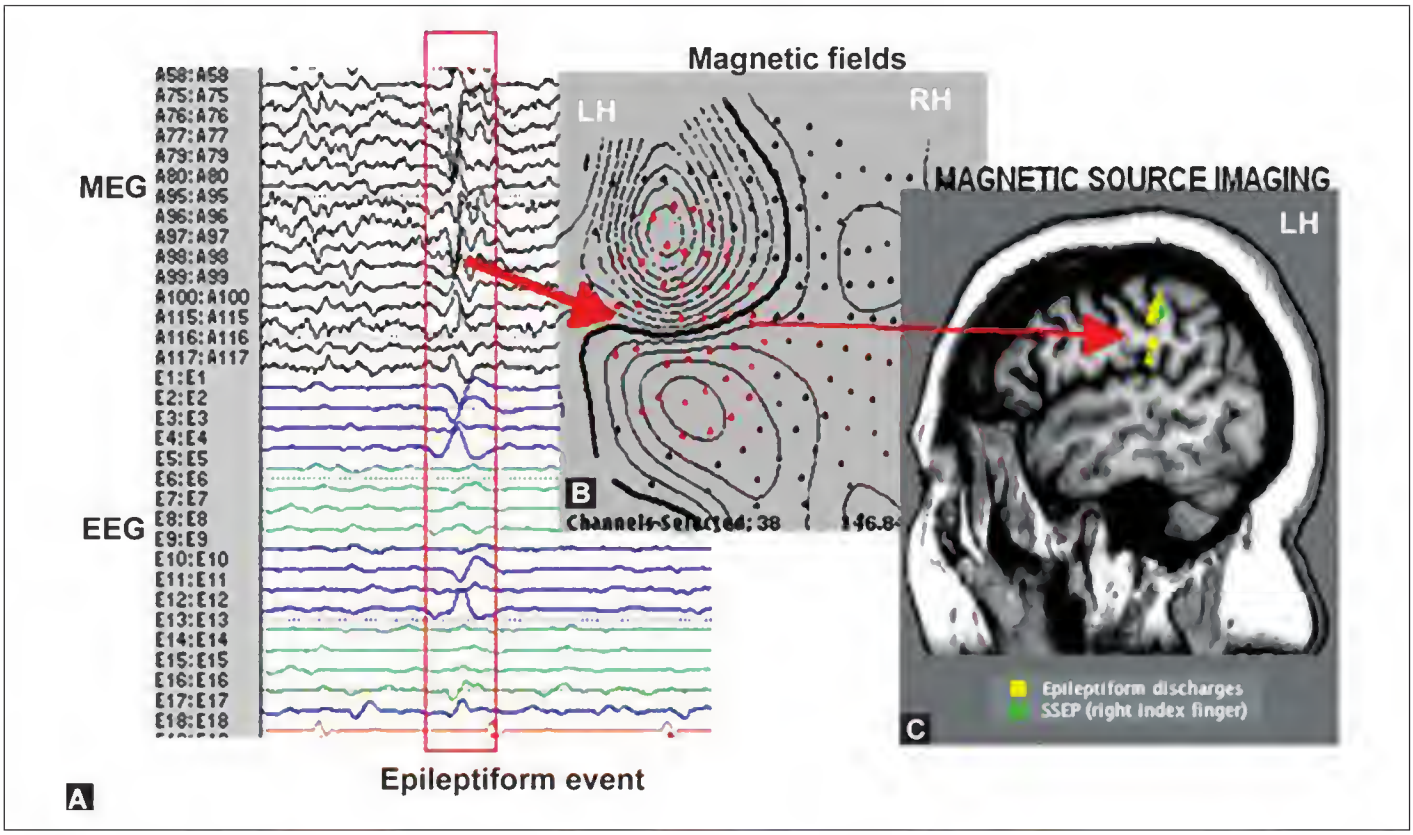
Neuroimaging is the corner stone in the classification of seizures and epilepsy syndromes. Calcifications of the brain and leptomeninges as in Sturge-Weber syndrome and tumours may occasionally be visible on good quality plain X-rays, yet a CT scan of the brain is ideal to delineate parenchymal calcifications as in neurocysticercosis, tuberculoma, tumours etc. Subtle changes like mesial temporal sclerosis and focal cortical dysplasia (**Figures 7A to C**) can be recognised only in high resolution MRI scans. Special sequences such as Fluid Attenuated Inversion Recovery images (FLAIR) can be particularly helpful to delineate these subtle changes. Ideally, all persons presenting with seizures should undergo brain imaging. Imaging is particularly indicated when the seizures have partial onset, they are medically refractory or when the semiology is changing over a period of time.

Functional Imaging

Functional imaging can contribute significantly in the evaluation of persons with epilepsy, especially when routine anatomical imaging is non-contributory.

Tc99m HMPAO SPECT

A gamma-emitting radioisotope (technetium 99) complexed to a ligand (hexamethylpropyleneamine oxime, HMPAO) is injected into the blood at the onset of a seizure. This low molecular weight compound readily passes the blood brain barrier and localises at the site of epileptogenesis proportionate to the increase in regional blood flow. The images of the resultant radiation is co-registered to an MRI or CT scan to generate images of the brain showing the epileptic focus. In order to correctly localise the focus, the T99 HMPAO needs to be injected at the beginning of the seizures. The interictal SPECT scans are not particularly useful in the evaluation of epilepsy.



Figures 7A to C: FCD. (A) MRI brain showing abnormally thickened cortex (arrow)in T1 weighted image. (B) The abnormal pool of neurons appear as hyperintense signals in T2 weighted image, and (C) in fluid attenuated inversion recovery –FLAIR image.

Positron emission tomography

Fluorodeoxyglucose (FDG) is a glucose analogue that carries the positron emitting radioactive isotope fluorine 18 substituted for a normal OH group in the glucose molecule. When injected in the blood it is selectively taken up by neurons and glia that have increased metabolism. The positrons emitted from these focal areas indicate epileptogenic foci and can be easily visualised when co-registered with CT or MRI images. PET scans have the advantage that inter-ictal studies may reveal epileptic foci as hypometabolic cold spots even when the anatomical images are normal.

Magnetoencephalography

Magnetoencephalography (MEG) is a relatively new method of recording the magnetic field associated with electrical activity of the brain. These dipole sources are co-registered on MRI images to obtain the precise anatomical localisation. MEG has several advantages over EEG that records the electrical field of the brain. MEG can record the activity emanating from the banks of sulci, which are relatively invisible to EEG. Three-dimensional source of the dipole can be co-registered on MRI scan. Epileptic foci as well as functionally important areas like centres for language and cognitive activities can be simultaneously recorded (**Figures 8A to C**).

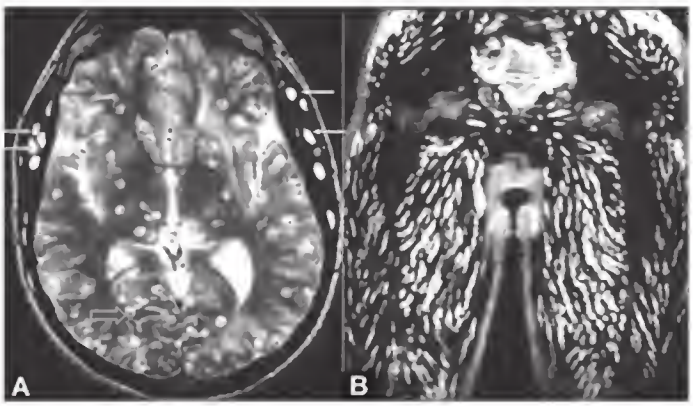
Figures 8A to C: MEG. (A) Magnetoencephalogram selected channels of MEG and corresponding EEG traces showing a epileptiform discharge. (B) The magnetic field related to this discharge is shown in and (C) the corresponding dipoles are marked out on the magnetic source image.

Functional MRI

Functional MRI (fMRI) is a powerful tool that can identify the precise localisation of the eloquent cortex such as language and memory centres in the brain. Most of the fMRI studies are carried out by the blood oxygen level dependent (BOLD) technique. Neural activity is associated with regional haemodynamic changes characterised by increase in regional cerebral blood flow and higher concentration of oxyhaemoglobin. Such fMRI maps closely relate to the functional areas of the brain. fMRI studies are particularly useful when a person with epilepsy is being evaluated for surgery. The spatial relationship of the epileptic foci to functionally eloquent areas would help the surgeon to tailor his surgery.

Neuropsychological evaluation

Neuropsychological evaluation includes assessment of certain global and lobar cognitive functions. A standard neuropsychological test battery would include tests for attention, frontal executive functions, memory, visuo-spatial functions, language and comprehension, higher visual and auditory functions. Memory assessment is particularly important when a mesial temporal resection including hippocampectomy is contemplated.



TREATMENT

Objectives

The primary objective of treatment is to prevent recurrence of seizures. The decision to initiate pharmacotherapy in a given situation depends on several issues, the type of seizure, its EEG correlate, severity of the seizures and disability or potential harms related to recurrence, age and occupation of the patient and co-morbidities (**Figures 9A and B**).

Anti-Epileptic Drugs

Introduction of phenobarbitone in 1912 marked the advent of appropriate anti-epileptic drug therapy. Since the 1990s, several new AEDs have been introduced in the market. The currently available drugs for pharmacotherapy of epilepsy are listed in (**Tables 5 to 7**). The dosage applicable to Indian population generally is about 25% less than the daily defined dose (DDD) as the average weight of adults in India is estimated as 50 kg.

Figures 9A and B: Neurocysticercosis. (A) MRI brain T2 weighted image showing widespread occurrence of cysts with central scolex in the brain parenchyma and interdiploic space and subcutaneous plane (B) MRI of gluteal region and thighs showing bullet shaped cysts in the muscular and subcutaneous plain. (Neurocysticercosis is a cause of epilepsy).

Table 5: Pharmacokinetic Properties of Commonly used Anti-Epileptic Drugs (AED)

AED	Half-Life (h)	Metabolism	Protein Bound Fraction (%)	Enzyme Induction
Phenobarbitone	100	90% hepatic	45	Inducer
Carbamazepine	8 to 22	90% hepatic	75	Inducer
Ethosuximide	60	65% hepatic	<5	Non-inducer
Gabapentin	5 to 7	95% hepatic	<5	Non-inducer
Lamotrigine	12 to 60	90% hepatic	55	Non-inducer
Levetiracetam	6 to 8	65% renal	<10	
Oxcarbazepine	8 to 10	90% hepatic	40	Mild inducer
Phenytoin	22	90% hepatic	90 to 95	Inducer
Pregabalin	6 to 7	95% renal	<5	
Tiagabine	5 to 13	90% hepatic	95	Non-inducer
Topiramate	19 to 25	30% hepatic	9 to 17	Non-inducer
Valproate	15 to 20	95% hepatic	80 to 90	Inhibitor
Zonisamide	63	70% hepatic	40	Non-inducer

Table 6: Dosage Schedule for Commonly Used Anti-Epileptic Drugs (AED)

AED	Starting Dose (mg/day)	Adult Dose (mg/day)	Dose Escalation	Paed (mg/kg/day)	DDD (mg)
Carbamazepine	200	600-1200	2-3 wks	10-30	1000
Ethosuximide	250	750-1000	2-3 wks	15-40	1250
Gabapentin	900	900-3600	2-3 days	30-90	1800
Lamotrigine	12.5	100-400	4-6 wks	5-15	300
Levetiracetam	500	1000-3000	3 wks	20	1500
Oxcarbazepine	300	900-1500	3 wks	20-40	1000
Phenobarbitone	30	60-180	2 wks	3-5	100
Primidone	125	1500	2 wks	10-25	1250
Phenytoin	100	200-450	3 wks	4-8	300
Pregabalin	150	150-600	1 wk	NA	300
Tiagabine	4	32	6 wks	NA	30
Topiramate	25	100-400	3-6 wks	5-6	300
Valproate	200	400-2400	3 wks	15-60	1500
Zonisamide	50	100-300	4-8 wks	NA	200
Stiripentol	50 mg/kg	100	4 wks	50-100	1000
Lacosamide	100	200-400	2-4 wks	NA	300
Clonazepam	0.5	2-8	4 wks	0.01	8
Clobazam	5	5-20	4 wks	0.5	20

DDD = Daily defined dose; NA = Not currently approved for use in children; Paed= Paediatric dose.

Single Seizure

The expert opinion is divided on whether to start treatment immediately after a single seizure. The overall risk of relapse after a single seizure is less than 50%. Nevertheless, the risk is higher when there is a definite epileptogenic lesion identified in the brain image or when EEG shows recurrent epileptiform discharges. The risk of relapse is relatively lower, when the interval between last seizure and evaluation is longer. The benefits as well as risk of starting treatment should be discussed with the patient along with the likely natural history of seizure for that patient so that the patient is involved in the decision making regarding treatment.

How to Start Treatment

Selection of a given AED for a patient is determined by the epilepsy syndrome, age, gender, occupation and the presence of co-morbidities. Most of the currently available AEDs have similar likelihood of achieving seizure remission when given in adequate dosage. Certain newer AEDs are not yet licensed for first line monotherapy in children. Drugs like sodium valproate may not be preferred for a young woman in reproductive age group, in view of its adverse reproductive effects and risk of teratogenicity, particularly at higher dosage. Enzyme-inducing AEDs such as carbamazepine, phenytoin or phenobarbitone may be avoided when a person is concomitantly using oral anticoagulants or oral contraceptive pills as it may adversely interact with these drugs. Topiramate may have to be avoided in patients with learning disability, speech problems and renal calcinosis as it can aggravate such conditions. Patients with severe liver or kidney dysfunction may require modification of AED dosage or selection of different AEDs (e.g. gabapentin) that may least interfere with these functions.

Drug levels are helpful, when non compliance with medications is suspected, during management of status epilepticus or when there are several co-medications that may interfere with the metabolism or bioavailability of AEDs.

Table 7: Selection of AEDs According to the Seizure Type

Seizure Type	First-Line Drugs	Second-Line Drugs	Other Drugs that may be Considered	Drugs to be Avoided (may Worsen Seizures)
Primary generalised tonic – clonic	Sodium valproate Lamotrigine Levetiracetam Topiramate	Clobazam Phenobarbitone	Primidone	Tiagabine Vigabatrin
Absence	Sodium valproate Lamotrigine	Clobazam Clonazepam Topiramate	Vigabatrin	Tiagabine
Myoclonic	Sodium valproate Levetiracetam	Clobazam Clonazepam Topiramate	Phenytoin	Lamotrigine
Tonic	Lamotrigine Sodium valproate	Clobazam Clonazepam Topiramate	Phenobarbitone	Carbamazepine Oxcarbazepine
Atonic	Lamotrigine Sodium valproate	Clobazam Clonazepam Levetiracetam Topiramate	Phenobarbitone	Carbamazepine Oxcarbazepine Phenytoin
Focal with/without secondary generalisation	Carbamazepine Lamotrigine Oxcarbazepine Phenytoin Topiramate	Clobazam Sodium valproate Levetiracetam Zonisamide	Clonazepam Phenobarbitone Primidone Gabapentin	

Rational Polytherapy

The objective of therapy is to manage epilepsy with a single drug, if possible. More than 60% of persons with epilepsy achieve remission with single drug therapy. Monotherapy carries lower risk of adverse effects, low cost, better compliance and remission rates and higher quality of life when compared to polytherapy. About a third of persons with epilepsy fail to respond to monotherapy. A second AED may be carefully selected as add on therapy. Ideally, the second drug should have a different mechanism of action, adverse effect profile or spectrum of seizure coverage compared to the first drug. Experience in India indicates that clobazam can be a good second drug to go with most other primary drugs. This AED is not approved for use in USA and certain other countries. Combinations of carbamazepine with sodium valproate or levetiracetam as well as combinations of lamotrigine with sodium valproate are found to be quite effective.

When to Stop Treatment

Epidemiological studies indicate that 60% to 70% of persons with epilepsy achieve seizure remission. According to data from general practice study of epilepsy in UK, 86% achieved 3 year remission and 68% achieved 5 year remission over a period of 9 years. About 60% of those who taper off and stop AED upon remission may relapse in the next 5 years. In children, normal growth and development, normal imaging findings and absence of inter-ictal discharges in the EEG are found to be good predictors of remission. Nevertheless, such clear markers of remission are not readily available for adults. A person who has remained seizure free for more than 3 years can be considered for AED withdrawal, provided the risk of a relapse is not excessive.

Management of Refractory Epilepsy

Large population-based studies have shown that about 20% to 30% of persons with epilepsy may prove to have seizures that do not respond to AED therapy. Their seizures may remain unabated with whatever drugs tried. Trials with newer AEDs may ameliorate seizures (50% reduction in seizure frequency) in about 20% to 40% instances. Recent studies have shown that this group of medically refractory epilepsy consists of several syndromes that respond well to epilepsy surgery.

Epilepsy Surgery

It is useful to understand the various zones relevant for surgical syndromes. A lesion responsible for the epilepsy such as gliosis or granuloma is considered as lesion zone. Seizure onset zone refers to that part of the cortex where the electrographic origin of seizure occurs. Epileptogenic zone is that part of the brain responsible for the seizure genesis. It is often overlapping or close to the lesion and needs to be excised to achieve seizure freedom. Symptomatic zone is that portion of the brain responsible for the initial ictal symptomatology. The symptomatic zone can be adjacent to the seizure onset zone or epileptogenic zone when the latter are in relatively silent areas of the brain. The functional deficit zone is that part of the brain responsible for the functional deficits associated with a seizure. The main objective of pre-surgical work up of a patient is to map out the epileptogenic zone as precisely as possible. This may require imaging, video EEG and occasionally intra-cranial recordings.

Recent studies indicate that certain epilepsy syndromes such as mesial temporal lobe epilepsy, focal cortical dysplasia, developmental tumours associated with epilepsy, Rasmussen's encephalitis selectively respond to appropriate surgical treatment. The indications for pre-surgical work up include the occurrence of frequent non-disabling seizures in spite of optimal AED therapy. The operational definition for such a condition is presence of two or more disabling partial or generalised seizures in 6 months, in spite of treatment with two or more appropriate AEDS therapy. Surgery for epilepsy could be broadly categorised as curative procedures aimed at achieving seizure remission and palliative procedures aimed at ameliorating seizure burden (**Table 8**). The primary objective of definitive epilepsy surgery is to remove sufficient amount of epileptogenic zone without compromising any eloquent cerebral functions in order to achieve permanent seizure remission. This goal can be achieved by systematically evaluating medically refractory epilepsy through several phases of non-invasive and invasive evaluation.

Table 8: Surgeries Performed to Ameliorate Epilepsy

Curative	Palliative
Anterior temporal lobectomy	Corpus callosotomy
Selective amygdalo-hippocampectomy	Vagus nerve stimulation
Lesionectomy	Multiple subpial transection
Focal cortical resection	
Lobar resection	
Multilobar resection	
Hemispherotomy/ Hemispherectomy	

The baseline non-invasive evaluation would include a good quality MRI imaging to look for structural lesions (e.g. mesial temporal sclerosis, focal cortical dysplasia or other localised lesions) and video EEG. The interictal and ictal data from the video EEG and imaging should support a coherent electro-clinical syndrome with an epileptogenic zone localised to a small area that can be resected without unacceptable adverse effects. In the case of temporal lobe epilepsy, this would involve triangulation of stable ictal semiology, focal inter-ictal epileptiform discharges, mesial temporal sclerosis and ictal onset to one temporal lobe. About 80% of patients who fulfil these criteria may achieve complete seizure freedom after standard anterior temporal lobe resection with amygdalohippocampectomy. Invasive monitoring with electrode array deployed in the subdural space (subdural strip or grid electrodes) or in the cortex (depth electrodes) may be necessary when recordings from the scalp are equivocal. Functional studies like ictal SPECT and inter-ictal PET scans can prove helpful in identifying the epileptogenic zone when the MRI fails to reveal any focal pathology. Such persons may require additional proof from invasive monitoring before they are offered epilepsy surgery. Assessment of memory by neuropsychological examination or by fMRI or intra-carotid amytal test would be necessary in persons considered for unilateral temporal lobe resection when there is suspicion that the contralateral temporal lobe is dysfunctional. Language lateralisation by fMRI, MEG or neuropsychological tests is necessary when the resection is likely to be in locations close to language areas of the brain.

Other Means

Persons with medically refractory epilepsy who are not candidates for epilepsy surgery can be offered other treatments.

Ketogenic diet

Ketogenic diet is a special diet, low in carbohydrate and high in fat, that induces a metabolic state similar to starvation ketosis. Several observational studies have shown that more than half of children with intractable epilepsy responded to ketogenic diet by reduction in seizure frequency by 50%. Ketogenic diet therapy had been found to be most helpful for children.

Vagus nerve stimulation

Vagus nerve stimulation (VNS) is a simple procedure in which the left vagus nerve is stimulated in the cervical region with a subcutaneously implanted pacemaker. The beneficial effects of VNS are not restricted to any particular seizure type but only 10% patients achieve seizure freedom.

Deep brain stimulation

Stimulation of the anterior nucleus of the thalamus (SANTE) with a stereotactically implanted electrode from a subcutaneously located pacemaker is undergoing clinical trials.

Responsive neurostimulation

In this system, a set of electrodes are implanted over the epileptogenic seizure onset zone of cerebral cortex in order to continuously monitor for onset of a seizure. As soon as an electrographic onset is detected, an electric impulse is delivered over that site to quench the electrographic seizure from progressing to a clinical seizure.

STATUS EPILEPTICUS

Status epilepticus (SE) is a common neurological emergency that occurs in about 6 to 18 persons per 100,000 population. The first operational definition of SE (American Epilepsy Society, 1993) defines SE as a single seizure lasting more than 30 minutes or the occurrence of two or more seizures, without recovery of consciousness in between. Based on more recent observations, the time duration for classifying a generalised tonic clonic seizure as status epilepticus is reduced to 10 minutes. The subgroups of patients with SE who fail to respond to standard treatment (~ 25%) are classified as refractory SE. They would require more aggressive therapy. Status epilepticus is broadly classified into convulsive and non-convulsive SE and is further sub-classified according to the seizure type.

The aetiology for SE may vary according to the age of the person and the geographic location (**Table 9**).

Sudden AED withdrawal, as in non-compliance, is the most common cause of SE in most locations. CNS infections are more frequent causes of SE in children than in adults. Cerebral malaria is an important cause for SE in endemic areas. CNS infections contribute to SE in patients with HIV infection. Alcohol excess as well as alcohol withdrawal can be important causes in communities where alcohol use is prevalent. Co-medication with certain antibiotics such as penicillins, cephalosporins, quinolones (particularly ciprofloxacin), anti-histamines and anti-depressants can predispose to SE.

Table 9: Causes of Status Epilepticus According to Age

Children	%	Adults	%
Infection and fever	35.7	Stroke	25
Medication changes	20	Medication change	18
Unknown	9	Alcohol/drugs	13
Metabolic precipitants	8	Anoxia	12
Congenital precipitants	7	Metabolic	9
Anoxia	5	Unknown	8
CNS infection	5	Infection	6
Trauma	3.5	Tumour and trauma	4.5

Convulsive SE (CSE) is relatively easy to diagnose because of the prominent motor manifestations and loss of consciousness. Nevertheless in certain situations, psychogenic status epilepticus, decerebrate spasm, tetanus, malignant hyperthermia or neuroleptic malignant syndrome can mimic CSE. Non convulsive SE may present as subtle alteration of sensorium or behavioural changes and an EEG only may reveal the diagnosis.

Management of Status Epilepticus

The first step in the management of SE is to ensure the safety of the patient. The subject should be moved to a location where there is less chance of injury. Airways should be cleared but it is unwise to force any object into the mouth of a convulsing patient as it may cause more harm. Gentle suction can be applied to remove the saliva and froth, and oxygen can be administered if it is available. Two secure intravenous cannulae can be placed for fluid resuscitation and pharmacotherapy. Blood samples may be drawn for biochemical analysis and drug levels (if available). In order to achieve early remission, it is important that the treatment is initiated early, preferably at home or in the pre-hospitalisation phase itself. Buccal or intranasal administration of midazolam or rectal administration of diazepam had been found to be an effective pre-hospital management step in clinical trials. The drug of choice for in-hospital management of SE is intravenous lorazepam. Intravenously administered lorazepam has longer duration of anticonvulsant effect (>6 hours) than diazepam (20 minutes) and carries lesser risk of respiratory depression. Lorazepam should be stored in light-proof containers, and should be restocked every 4 months to 6 months. Intravenous fosphenytoin (pro-drug of phenytoin without the propylene glycol carrier) is the best second-line therapy in SE. It is quickly dephosphorylated to phenytoin when given intramuscular or intravenous. Fosphenytoin has several advantages over phenytoin. It can be infused using standard intravenous solutions, whereas phenytoin should not be given in dextrose-containing fluids (because of drug precipitation). It can be given intramuscularly if required. Fosphenytoin can be infused at a faster rate (150 mg/minute) than phenytoin which carries some risk of cardiac arrhythmia and hypotension. The pharma-cokinetic parameters of commonly used AEDs are given in **Table 10**.

Patients who fail to respond to these two standard drugs are designated as refractory SE. They would require more aggressive management, preferably after securing endo-tracheal intubation and ventilator assistance. If ventilator support cannot be ensured it would be worthwhile administering intravenously non-sedating AEDs such as

sodium valproate or levetiracetam. Recent clinical trials indicate that these two drugs have the potential to abort SE even when the primary drugs have failed.

Table 10: Pharmacokinetic Parameters for Commonly Used Drugs for Status Epilepticus

Drug (route)	Initial Dosage	Latency (Minutes)	Duration (Hours)
Lorazepam (IV)	4 to 8 mg	3 to 10	12 to 24
Diazepam (rectal)	0.5 mg/kg	5 to 15	<1
Diazepam (IV)	10 to 20 mg	1 to 5	<1
Midazolam (IM)	0.15 to 0.3 mg/kg	5 to 10	<1
Midazolam (buccal)	0.3 mg/kg (max 10 mg)	5 to 10	<1
Midazolam (IV)	0.2 mg/kg	10 to 30	12 to 2
Phenytoin (IV)	20 mg/kg	10 to 30	12 to 24
Fosphenytoin (IV)	20 mg/kg PE	10 to 30	12 to 24
Phenobarbitone (IV)	20 mg/kg	5 to 30	48 to 72
Sodium Valproate (IV)	30 mg/kg	<20	8 to 24

Latency = Time interval between commencement of infusion and onset of action.
Duration = The duration of time from onset of infusion for which the drug may maintain adequate anticonvulsant property in the blood.
PE = Phenytoin equivalents; IV = Intravenous.

If patients have failed the above AEDs, they would require management after securing endotracheal intubation and ventilation in an ICU. Intravenous infusion of pentobarbitone, thiopentone, midazolam or propofol is another option at this stage. Most often the dosage is tailored to suppress all clinical seizures and achieve burst suppression pattern in the EEG. Such patients in SE require close monitoring of various metabolic parameters and organ functioning as they are prone to multiple organ dysfunctions.

PREVENTION OF EPILEPSY

Head trauma accounts for 10% of all epilepsy. Safety at work place and on road, especially use of helmet while driving can reduce the risk of head injury and subsequent occurrence of epilepsy. Neurocysticercosis is the most important cause of epilepsy in several parts of India and other countries (**Figure 9**). A substantial proportion of this can be prevented by controlling taeniasis.

20.6 Disorders of Speech

Apoorva Pauranik

INTRODUCTION

Speech, communication and language disorders are multiple and heterogeneous (**Table 1**). Aphasia is one of them and involves a deficit in expression (motor), comprehension (sensory) or both. The modes of communication affected could be verbal, written or both and other unusual ones such as sign language in deaf mutes. At the core of aphasia lies a disturbance in language functions.

Table 1: Disorders of Speech Language and Communication

Type of Disorder	Comment
Disorders of phonation Aphonia Dysphonia	Almost always due to laryngeal dysfunction (local, non neurogenic or neurogenic paralysis of vocal cord muscles)
Disorders of articulation Anarthria Dysarthria	Non neurological local causes Neurological causes Muscles: polymyositis Neuromuscular: myasthenia gravis Neuropathic: GB Syndrome Brainstem, cerebellum, basal ganglia: CVA, neoplasia, infection, degeneration (Parkinsonism), trauma, developmental
Disorders of fluency Stammering (Stuttering) Cluttering	Usually developmental No visible underlying pathology in most
Disorder of language Aphasia Alexia/Dyslexia Agraphia	Cortical speech areas: Stroke Other causes less common Developmental: mental retardation, cerebral palsy Degenerative: Young age: Autism, Rett's syndrome, leucodystrophies and poliodystrophies Old age: Alzheimer's and other dementias

Language is an instinct whose biological substrate is also conducive to other learned traits like reading, writing and probably mathematics and music. This chapter mainly focus on aphasias, that too following cerebrovascular accidents. Other disorders will be briefly covered.

These subjects are common and contribute significantly to disability adjusted years of life (DALY's). Seminal advances in theoretical understanding and practical applications have occurred in last two decades improving prospects of rehabilitation. Research into these disorders provides crucial insight and better understanding.

EPIDEMIOLOGY AND AETIOLOGY

Aphasia occurs in about 25% of patients with stroke. Non-fluent aphasia predominates in young patients suggesting an anterior lesion, while in elderly patients fluent aphasia is attributed to more frequent posterior infarcts.

Global aphasia would suggest occlusion of internal carotid artery (ICA) or stem of middle cerebral artery (MCA) or large deep basal ganglionic plus thalamic haemorrhage. Most aphasia syndromes occur due to infarctions in left MCA territory with the exception of transcortical motor aphasia [anterior cerebral artery (ACA)] and pure alexia without agraphia [posterior cerebral artery (PCA)]. Transcortical aphasia syndromes (those with preserved repetition) suggest ischaemic infarctions in watershed territories between ACA-MCA-PCA, thereby disconnecting core speech centres in sylvian region from more peripheral association cortices in fronto-parietal-occipital regions. Haemodynamic compromises, like those in severe sustained hypotension, reduced cardiac output and proximal vascular occlusion in aorta and carotid arteries would typically predispose to lesions in watershed areas.

Aphasia associated with head injury can develop hours or even weeks after the initial event. It is most commonly associated with right side blunt orbito-frontal trauma with a contre-coup left temporoparietal injury. Trauma pathology trends to be less localised than ischaemic stroke (except gun-shot wounds), hence aphasic syndromes are often not pure or classical, but rather mixed with signs of more diffuse pathologies like altered sensorium, delirium and amnesia.

Aphasia due to tumours of left cerebral hemisphere will usually have gradual onset, poor syndromic phenotype and additional clinical deficits due to cerebral oedema and increased intracranial pressure

DEVELOPMENTAL DISORDERS

In autism spectrum disorders (more in boys) and Rett' syndrome (girls) there is normal development up to the age of 18 to 24 months, followed by rapid and severe regression of cognitive milestones. Speech communication is severely affected. Developmental dyslexias are rather common (5% or more) example of learning disability in reading and writing that persists throughout life, though somewhat overcome by extra-laborious effort and training. Verbal communication remains fine but the rules governing relationship between written symbols and their sound are not well developed in dyslexia. They remain slow readers.

Language impairment is an important diagnostic feature of dementias. Generally we presume that disease like Alzheimer's dementia are a diffuse pathology, hence language deficits likewise will also be of a general nature, rather than resembling a well defined syndrome. Yet there are a few degenerative dementing disorders whose pathology remains focal or restricted. For example, primary progressive aphasia and semantic dementia.

ANATOMICAL SUBSTRATE OF APHASIA

Approximately 90% of people are right-handed and 10% are non right-handed (left-handed and ambidextrous). The left

hemisphere controls speech and language functions in 98% of right-handed persons and also in about 50% of the non right-handed persons. These facts explain the low incidence (2% to 3%) of crossed aphasia, i.e. aphasia occurring in a right-handed person with a lesion in the right cerebral hemisphere.

The association cortex in the region of the left sylvian fissure is mainly responsible for language capability. Holistic models maintain that the entire region, or at least large portions of it, acts as a whole to support all language functions. Localisation models argue that specific language process are carried out in relatively restricted areas of this region.

Auditory perception occurs in superior temporal gyrus but recognition of meaningful words by decoding the noise takes place in Wernicke's area. The later is linked to tertiary association cortices in supramarginal and angular gyri posterosuperiorly which assign and store word meanings. All this information has to reach Broca's area anteriorly for repetition and spontaneous speech. The encoding of information into pronounceable or writable words and sentences is accomplished in Broca's area which then executes the motor programme for muscles of articulation. For reading comprehension visual stimuli from occipital cortex reach angular gyrus.

Many *subcortical structures* (posterior thalamus, basal ganglia, deep white matter, temporal isthmus, insula) mainly on left or dominant side, are an important and integral component of language circuits. Aphasic syndromes due to discrete subcortical lesions are well described, but they are generally less precise, not fitting into well established syndromes and usually recovers well in short period.

The right hemipshere has some rudimentary linguistic capability, which can be improved by training and is probably responsible for significant proportion of recovery. Emotional speech, stress, tone, melody and rhythm or prosody of speech (both in production and comprehension) and use of metaphor, humour, sarcasm and irony as means of communication are in greater control by right or non-dominant hemisphere.

CLINICAL APPROACH TO APHASIA

One must begin with patient's mother tongue and other languages, handedness and level of literacy. The handedness should be assessed by enquiring about the preferred use of a hand for many activities of daily-life in addition to eating and writing.

Associated neurological deficits like hemiparesis, facial paresis, visual field defects, hemisensory loss and amnesia should be documented. A brief examination can be completed in 5 to 10 minutes and will provide basic data about presence of aphasia, its severity and a tentative diagnosis of aphasia syndrome. More detailed assessments spanning over 1 to 2 hours in one or more sessions will be required in most subjects for comprehensive profiling and planning the rehabilitative speech therapy.

Oral Expression, Articulation and Fluency

Make your observations throughout history which try to ask questions which force the patients to utter some sentences. Like tell me about your illness, your family, the work done by you at your job.

An adequate sample of narrative speech is needed to detect the types of deficits. One can use picture description task. Aphasics produce incomplete, halting, sparse description, failing to grasp the totality of the environment despite being repeatedly pointed to the different parts of the picture.

Defective articulation and phonation are recognised during ordinary conversation. Test phrases or attempts at rapid repetition of consonant clusters bring out particular abnormality. Dysarthria is an important and common deficit in many aphasics particularly those with non-fluent speech. Pure dysarthria, however, occurs in many disorders other than aphasia. They involve basal ganglia (e.g. Parkinsonism), descending corticospinal pathway (e.g. pseudobulbar palsy), cerebellar hemispheres and connections to brainstem (e.g. stroke, demyelination, tumours), cranial nerve nuclei and trunks of 5th, 7th, 9th to 12th nerves (e.g. infective polyneuropathy), muscles of articulation in pharynx, palate, face, tongue (e.g. myasthenia gravis). Dysarthria in aphasic patients is almost always accompanied by other deficits in language communication.

Reduced verbal output can be described as reduced phrase length, speaking monosyllables or single words or short sentences. Severe non-fluent aphasics some times repetitively utter a single word intoning it differently to convey some meaning like yes!, yes?, y..y..es ?.. Other manifestations of reduced verbal output are delay in initiation of a response, increased effort or apparent strain while generating the response, pauses in between words and sentences, interruption and word finding difficulties. The non-fluent speech in Broca's aphasics is also described as *'agrammatic'*. Grammar means rule based use of many 'function words' (conjunction, articles, prepositions, auxiliaries) to join 'content words' (nouns, verbs, adjectives) into phrases and sentences. Agrammatic speech shows absence or paucity of function words. The short phrases are composed of content words only. Meaning is conveyed somehow in a manner resembling 'telegraphic language' as if to economise on words.

Circumlocution is replacing the unavailable word with round about description. *Paraphasia* exists, when instead of a word to be generated (target-word), another word is used. The distortion in the abnormal response word may be phonemic (sound related) or semantic (meaning related). *Neologism* means sound utterance of words, which do not exist in the vocabulary of the language being used by the patient. *Jargon* is a string of expression (verbal or written), which does not convey any meaning. Many of the so-called 'words' in a jargon are neologisms. Some others may be true words but are used in a jumbled up way without any context and without any grammatical rules hence no information is carried.

A small but significant minority of aphasics has *fluent but empty* speech. It is contrasting and opposite to non-fluent agrammatic speech. It appears to be fluent, effortless, with normal melody, accent, prosody and mannerisms. On close observation, however, speech is not normal. Phrases and sentences are of normal length or sometimes overly lengthy without a sense of completion. There are many paraphasias, circumlocutions and abundance of function words or grammar words whose information load is low. The content words, which really carry information, are in paucity and used flouting the rules of

grammar. Jargon is common. Such patients have profound defects in auditory and reading compression. Classical example is Wernicke's aphasia.

Auditory Comprehension

Auditory comprehension is tested at one word level, sentence level and discourse level. At one word level the examiner speaks out the word at a slow and regular rate without repetition and asks the patient to point to corresponding picture or real object or body part. We should resist the temptation to act out the command ourselves. Patient's performance is scored in terms of correct answers with respect to help or cues and time latency.

Sentence level comprehension is tested by multiple step commands : 'fold this piece of paper and put into pocket', 'pick up the piece of cloth, put it into the glass and then invert the glass on the table'. Silly questions can be asked for which only yes or no answers are possible. Example: does the stone sink in water?, is elephant larger than an ant? A short story is narrated and questions are asked based on it.

Sentence level comprehension tasks also involve picture sentence matching. There can be one sentence and many picture choices or vice-versa.

Repetition

The examiner asks the patient to repeat after him words and sentences. Initial stimuli are simple, short, common, and later they are made long, hard to pronounce and uncommon. The patient may totally fail, remain mute or come out with wrong responses. The errors may be sound disorders, incomplete responses, deletions or paraphasias. Some patient may perform fairly well on tests of auditory comprehension and also do well during daily life but fail miserably on repeating simple words or phrases (conduction aphasia). In contrast patient with transcortical sensory and mixed aphasia repeat long complex phrases mechanically or slavishly but do not follow or extract a bit of meaning from whatever they are listening and repeating.

Naming

We begin with naming objects, pictures, body parts or persons. Examiner puts his finger on the object or photo and asks the patient to name it. Many patients with aphasia fail in different manner. Some may not come out with any response. There may be delay. The response word may be altered yet be related to target word either by sound (phonemic paraphasia) or by meaning (semantic paraphasia). The response word may be phonemic jargon (non word) or semantic jargon (dictionary word but totally unconnected). Some patients may describe the word in a round about way (circumlocution). Cues or helps can be given. Phonemic cue means, uttering first one or two phonemes of the word or producing its rhythm. Semantic cue involves giving hint about synonyms or attributes of that word. In case of persistent failure, the examiner then offers the answer in two ways:

- Suggesting a wrong answer and asking if it is correct or not.
- Suggesting the correct answer and again looking if patient accepts it or not. In patients with total disruption of semantic memory of lexicon or access to it the offered correct answers are not accepted.

The naming of objects can be made category-wise. Pictures or photographs of action verbs are one important category, others being colours, geometric figures, numbers, letters, body parts.

Reading

The subject is made to demonstrate ability to recognise, match and discriminate the graphic symbols of alphabets. Then he is asked to read aloud words, phrases or paragraph without paying attention to the meaning. Reading comprehension involves word-picture or word-object matching and carrying out some commands written on a paper (e.g. touch your hair, make a fist, etc.). Somewhat difficult task is to fill in the blanks in progressively difficult sentences from amongst a choice of detractors. Large paragraphs (unseen passage) are given to read and written questions are asked based on it. A mixed list of words and non-words is provided and patient is asked to separate them out.

Writing

If the motor dexterity of writing hand is fair it is expected that patient would be able to reproduce his premorbid handwriting, at least in such mechanical tasks like copying from written stimuli, writing to dictation and serial writing of automatised sequences (like name, address, numbers, alphabets, weekdays, months). But patients with non-fluent aphasia fail in written expression too. In addition to various aspects of non-fluency (reduced output, laborious start, pauses, agrammatism), the mechanics of writing and calligraphy are also distorted. Fluent aphasics may write legibly but the written output will exhibit similar deficits of emptiness, paraphasias, jargon, circumlocution, etc. Picture naming, object naming, describing the events going on in a painted or sketched scene are further tests of written expression.

CLASSIFICATION AND SYNDROMES

The classical aphasic syndromes have been grouped on the basis of speech and language performance in stroke survivors. Their distinction depends on the presence or absence of a constellation of speech behavioural aspects. The syndromes may be artefactual, arbitrary or artificial. New ways of classifying and describing aphasic phenotypes have been proposed. Yet they serve a useful purpose (**Table 2; Figures 1A to D and Figures 2A to D**). Diagnosing an aphasia syndrome may have localising value. Prognostication can be attempted on their bases.

Classification is a useful tool for summarising the patient's symptoms and for capturing some regularities of language disruption due to the anatomical peculiarities of the brain vessels. However, there is overlap and many aphasias are unclassifiable.

DIFFERENTIAL DIAGNOSIS OF APHASIA

Aphasia is an acquired disorder in a person who had attained certain degree of speech development. Hence *developmental disorders of speech* are not aphasia. Many children with brain damage (antenatal, perinatal, postnatal) and mental retardation learn speaking, reading and related skills late or incompletely or not at all. They are not aphasic.

A *developmental suppression of the motor fluency* of speech is very common. Stuttering or stammering is not a part of the

A

Clinical: Sparse, halting speech, often misarticulated, frequently missing function words and bound morphemes. Disturbance in speech planning and production mechanism.

Anatomy: Primary posterior aspects of the 3rd frontal convolution and adjacent inferior aspects of the precentral gyrus. Prerolandic branch of middle cerebral artery. A lesion restricted to classical Broca's area causes a mild reversible non-fluent aphasia. More severe and well known type of classical Broca's aphasia requires a much larger lesion surrounding regions other than Broca's area.

B

Clinical: Poor reading and auditory comprehension, fluent speech with phonemic, morphological and semantic paraphasias. Disturbance of permanent representations of the sound structures of words.

Anatomy: Posterior half of the 1st temporal gyrus and possibly adjacent cortex.Posterior temporal branch of left middle cerebral artery.

C

Clinical: Disruption of all language processing components and severe diminution or loss of all language.

Anatomy: Large portion of the peri-sylvian association cortex. Combined lesions involving Broca's and Wernicke's area. Infarction due to occlusion of stem of left MCA or internal carotid artery.

D

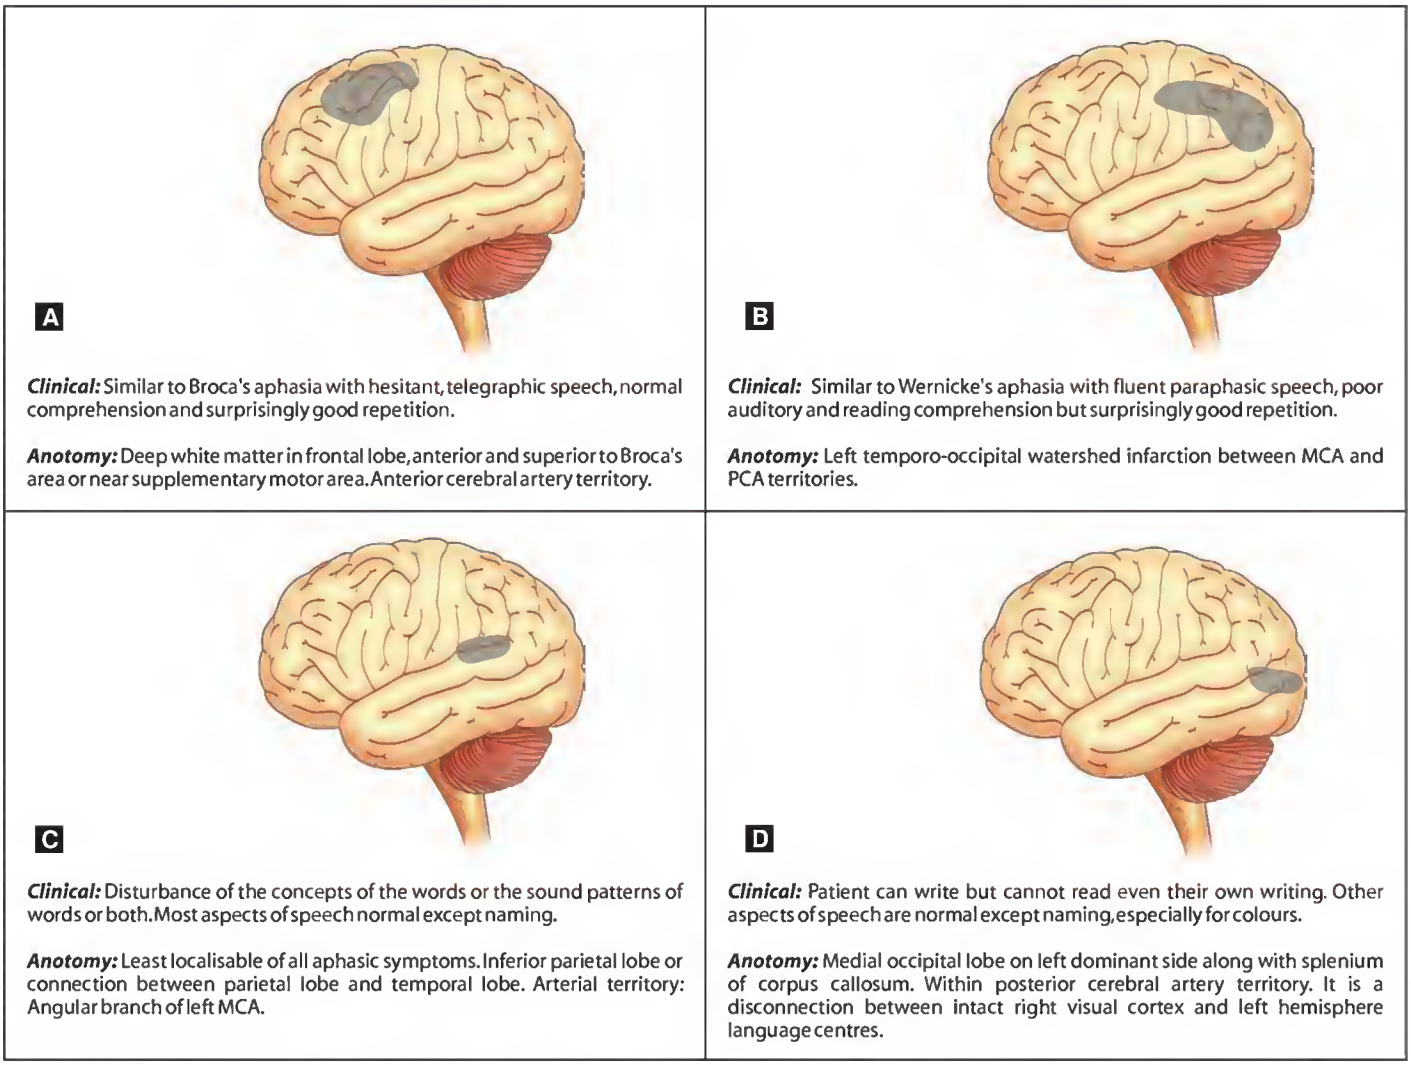
Clinical: Repetition is severely impaired out of proportion to verbal expression, fluency and comprehension, literal paraphasic errors are common with frequent attempts at self correction.

Anatomy: A disconnection between Wernicke's and Broca's area due to arcuate fasiculus, a white matter tract in deep temporal lobe. Also due to lesion in superior temporal or inferior parietal region.

Figures 1A to D: Various forms of aphasia and their neuroanatomical lesions (Peri-sylvian region). (A) Broca's aphasia; (B) Wernicke's aphasia; (C) Global's aphasia; (D) Conduction's aphasia.

aphasia rubric. Early damage to the function of hearing influences the development of speech and an extreme example is *congenital deaf-mutism*.

Pure dysarthria hampers the pronunciation and intelligibility of speech but language, vocabulary, grammar, reading, writing, and auditory comprehension are intact. In severe cases, hardly any sound emanates from the articulatory apparatus and results in *anarthria*. *Disorders of phonation* occur due to diseases of the larynx, vocal cord and respiratory weakness (no enough air during expiration).



In all the above conditions, the cortical areas concerned with cerebral organisation of linguistic functions are intact. Written expression (if the patient is literate) is normal while in aphasia written and verbal deficits almost always run parallel to each other. Auditory and/or reading comprehension are also normal while in patients with aphasia these are often abnormal.

Regression of normal acquired speech and communicative ability, and other cognitive functions occur in a group of *pervasive disorders in children* such as autism, Asperger syndrome and Rett syndrome. Landau-Kleifner syndrome in children is also a disorder of acquired aphasia and epilepsy.

Patients with *conversion reaction* may become mute, speak in whispers or in a bizarre, abnormal manner. Rarely, some patients may behave as if they are not able to listen or comprehend any speech. This should raise the possibility of *malingering* or *Munchausen syndrome*.

Speech in *psychosis*, particularly *schizophrenia* is sometimes confused with aphasia. Verbal or written output may be sparse or excessive, bizarre and absurd. Responses may sound like jargon or other less severe distortions described in oral expression. Flight of ideas, pressure of speech and evasive, tangential answers may create an impression of logorrhoeic speech or Wernicke's aphasia with defects in auditory comprehension. Howsoever absurd the thoughts and speech in a patient with schizophrenia, grammar and logic are largely retained, which is not the case in those with aphasia.

One of the important prerequisites for a definition of aphasia is a *state of normal alertness or sensorium* and normal intellectual or cognitive functions. It does not mean that the two cannot coexist but in such a situation it becomes difficult to decide about the relative contribution of each of them to the clinical deficit. Patients who are stuporouse, drowsy or have an acute confusional state or delirium may be labelled as aphasic due to

Figures 2A to D: Various forms of aphasia and their neuroanatomical lesions (peripheral to peri-sylvian region). (A) Transcortical motor; (B) Transcortical sensory; (C) Anomic; (D) Alexia without agraphia.

delayed and incorrect responses. Irrelevant muttering may be mistaken as fluent jargon or vice versa. Aphasic patients with defective auditory comprehension may be wrongly considered as having *hearing impairment*. Loss of the naming function in aphasia is commonly mistaken as *loss of memory*. The contrary may also be true. Patients with amnesia, dementia and Korasokoff psychosis may involuntary fill in the gaps in their memory and be diagnosed as suffering from anomic or Wernicke's aphasia.

A patient may fail to comply with a verbal command due to *motor apraxia* and not because of a defect in auditory comprehension. Visual or tactile *agnosia* may be responsible for a naming defect rather than aphasia.

Total loss of speech or *'mutism'* is a clinical situation caused by a very wide variety of disorders, aphasia being only one of them. Congenital deaf mutism is easily identified since early childhood. Patients with severe Broca's and global aphasia may be mute for many initial days to weeks. Anarthria and aphonia (laryngeal) may resemble muteness. Frontal lobe dysfunctions are known to cause akinetic mutism. Psychogenic syndromes (conversion or dissociative states, catatonia) can also render a person totally speechless for a variable period of time.

NEUROIMAGING IN APHASIA

Clinicoanatomical correlations between lesions depicted on imaging and the aphasia profile. In the majority of patients these are along expected lines. However, about 30% exhibit misfits such as non-fluent aphasias with retro-rolandic or posteriorly placed lesions, fluent aphasias with prerolandic or anterior lesions, instance of the lesion being present in an unexpected area, discrepancies between lesion size/volume and clinical severity of and recovery from aphaisa. The most probable explanation is inter-individual variations in the anatomical substrate for language functions in brain. Factors, such as handedness, dominance, age, sex, literacy and multilingualism, may play a role in the degree of bilateral representation and other anomalous organisation of speech function.

MRI has a high sensitivity and is better for three-dimensional volumetric analysis of various discrete areas of the brain. Functional neuroimaging (fMRI), PET, SPECT) techniques are now paving the way for defining discrete neural modules or networks (not areas or centres) concerned with cognitive functions such as speech. Well-defined linguistic tasks are performed by subjects while imaging study results are compared before, during and after the task.

NEUROLINGUISTICS AND COGNITIVE NEUROPSYCHOLOGY

Linguistic analysis refers to theoretical concepts such as phonology (sound patterns, phonemes, phonetic features), morphology (word formation, morphemes), syntax (rule-based grammar, function words), semantics (lexicon, dictionary words,

their meaning) and discourse (dyadic conversation, paragraphs, long speeches).

The classical anatomicoclinical approach provided knowledge about the relationship between lesion and function. Neuropsychologist found the existence of many selective deficits, suggesting that the brain is organised into distinctive systems or modules of relative functional independence.

Linguistically oriented aphasiologists are now keen to analyse the difficulties (faced by patients) in terms of the structure and systemic features that are disrupted or retained. Details are beyond scope of this book.

Neurolinguistics has also helped in speech therapy and rehabilitation. By more precise and detailed description of the language function of brain-damaged subjects, it is possible to plan novel re-educative strategies and to monitor the recovery if performance.

It is possible to examine in detail the linguistic performance of a subject and pinpoint the boxes or arrows in the diagram, where one thinks that the functional deficit is present. The tasks are simple and not too lengthy. They ingeniously make use of reading aloud and writing to dictation words and nonwords, regular and irregular words and exception words.

Prognosis

Prognosis depends upon aetiology and site and size of lesion. Aphasia due to stroke and head injury tends to improve steadily over a period of few weeks to many months. Younger age, female sex, non right-handedness and multilingualism may be good prognostic indicators. Type and severity of aphasia matters most. Global aphasia, severe Broca's and severe Wernicke's aphasia may not improve much. Aphasic syndromes due to disconnection (conduction aphasia, alexia without agraphia) tend to improve rapidly and often completely. Aphasic syndromes may evolve from one type into another, global into severe Broca's, Wernicke's, transcortical and conduction into anomic.

By around one and half year after stroke only about quarter of aphasics regain near normal speech function while double that proportion will still be having significant difficulty in communication.

Mortality in patients with aphasia due to stroke may be about twice as high as in those without aphasia. Cardiac embolism, atrial fibrillation and a larger volume of cerebral lesion are associated with a higher probability of aphasia as well as mortality. Possibly for the same reasons and due to the presence of aphasia itself, long-term functional recovery in survivors of stroke with aphasia is poorer compared to those without it.

Management, Speech Therapy and Rehabilitation

Therapy requires teamwork involving a neurologist, psychologist, speech therapist, social worker, linguist and the relatives and colleagues of the patient. Aims of all therapies for people with aphasia should be to improve their functioning in the real social world, to enable them to cope with barriers to participation.

Speech therapy is an interactive process and it is not a mechanical application of a predefined behaviour. During therapy patient must be an active participant.

Various methods of speech therapy can be grouped into two: those reducing specific impairment and those aiming for overall functional social gain. There is no contradiction between the two. In music, one practice scales not because a performance consists of playing scales, but because doing this develops skills that results in better performance.

The intensive phase of speech therapy usually lasts a couple of months. The frequency of sessions could be twice a week to twice per day, each session lasting for about an hour. Take-home exercises are also given, which should be carried out under the supervision of family members.

The methods of speech therapy and material used are tailored according to the individual patient's needs. Psycholinguistically based therapeutics is in its infancy, but some early reports are encouraging.

For patients with very severe aphasia, *pragmatics based approaches* are recommended which relate to analysis and repair of conversation in holistic sense. The therapist follows conversational coaching approach with the help of different themes or scripts, video taps and replay and turn taking.

It is difficult to evaluate the effectiveness of formal speech therapy because so many factors influence the recovery from aphasia. Yet in recent years, a few studies have supported the utility of speech therapy, as it satisfies the stringent criteria of evidence-based medicine. Training-induced plasticity in the brain during recovery from aphasia has now been documented with the help of PET scan. It shows significant activation of the non-dominant (right) hemisphere. It is a wrong question to ask whether speech therapy (in general) is effective for aphasic patients (in general)? The right question should be: which specific modes of speech therapy can be beneficial to which particular types of patients?

Technological advances have improved the quality of life of many patients with aphasia. Audiovisual augmentative methods of communication are now possible and affordable. Computers, multimedia, speech synthesisers, touch screens and special software are being used. Melodic intonation therapy and music therapy were reported to be useful for patients with non-fluent aphasia to convey meaning through variations in tone and accent, despite a very limited repertoire of vocabulary.

Drug therapy

Randomised controlled trials have been reported with dopamine agonists (brombocriptine), nootropics (piracetam) and cholinesterase inhibitors (donepezil). There is weak evidence in favour of a mild efficacy particularly in non-fluent aphasias.

Transcranial magnetic stimulation (TMS)

It has been reported to be useful in a few case reports on chronic global aphasics. The effects are long lasting. TMS may modulate activity in the surviving left and right hemispheric neural networks for naming.

THE INDIAN CONTEXT

The burden of aphasia and other disorders of speech and communication is high in developing countries including India, as can be judged from **Table 2**, listing various aetiologies. We

Table 2: Salient Features of Major Aphasic Syndromes

Type and Aphasia	Fluency (Oral, Written)	Comprehension (Listening, Reading)	Repetition	Naming
Broca's	Severely non-fluent	Normal or mildly affected	As severely impaired as fluency	As severely impaired as fluency
Wernicke's	Fluent but empty	Severely impaired	As impaired as comprehension	As impaired as comprehension
Global	Non-fluent	Severely impaired	Severely impaired	Severely impaired
Anomic	Fluent	Mildly affected	Mildly affected	Severely impaired
Conduction	Fluent or slightly non-fluent	Mildly affected or normal	Severely impaired	Normal or mildly impaired
Transcortical motor	Mildly non-fluent	Nearly normal or normal	Paradoxically normal	Moderately impaired
Transcortical sensory	Fluent	Severely impaired	Paradoxically normal	Severely impaired
Transcortical mixed (isolation of the language Zone)	Non-fluent	Severely impaired	Paradoxically better preserved	Severely impaired

Table 3: Community Burden of Aphasia and Other Disorders of Speech and Communication

S.No.	Disease Condition	Overall Burden	Percentage with Aphasia
1.	Stroke	Prevalence 0.5%	25%
2.	Head injury	Prevalence 1.2%	5% to 10 %
3.	Dementia	10% above the age of 60 years	Almost all have variable impairment of language functions depending on severity
4.	Mental retardation	5% (all) 1% (severe)	Almost all have variable impairment of language function depending on severity
5.	Learning disabilities (e.g. dyslexia)	5%	All have variable handicap in reading and writing skills
6.	Fluency and articulation disorders: Stuttering, stammering lisping, cluttering, lalling	1%	Variable handicap in all

Table 4: Contemporary Tests and Methods of Speech Assessment

Clinical bedside examination

Screening tests

Tests of specific aspects of language behaviour
- Boston naming test
- Peabody picture vocabulary tests
- Token test (Auditory comprehension)

Functional communication
- ASHA functional assessment
- Communication activities of daily living

Comprehensive examination
- Boston diagnostic aphasia
- Porch index of communicative ability (PICA)
- Psycholinguistic assessment of language processing in aphasia (PALPA)
- Western aphasia battery

Tests for special populations
- Infants and children
- Head trauma
- Right hemisphere lesions
- Elderly and dementia subjects
- Multilingual subjects

have higher proportion of younger patients as compared to developed countries. Only a few clinicians have been working in the field of aphasiology in India. No indigenous test battery in the Indian languages has been developed, which fulfills the stringent requirements of originality, sound theoretical basis and documented standardisation and validity. Some local adaptations of the Boston Diagnostic Aphasia Examination or Western Aphasia Battery are in use. Multilingualism and illiteracy are additional challenges.

There is a paucity of speech pathologists and therapists in India. Speech therapy is laborious, time-consuming and requires motivation on the part of patient as well as therapist. Positive results may not be forthcoming in a large proportion of patients.

Physicians should be familiar with the assessment required for aphasia and its therapy (**Table 4**). Clinicians will do well if they carry a pocket book of testing cards. The tools of speech assessment can be used for therapy to some extent.

There is great need for aphasia workbooks in the Indian languages, which can be given to patients for home exercises. Computer-based and web-based programms for diagnostic evaluation and therapeutic practices have to be created in the Indian languages.

20.7 Disorders of Cranial Nerves

Sankar Prasad Gorthi, Sundaram Venkatraman

There are twelve cranial nerves (CN I to XII) which pass to and from the brain through foramina and fissures in the bony skull. All these cranial nerves have their distribution in head and neck except cranial nerve X (the vagus) which extends down to supply other structures in the thorax and abdomen. Cranial nerves are either sensory, motor or mixed. CNs I, II, and VIII are purely sensory; CNs III, IV, VI, XI, and XII are purely motor; and the remainder are mixed. CNs III, VII, IX, and X have parasympathetic fibres. These cranial nerves have centrally situated nuclei in the brainstem. All cranial nerves (CNs) originate from the brainstem, except CNs I and II. The location of CNs III and IV nuclei are in the midbrain; CNs V, VI, VII, and VIII are in the pons; and CNs IX, X, XI, and XII are in the medulla.

Motor nuclei receive impulses from cerebral cortex through the corticobulbar fibres. These fibres originate from the precentral gyrus and descend through the corona radiata, genu of the internal capsule and reach cranial motor nuclei. Bilateral connections are present for all nuclei except for part of facial nucleus. For sensory neurons, the first order neuron cells are found in special ganglia or in sensory ganglia (Gasserian, Geniculate, etc.) or in sensory organs (nose, eye or ear). Cells in the cranial sensory nuclei are considered 2nd order neurons and their axons cross the midline to reach the thalamus. The thalamic outflow to primary sensory cortex constitutes the third order neuron.

The cranial nerves are different from the spinal nerves in that the myelin sheath surrounding them is derived from oligodendroglia whereas those for the spinal nerves are derived from the Schwann cells. Consequently, it is observed that disorders of peripheral myelin rarely affect the cranial nerves and vice versa. In addition, the cranial nerves are involved in several other disorders of the brain such as tumours, trauma, inflammation and vascular and congenital disorders. In the following section, we shall describe the cranial nerves and their disorders.

OLFACTORY NERVE

Olfactory function is very important for safety, nutrition and quality of life. Olfactory dysfunction is one of the earliest 'preclinical signs' of neurodegenerative diseases like Alzheimer's disease and Parkinson's disease.

Anatomy and Physiology

The olfactory system is made up of the olfactory neuroepithelium, olfactory bulbs, and tracts together with olfactory areas in the brain (temporal lobe and septal areas) and their connections with other brain centres. The olfactory neuroepithelium situated in the superior-posterior roof of the nasal cavity houses approximately six million bipolar olfactory receptor cells, their dendrites and also the initial part of the axons. These penetrate the cribriform plate of the ethmoid bone and enter the olfactory bulb. The axons leave the olfactory bulb and course posteriorly, as the olfactory tract in the olfactory sulcus. The olfactory tract divides into medial and lateral olfactory stria on either side of the anterior perforated substance. A small minority of the olfactory tract fibres decussate in the anterior commissure, while rest supply the ipsilateral pyriform lobe of temporal cortex and probably terminate in the amygdaloid and septal nuclei and the hypothalamus.

Clinical Evaluation of Smell

Olfactory dysfunction can be binasal or uninasal, can be complete or incomplete (Anosmia and Partial anosmia, Hyposmia, Microsmia). There may be olfactory distortions (parosmias) like dysosmia (rotten-egg like smell when sniffing a rose) or phantosmia (the presence of a smell when no stimulus is present) or olfactory agnosias (normal olfactory function but inability to process olfactory information in association cortex). Acute onset increased sensitivity to smell is hyperosmia.

Unilateral loss of smell, usually found on examination can be a helpful sign of focal neurological dysfunction. Such patients should be enquired about head trauma, recent upper respiratory tract infection, drug abuse, toxin exposure, smoking and alcohol use, seizures and radiation.

Causes of Disturbance of Olfactory Nerve

The causes of disturbances of smell are diverse (**Table 1**), but nasal and paranasal sinus disorders, upper respiratory tract disorders and head trauma account for most of them. Head trauma can cause direct damage to the olfactory bulb, olfactory nerve as it enters the skull, or direct cortical injury. Anosmia, usually bilateral, can be the first symptom of olfactory groove meningioma. Ageing, Parkinson's disease, Alzheimer's disease and Korsakoff's psychosis are important causes of hyposmia. Olfactory hallucinations occur in uncinate seizures, Alzheimer's disease, seizures, alcohol withdrawal, and depression.

Examination

Traditionally, the sense of smell is tested by asking the patient to sniff various non-irritating substances (coffee, oil of cloves and oil of peppermint), testing each nostril separately, while occluding the other nostril by a finger. Once patient detects odour, he is then asked to identify the smell (perception of smell is more important than identification of specific substance). Irritating substances are avoided as they simultaneously stimulate the trigeminal nerve fibres. University of Pennsylvania smell identification test (UPSIT) is an objective test in which 40 micro capsulated odorants with a forced choice of one of four alternative responses for each item is used.

OPTIC NERVE

The visual system consisting of both eyes and their connections to both the cerebral hemispheres accurately portrays the

environment and abstracts meaning from various items in environment. Both olfactory and optic nerves contain secondary sensory axons and are, in the true sense, tracts of central nervous system rather than a nerve.

Table 1: Causes of Dysfunction of Smell

Tumours	**Traumatic**
Olfactory groove meningioma	**Drugs/Toxins**
Frontal lobe glioma	Zinc
Deficiency states	Ciguatera fish poisoning
Vitamin B12	**Degenerative disorders**
Vascular	Alzheimer's disease
Anterior cerebral artery aneurysm	Parkinson's disease
Subarachnoid haemorrhage	Lewy body disease
Infection/Inflammation	**Systemic illness**
Creutzfeldt-Jakob's disease	Diabetes mellitus
Viral encephalitis	Renal failure
Meningitis	Turner syndrome
Kallmann's syndrome	Cushing syndrome
Leprosy	Epilepsy
Acute viral infection	**Others**
Sarcoidosis	Smoking
Rhino-sinusitis	Pregnancy
Bell's palsy	Ageing
Multiple sclerosis	Congenital or hereditary
Psychogenic	Albinism

Anatomy and Physiology

The optic nerve originates from nearly 1.2 million axons of the ganglion cells in the visual retina and travels postero-medially through the optic canal situated in the lesser wing of the sphenoid bone. At the posterior end of the optic canal optic nerves from both sides decussate to form the optic chiasma wherein one half of the axons cross the midline to join the uncrossed axons from the other eye to form the optic tract. This arrangement facilitates the left optic tract to carry visual information from the right half of the visual field and vice versa. The optic tracts encircle the cerebral peduncles on both sides to reach the lateral geniculate bodies of thalamus where few axons subserving the pupillary pathway separate and join the pretectal nucleus of midbrain. From the geniculate bodies the geniculocalcarine tract (optic radiation) reach its destination in the occipital cortex by forming the Meyer's loop anteriorly and lateral and superior to the inferior horn of lateral ventricle. From the primary visual cortex, integrated visual signals are processed in the visual association areas for interpretation and then conducted to the frontal eye fields to effect changes in visual fixation.

Cardinal Features of Optic Nerve Dysfunction

Optic nerve disorders lead to disturbance in the three chief components of vision-contrast, brightness and colour. Blurred and diminished vision suggests loss of axonal transmission. On the contrary, blurred and bright vision suggests refractory error. According to the division of optic nerve, the disorders affecting optic nerve can be divided into four groups as shown in **Table 2** and four tests are used to assess its functional integrity. In the evaluation of optic nerve the following are important: optic disc, visual acuity, colour vision (colour discrimination, and contrast sensitivity), visual fields and light reflex.

Table 2: Optic Nerve Characteristics of Various Parts and their Tests

Part of Optic Nerve	Length	Disorders	Test
Intra-ocular	1 to 2 mm	Papilloedema, anterior ischaemic optic neuropathy	Opthalmoscopy for abnormal fundus
Intra-orbital	25 to 30 mm	Thyroid opthalmopathy, optic nerve sheath meningioma	Visual acuity
Intra-canalicular	5 to 9 mm	Traumatic optic neuropathy	Visual acuity
Intra-cranial	9 to 10 mm	Pituitary tumours/ suprasellar masses	Visual fields

Papilloedema refers to swelling of the optic nerve associated with increased intra-cranial pressure. The elevated intra-cranial pressure is transmitted onto the optic nerve up to lamina cribrosa along the sleeve of the subarachnoid space leading to dilatation of retinal veins and hyperaemia. Inflammation of the optic nerve (optic neuritis) interferes with transmission of signals from retina to the occipital cortex and leads to visual blurring.

Visual defects can be classified as pre-chiasmatic, chiasmatic and post-chiasmatic. Pre-chiasmatic lesions always cause visual impairment in one eye unless the lesion is bilateral. Characteristically, chiasmatic lesions result in a bitemporal field defect as seen in pituitary tumours. Rarely, bilateral aneurysms of carotid arteries in the supra-clinoid portion can give rise to binasal field defect. The retro-chiasmatic lesions, on the other hand, give rise to a homonymous hemianopia which becomes congruous if they become closer to the occipital pole. In addition, if the lesion is in the temporal lobe in the optic radiation, the resultant field defect is upper quadrantic incongruous homonymous hemianopia. **Table 2** briefly reviews the aetiology of optic nerve diseases.

Pupillary Abnormalities

The afferent sensory signals are carried in the optic nerve to the Edinger-Westphal nucleus in the midbrain and the efferent motor signals are carried in the oculomotor nerve to the papillary constrictor muscles. The normal light reflex consists of constriction of ipsilateral as well as contralateral pupils on shining light into the eye. Inflammation of the optic nerve blocks transmission of optic signals in the afferent limb leading to poor direct and consensual papillary responses, called relative afferent pupillary defect (RAPD).

CRANIAL NERVES OCULOMOTOR TROCHLEAR AND ABDUCENS NERVES

The oculomotor nerve (CN III), trochlear nerve (CN IV) and abducens nerve (CN VI) are motor nerves of the eye ball. In addition, oculomotor nerve also provides parasympathetic innervation to the eye. Together, all these three nerves are responsible for all the eye movements.

Anatomy and Physiology

The oculomotor nerve originates from a paired nuclear complex in the periaqueductal midbrain. It is composed of several sub nuclei that innervate the following target structures in each eye:

medial rectus, inferior rectus, inferior oblique, levator palpebrae superioris, and the ciliary ganglion. Each subnucleus is paired and sends its projections ipsilaterally with two exceptions. Fibres supplying levator palpebrae superioris, initiate from cell bodies in the unpaired midline central caudal nucleus, and fibres innervating the superior rectus muscles originate from contra lateral superior rectus subnucleus. Parasympathetic preganglionic axons projecting to the ciliary ganglion originate from the Edinger-Westphal nuclei. Axons arising from oculomotor nuclei form fascicles that project anteriorly through midbrain to emerge from its ventral surface. They pass through the red nucleus and run adjacent to the substantia nigra and cerebral peduncle. The nerve travels between the superior cerebellar artery and posterior cerebral artery to enter the cavernous sinus. In subarachnoid space, the nerve lies adjacent to the posterior communicating artery and the tip of the basilar artery. Therefore, aneurysms of these arteries often compress the third nerve. In the wall of the cavernous sinus, it lies superiorly, adjacent to the fourth cranial nerve. As it emerges from the cavernous sinus, it passes through the superior orbital fissure and divides into superior and inferior branches. The superior branch innervates the superior rectus and levator palpebrae. The inferior branch innervates the inferior rectus, medial rectus, inferior oblique, and the ciliary ganglion.

The fourth nerve nucleus is located in the midbrain, inferior to the oculomotor nuclear complex and dorsal to the medial longitudinal fasciculus. The fascicles leave the nucleus and exit posteriorly and inferiorly from the most dorsal portion of midbrain after decussating in the superior medullary velum. It emerges from the brainstem at the level of inferior colliculus, runs anteriorly between the lateral midbrain and the tentorium cerebelli in the subarachnoid space and passes between the superior cerebellar and posterior cerebral arteries. Coursing around the cerebral peduncles, it enters the cavernous sinus, lying inferior to the third nerve and superior to the first division of the trigeminal nerve. From the cavernous sinus it enters the orbit through the superior orbital fissure and innervates the superior oblique muscle.

The abducens nerve nucleus is located in the floor of the fourth ventricle in the dorsal pons adjacent to the medial longitudinal fasciculus (MLF), the paramedian reticular formation, and the fascicles of the seventh nerve. The nucleus contains two populations of motor neurons, one population projects fibres to the ipsilateral lateral rectus muscle. The other group sends axons to the contralateral medial rectus via the medial longitudinal fasciculus. The nerve has a rather long course. After emerging from the caudal pons it courses superiorly along the clivus to the level of the petroclinoid (Gruber's) ligament. At this point it leaves the subarachnoid space, and enters Dorello's canal. It then travels ventrally and enters the cavernous sinus, lying adjacent to the carotid artery. It then enters the orbit through the superior orbital fissure to innervate the lateral rectus muscle.

Physiology of Eye Movements

The six extra-ocular muscles form three complimentary 'yoked' eye muscle pairs and induce eye movements. There are four major types of eye movements: saccades, pursuits, conjugate or vergent and disconjugate eye movements and these movements are executed by five neural mechanisms namely: the vestibulo-ocular reflex (VOR), optokinetic reflex (OKR), pursuit system, saccadic system, and vergence system. Conjugate eye movements are defined as movements of both eyes in the same direction by the same amount.

Vestibulo-ocular reflex maintains visual fixation during locomotion. Rapid eye movements are required to match the frequency of head rotation during locomotion. If the VOR is compromised, the visual acuity during locomotion is degraded significantly.

The optokinetic reflex generates a smooth pursuit movement that tracks a passing object for a distance and a saccade brings the eyes back to the neutral position. The VOR adapts rapidly but the OKR does not adapt rapidly. The OKR is mediated by the sensory signals originating in the retina which are conducted through the optic nerve to the pretectal region and further to vestibular nuclei and III, IV and VI CN nuclei.

Pursuit eye movements come into play in following a moving object against a stationary background. The extra striate visual cortex in the temporal lobe mediates the voluntary pursuits.

The saccadic eye movements facilitate rapid shifts of the fovea from one target to another to the tune of 900 degrees per second. The neural mechanisms controlling the saccadic eye-movements are the retinae, the somatosensory system and the auditory system that send signals to the superior colliculi in midbrain. The frontal eye fields and the superior colliculi project to the 'gaze centres' in the reticular formation of the brainstem especially interstitial nucleus of MLF for vertical gaze and the para pontine reticular formation (PPRF) for horizontal gaze. These in turn project to cranial nerve nuclei III, IV and VI.

The vergence system moves the eyes in the accommodation reflex wherein the eyes converge or diverge to perceive one image when attention is shifted from one object to another. For convergence, both the medial recti are activated and both lateral rectus muscles are inhibited. For divergence, vice versa is true. Vergence centre is not yet described.

Internuclear ophthalmoplegia (INO) is characterised by paresis of adduction in one eye and horizontal nystagmus in the contra lateral eye. Lesion in the MLF is on the side of the adducting eye. The palsy of medial rectus muscle can be either due to damage of lower motor neuron or due to MLF. If medial rectus muscle can be activated by convergence but not by lateral gaze then the lesion is likely in the MLF

Cardinal Features of Dysfunction

Lesions of these oculomotor nerves can be anywhere along their course from their nuclei in the brainstem to their target muscles in the orbit, with distinct clinical presentations. These sites can be nuclear, fascicular, subarachnoid space, cavernous sinus and orbit.

Nuclear lesions of the third (oculomotor nerve) can be complete or incomplete lesion depending upon the extent of the involvement. The classical presentation is bilateral ptosis, unilateral medial rectus paresis, and superior rectus paresis. Rostral lesions may spare the levator complex and dorsal lesions may spare the Edinger-Westphal nucleus. These commonly involve the nearby nuclei that are important for vertical conjugate gaze. Nuclear lesion of trochlear nerve (IV Cranial nerve) results in contralateral superior oblique weakness. Isolated fourth nerve

palsies due to nuclear lesions are rare. Associated findings include contralateral internuclear ophthalmoplegia, contralateral Horner's syndrome, and ipsilateral afferent pupillary defect.

Nuclear lesions of abducens nerve (VIth cranial nerve) nucleus produce conjugate, horizontal gaze palsy towards the side of the lesion. Other associated neurological signs include ipsilateral, peripheral seventh nerve palsy. Additional involvement of the MLF results in one-and-a-half syndrome, in which there is loss of conjugate gaze toward the side of the lesion (one), and impaired adduction with gaze away from the lesion (half). A combination of one-and-a-half syndrome with seventh nerve palsy is referred to as eight-and-a-half syndrome. Congenital abducens palsies are rare and they may be seen in association with other congenital anomalies. Möbius' syndrome is characterised by facial diplegia, and bilateral sixth nerve palsies. In Duane's congenital retraction syndrome there is impairment of abduction, variable impairment of adduction and narrowing of the palpebral fissure with co-contraction of the ipsilateral medial and lateral recti muscles.

Fascicular lesion is accompanied by neurological signs as the adjacent structures are commonly involved. In fascicular lesions of the third cranial nerve contralateral hemiparesis due to involvement of crus cerebri (Weber's syndrome), contralateral tremor due to involvement of red nucleus (Benedict's syndrome), and ipsilateral ataxia due to involvement of superior cerebellar peduncle (Nothnagel's syndrome) are some of the named syndromes. These lesions may spare the pupil, involve only a single division of the nerve, or result in isolated weakness of an individual muscle. Fascicular lesions of trochlear nerve are impossible to distinguish from nuclear lesions as the nerve travels a very short distance in the midbrain. Causes and associated findings are identical to nuclear lesions. Fascicular lesions of abducens nerve result in ipsilateral abduction dysfunction. A lesion in the anterior paramedian pons leads to a combination of ipsilateral facial nerve palsy, ipsilateral abduction deficit and contralateral hemiplegia, referred to as Millard-Gubler syndrome. Foville's syndrome is characterised by a combination of ipsilateral abducens and facial nerve palsies, loss of taste on anterior two-thirds of the tongue, ipsilateral Horner's syndrome, deafness, and trigeminal dysfunction. This is caused by infarction in the territory of anterior inferior cerebellar artery.

Lesion in subarachnoid space is varied and depends on the cause. Trochlear nerve in the subarachnoid space is most susceptible to injury because of its long intra-cranial course. Associated neurological signs often provide the clue to localisation. Abducens nerve lesion in subarachnoid space results in isolated abduction defect. A variety of mechanisms including ischaemia, mass lesions, trauma, meningitis, and elevated intra-cranial pressure may be responsible. Because of its unique course, the nerve may be pressed between the pons and basilar artery or clivus with increase in the intra-cranial pressure, or may get stretched along the edge of the temporal bone. Patients presenting with headache and sixth nerve palsy should be evaluated for raised intra-cranial pressure.

Lesions in the cavernous sinus and superior orbital fissure result in well described clinical syndromes like cavernous sinus syndrome and orbital fissure syndrome with features of combinations of cranial nerves III, IV and VI dysfunction. On occasion, oculosympathetic dysfunction is also observed. Exophthalmos, chemosis, and visual loss may be the other accompanying features. Sensory fibres from the opthalmic division of the fifth cranial nerve travel to join the third nerve in the lateral wall of the cavernous sinus. Hence lateral cavernous sinus lesions cause painful ophthalmoplegia and medial cavernous sinus lesions cause painless ophthalmoplegia.

Orbital lesions cause concerned cranial nerve lesion, optic neuropathy and proptosis. Orbital apex lesions of third cranial nerve result in involvement of either superior or inferior division. Superior division involvement causes ptosis and superior rectus weakness whereas inferior lesion causes weakness of inferior rectus and inferior oblique muscles. When vision is affected, the lesion is almost always in the orbital apex.

Clinical Evaluation

Oculomotor nerve assessment involves the assessment of i) eyelid position, ii) pupillary response to light, iii) extra-ocular movements, and iv) accommodation.

i. Levator palpebrae superioris muscle is responsible for lid elevation. Bilateral or unilateral drooping of the eyelids is encountered in damage to cranial nerve III. Normally, the eyelid should not drop over the pupil and eyelid position should be symmetrical on both sides.

ii. Pupillary light reflex is mediated by cranial nerve II in the afferent arc and by cranial nerve III (the parasympathetic fibres travelling in the oculomotor nerve) in the efferent arc. In the normal light reflex not only the ipsilateral pupil constricts in response to a focused beam of light but also the contralateral pupil (consensual response). If the afferent arc subserved by the optic nerve is intact but the efferent arc subserved by the oculomotor nerve is damaged then the ipsilateral pupil will not constrict but the contralateral pupil will. Pupillary dilatation and unresponsiveness occurs when the third nerve gets compressed due to an aneurysm. A normal pupil in the setting of complete third nerve palsy excludes an aneurysm. Conversely, an isolated pupillary paralysis without ptosis or opthalmoparesis is rarely caused by an aneurysm. Third nerve palsy with a normal pupillary sphincter and complete paralysis of EOM is most commonly caused by ischaemia especially associated with diabetes mellitus. All patients with ischaemic third nerve palsy improve within 4 weeks to 12 weeks of onset. Patients with complete third nerve palsy with normal pupil do not require neuroimaging if they are not progressing after the first week of onset. Patients with incomplete third nerve palsy with pupillary sparing require an MRI and or cerebral angiography to reveal an ICSOL, aneurysm, dural-cavernous sinus fistula or high grade stenosis.

iii. Cranial nerve III is assessed by observing adduction and vertical eye movements. Eye adduction is impaired because of medial rectus weakness. Weakness of inferior rectus, superior rectus and inferior oblique muscles affects the vertical eye movements.

iv. Accommodation reflex consists of convergence of eyes and pupillary constriction of both eyes. Patient's eyes converge and pupils constrict as the examiner's finger is brought from a distance towards the patient's nose.

The trochlear nerve assessment consists of assessment of direction of diplopia and head tilt. The most common cause of vertical diplopia is a fourth nerve palsy. A patient with unilateral fourth nerve palsy complains of binocular, vertical diplopia,

which worsens on down-gaze. As the superior oblique muscle depresses the eye in adduction and intorts the eye in abduction, examination of a case of trochlear nerve palsy reveals hyperdeviation on the side of the paretic muscle that is worse on down-gaze and adduction. The three step test (Parks-Bielschowsky) can be used to verify the fourth nerve palsy and is best applied with Maddox rod instruments. The three steps are: firstly, determine which eye is hyperdeviated in the primary position; secondly, measure the hyperdeviation in the lateral gaze; and thirdly, measure the hyperdeviation with head tilt. Thus, left fourth nerve palsy would result in a left hypertropia that is worse in right lateral gaze and with left head tilt.

Cranial nerves IV and VI are also tested along with cranial nerve III in the assessment of eye movements

Examination of Eye Movements

The combined action of medial rectus, superior rectus, inferior oblique (cranial nerve III) plus the superior oblique (IV) and lateral rectus (VI) muscle enables eye movements around the three axes of the eye: x, y and z. To examine eye movements draw a large 'H' in the air a few feet in front of the patient and ask him to follow your finger with his eyes in a smooth and co-ordinated fashion. The horizontal bar of 'H' will test the medial and lateral rectus muscles. The two vertical bars of the 'H' will test the motion of the superior and inferior rectus muscles and the inferior or superior oblique muscles.

Causes of Disturbance of Function

The nuclei of these three oculomotor nerves can be damaged by infection, tumour or demyelination. These nerves can become ischaemic (especially diabetes or hypertension). Meningeal infection, cerebellopontine angle tumours and mastoiditis can affect them. Carotid aneurysm, cavernous sinus thrombosis, inflammation or tumour can involve them in cavernous sinus thrombosis. Fractures of orbit or orbital tumours may involve these nerves in the superior orbital fissure. The various aetiologies can be classified into non-isolated palsies, traumatic palsies, congenital palsies, acquired non-traumatic palsies, and progressive or unresolved palsies. The various types of palsies, the corresponding clinical features, localisation of lesions and the suggested investigations are summarised in **Tables 3 and 4**.

TRIGEMINAL NERVE

This is a mixed nerve that provides sensory innervation to the face and mucous membranes of oronasal cavities and motor innervation to the muscles of mastication.

Anatomy and Physiology

The complex anatomy of trigeminal nerve extends from the peripheral nerve endings in face, sinuses, and meninges through the skull base, cavernous sinus (V1, V2 only), and trigeminal ganglion, to the intra-axial nuclei, tracts, thalamus and cerebral cortex.

Motor Portion (*Portio Minor*)

The motor nucleus is situated at the midpontine level. It receives its supranuclear control through corticobulbar fibres originating in the lower third of the precentral gyrus. These bilateral connections travel through the corona radiata, internal capsule and decussate in the pons to supply the motor nuclei.

The motor root exits from the motor nucleus, emerging from the pons anteromedial to the sensory root, passes through the posterior fossa, enters the Meckel's cave and leaves the skull via the foramen ovale. It then joins the mandibular division of the trigeminal nerve to form the mandibular nerve which supplies the muscles of mastication (masseter, temporalis and pterygoids). It also supplies tensor tympani, tensor veli palatini, mylohyoid and anterior belly of digastric muscles. The masseter, along with the temporalis and medial pterygoid muscles, closes the jaw. The lateral pterygoid, anterior bellies of the digastric and mylohyoid muscles, along with cervically innervated anterior neck muscles, work together to open the jaw. The lateral pterygoid muscles protrude the jaw and injury to one lateral pterygoid muscle causes the mandible to deviate towards the injured side.

Sensory Portion (*Portio Major*)

All the three divisions of the trigeminal nerve, ophthalmic, maxillary and mandibular join together at the trigeminal ganglion (the Gasserian ganglion) where most of the sensory cell bodies are located. Central processes of these neurons constitute the sensory root of the trigeminal nerve. These axons terminate by synapsing with second-order sensory neurons in the three major nuclear complexes within the trigeminal nucleus in the brainstem. The trigeminal nucleus extends caudally from midbrain into the spinal cord as far as the second cervical segment where it becomes continuous with the dorsal horn of the spinal cord. It has three sub nuclei: the mesencephalic nucleus, the pontine trigeminal (chief sensory, main, principal or superior) nucleus and the spinal nucleus of the trigeminal nerve.

There are two major sensory pathways that carry sensory information from face and sinuses to the cerebrum, namely: a) the discriminative touch pathway; and b) the pain and sensory pathway. The first order neurons carrying proprioceptive and tactile sensation carry information from specific areas of face and meninges to the pontine trigeminal nucleus. From this chief sensory nucleus second order neurons cross the midline in the trigeminothalamic tract and join the medial lemniscus enroute to the thalamus. The third order neurons from thalamus travel to the primary sensory cortex through the posterior limb of internal capsule and corona radiata.

The first order neurons carrying pain and temperature sensation enter the pons along with the central processes of the discriminative touch neurons. In pons, these sensory fibres descend as the spinal tract of the trigeminal nucleus to the caudal end of medulla and down up to the second cervical cord segment level. While descending, the spinal tract also gives off fibres to the nucleus of the spinal tract of the trigeminal nerve. This nucleus is divided into pars oralis (from midpons to inferior olive), a pars interpolaris (from rostral inferior olive to obex), and a pars caudalis (extends to the cervical spinal cord). The somatotopic arrangement of fibres within this nucleus gives rise to the onion-skin type of sensory loss over face. The spinal nucleus receives fibres that convey the sensations of pain and temperature from face and mucous membrane. The ascending fibres from this nucleus terminate in the thalamus. Axons of third-order neurons project to the appropriate regions of sensory cortex. The third sensory trigeminal nucleus, the mesencephalic nucleus, extends up to the superior colliculus. This receives proprioceptive impulses from masticatory muscles.

Table 3: Localisation of Lesions of Oculomotor Nerve, Trochlear Nerve and Abducens Nerve

Anatomic Localisation	Cause	Associated Symptoms			
		Oculomotor	Trochlear	Abducens	Investigations
Nuclear	Infarction, mass lesion, infection, inflammation, compression, Wernicke-Korsakoff syndrome	Bilateral ptosis, paresis of contralateral superior rectus, ataxia, abducens nerve palsy, nystagmus, altered mentation	Internuclear ophthalmoplegia, Horner's syndrome, afferent pupillary defect	Internuclear ophthalmoplegia, ipsilateral facial paresis ataxia, abducens palsy, nystagmus, altered mentation	MRI
Fascicular	Infarction, mass lesion, infection, inflammation, compression, demyelination	Contralateral hemiparesis, tremor, pupil may be spared	Internuclear ophthalmoplegia, Horner's syndrome, afferent pupillary defect	Ipsilateral facial paresis, contralateral hemiplegial, ipsilateral facial paresis, loss of taste, Horner's syndrome, trigeminal dysfunction, deafness	MRI
Subarachnoid space	Aneurysm Vasculopathic Meningitis Miller-Fisher syndrome Migraine Uncal herniation	Headache, stiff neck, pupil involved Pupil spared Headache, neck stiffness, other cranial nerve involvement Ataxia, areflexia Headache, positive family history, paediatric age group, early pupil involvement, altered mentation, ipsilateral hemiparesis	May be bilateral Usually isolated Contralateral hemiparesis or ipsilateral ataxia	Headache - usually isolated, contralateral hemiparesis, usually isolated papilloedema, petrous part of temporal bone - may be involved in mastoiditis, skull fracture, lateral sinus thrombosis, neoplasm Ipsilateral facial paresis, severe facial pain	MRI, MRA, Angiogram BP, sugar, ESR, CRP, CSF examination, MRI Nerve conduction study, CSF MRI, Urgent CT scan
Cavernous sinus	Neoplasm, fistula, thrombosis, Tolosa-Hunt syndrome, apoplexy	Pain, chemosis, proptosis, pupil involvement, ophthalmoplegia, sensory loss, bruit	Pain, chemosis, proptosis, pupil involved, ophthalmoplegia, trigeminal sensory loss		MRI, CSF, MRA
Superior orbital fissure	Neoplasm, infiltration	Superior division involvement (ptosis and superior rectus paresis)	Oculomotor, abducens, optic nerve dysfunction, proptosis		MRI
Neuro-muscular Junction		Pupils spared, frequent fluctuation, ptosis, ophthalmoparesis	Pupils spared, frequent fluctuation, ptosis, ophthalmoparesis	Pupils spared, frequent fluctuation, ptosis, ophthalmoparesis	Tensilon test and Repetitive nerve stimulation

The sensory and motor roots together form the trigeminal (Gasserian) ganglion in the Meckel's cave which lies near the cavernous sinus and internal carotid artery and gives rise to the three nerve trunks, i.e. ophthalmic division, maxillary division and mandibular division. The ophthalmic division lies in the lateral wall of cavernous sinus and enters the orbit with the third, fourth and sixth cranial nerves through the superior orbital fissure. Through numerous branches it supplies the skin of the nose, the upper eyelid, the forehead and scalp, upper half of cornea, paranasal sinuses, nasal cavity, lacrimal canal, conjunctiva, lacrimal gland, constrictor of pupil and ciliary muscle. The maxillary division enters the orbit through the inferior orbital fissure. It supplies the skin of lower eyelid, lateral nose, upper lip, cheek, lower cornea, conjunctiva and iris, palate, upper gum and teeth. The mandibular division supplies muscles of mastication (listed earlier) and skin of lower lip, lower jaw, chin, tympanic membrane, auditory meatus, upper part of ear and mucous membrane of the floor of the mouth and lower gums.

Trigeminal Reflexes

1. The corneal reflex is mediated by the afferent ciliary branch of the nasociliary nerve, its projections to bilateral facial nuclei, and facial nerve efferents.
2. The blink and lacrimal reflexes are mediated through the ophthalmic branch as the afferent arc and facial nerve as the efferent arc.
3. In the oculocardiac reflex, afferent input from pressure on the eyeball is carried via the ophthalmic branch to the efferent vagus nerve and leads to bradycardia.
4. The jaw jerk reflex is a muscle stretch reflex with afferent and efferent limbs both comprised of by the mandibular branch fibres.

The electrophysiological (EP) recording of the blink reflex, masseter inhibitory reflex, and jaw jerk reflex provides a means to evaluate the physiologic function of the trigeminal system. Patients with classical trigeminal neuralgia usually have normal or only mildly abnormal trigeminal reflexes, whereas those with symptomatic trigeminal neuralgia typically have reflex abnormalities.

Clinical Evaluation

Sensory evaluation

Exteroceptive sensations (touch, pain, temperature) are tested on the face, testing each division separately, comparing it with the opposite side. Lesions distal to Gasserian ganglion result in sensory loss in the territory of the individual branch, while lesions at or proximal to Gasserian ganglion cause ipsilateral loss over face. Lesions within the brainstem may result in onion-skin pattern of sensory loss. Presence of dissociated sensory loss over the face characterises lesions affecting the spinal tract and nucleus of the trigeminal nerve and differentiates it from lesion affecting the main sensory nucleus.

Table 4: Types of Palsies of Oculomotor Nerves (Cranial Nerves III, IV and VI)

Types of Palsy	Oculomotor	Trochlear	Abducens
Type 1: Non-isolated	Third nerve palsy is considered nonisolated in the presence of the following features: 1. Orbital disease 2. Myasthenia gravis 3. Multiple cranial nerve palsies (including bilateral third nerve palsy) or radiculopathy 4. Brainstem signs (e.g. hemiplegia, cerebellar signs, other cranial nerve deficits) 5. Systemic, infectious, or inflammatory risk factors for third nerve palsy (e.g. history of previous malignancy, giant cell arteritis, collagen vascular disease) 6. Severe headache	Fourth nerve palsies are considered non-isolated in the presence of the following features: 1. Other neurologic or neuro-ophthalmological signs 2. Evidence to suggest myasthenia gravis such as ptosis, or fatiguability of the of the motility deficit 3. Evidence for systemic inflammatory disorders such as giant cell arteritis	Sixth nerve palsies are considered non-isolated in the presence of the following features: 1. Other neurologic or neuro-ophthalmological signs 2. Evidence to suggest myasthenia gravis such as ptosis, or fatiguability motility deficit 3. Evidence for systemic inflammatory disorders such as giant cell arteritis
Type 2: Traumatic	A clear temporal relationship to significant previous head trauma and no progression	Isolated, unilateral, or bilateral fourth nerve palsies, which have a clearly established temporal relationship to previous head trauma and do not progress, are considered traumatic in origin. Patients have no neurologic deficits other than those associated with the initial traumatic event	Isolated unilateral sixth nerve palsy, which has a clearly established temporal relationship to significant previous head trauma and does not progress, is considered traumatic in origin
Type 3: Congenital	Patient born with an isolated third nerve palsy or noted to have a third nerve palsy within the first 3 months of life	Congenital fourth nerve palsy, in addition to the features described above for fourth nerve palsy in general, may show the following: 1. Large vertical fusional amplitudes (greater than 6 to 8 prism diopters) 2. Facial asymmetry or sternocleidomastoid muscle hypertrophy 3. Long-standing anomalous head position that may be present in old photographs	Patients born with sixth nerve palsy or noted to have a sixth nerve palsy within the first 3 months of life
Type 4: Acquired, Nontraumatic isolated palsy	Type A: Third nerve palsy with a normal pupillary sphincter with completely palsied extra-ocular muscles Type B: Third nerve palsy with normal pupillary sphincter and in completely palsied extra-ocular muscles Type C: Third nerve palsy with subnormal pupillary sphincter dysfunction and partial or complete extra-ocular muscle palsies	Vasculopathic fourth nerve palsy occurs in patients greater than 50 years of age with or without known hypertension or diabetes, or in younger patients with known vasculopathic risk factors. Patients without vasculopathic risk factors and not classified as any of the above has non-vasculopathic fourth nerve palsies	Vasculopathic sixth nerve palsy occurs in patients older than age 55 or those with known vasculopathic risk factors (e.g. hypertension or diabetes). Patients without vasculopathic risk factors defined above are considered to have non-vasculopathic sixth nerve palsy
Type 5: Progressive or Unresolved Palsy	Patients with third nerve palsy that worsen acute stage (>2 weeks) or who develop new neurologic findings are considered to have progressive third nerve palsy. Patients without resolution of third nerve palsy after 12 to 16 considered unresolved	Fourth nerve palsies that worsen after the acute stage (greater than 1 week) as defined by a significant in the measured ocular vertical deviation are considered to be progressive, and patients without improvement in the measured ocular vertical deviation after 6 to 8 weeks are considered unresolved	Sixth nerve palsy that worsens after the acute stage (>2 weeks) as defined by a significant increase in the measured ocular deviation or a new neurologic finding develops is considered progressive or non-isolated. Patients without resolution in the measured horizontal deviation after 12 to 16 weeks are considered unresolved
Type 6: Cranial nerve palsy with signs of aberrant regeneration			

Motor evaluation

A lesion of this part results in weakness and wasting of muscles of mastication; other muscles are difficult to examine.

Reflex evaluation

Corneal reflex and jaw jerk are important reflexes conveyed by the trigeminal nerve. Blink reflex and corneomandibular reflex are partly carried by the trigeminal nerve.

Cardinal Features of Dysfunction

Nuclear lesions of trigeminal nerve

Nuclear lesions affect other brainstem structures as well and are diagnosed by 'the company they keep'. Hemiparesis (due to involvement of basis pontis), contralateral sensory loss (due to spinothalamic tract involvement), ipsilateral tremor (due to involvement of brachium conjunctivum), internuclear ophthalmoplegia (due to involvement of medial longitudinal fasciculus), Horner's syndrome (due to involvement of the descending sympathetic fibres) are some of the common findings pointing at a lesion in the brainstem. Infarction, small brainstem haemorrhage, demyelination, metastatic tumours, arteriovenous malformations, syringobulbia can cause nuclear lesions. Lateral medullary syndrome characteristically affects the spinal nucleus, while lesions of mesencephalic nucleus cause apparently no neurological dysfunction except a depression of jaw jerk.

Preganglionic trigeminal nerve lesion

Common causes of lesion at this site are tumours (meningioma, Schwannoma, and metastasis), meningitis (infectious, inflammatory, and carcinomatous), trauma, and aneurysm. Cerebellopontine angle tumours involve the trigeminal nerve roots by extension of the pathological process and cause ipsilateral facial pain, paresis of masseter, paraesthesia, depressed corneal reflex, tinnitus, deafness and ataxia. Rarely nystagmus, facial and other lower cranial nerves involvement may be associated. Trigeminal neuralgia is characterised by sudden, excruciating, lancinating, usually unilateral and paroxysmal pain, often in maxillary or mandibular divisions. It is more common in females, especially older ones and is slightly more common on the right side. Pain usually lasts for a few seconds, may recur several times a day and is triggered by nociceptive facial stimulation. Many cases are probably due to compression or irritation of the entry of trigeminal nerve roots (aberrant vessel, demyelinating plaque, infarction, and tumour).

Lesions of the Gasserian Ganglion

This leads to severe, paroxysmal, usually hemifacial (sparing the angle of mandible) paraesthesia and pain. Vascular malformations, tumour, infections, granulomas are some of the common causes. Sjögren's syndrome, rheumatoid arthritis, SLE and dermatomyositis can cause bilateral sensory trigeminal neuropathy.

Lesions in Middle Cranial Fossa

Variable degree of trigeminal involvement is seen in middle cranial fossa lesions; Gradenigo's syndrome (ophthalmic division and abducens nerve involvement, usually secondary to otitis media), cavernous sinus and superior orbital fissure syndromes are some of the common causes.

FACIAL NERVE

Anatomy and Physiology

This nerve is motor nerve to the mimetic muscles of the face. It also has secretory fibres to the salivary and lacrimal glands and mucous membrane of the oral and nasal cavities. In addition, there are somatic pain fibres from the external auditory canal and a small strip of skin between the mastoid process and pinna and taste fibres from the ipsilateral anterior two-thirds of the tongue. Seventy per cent of the facial nerve fibres arise from the motor neurons of the facial nucleus, the remaining 30% are mixed sensory and autonomic fibres forming nervus intermedius. The motor nucleus is located in the ventrolateral portion of the caudal pons. Fibres course medially, curving around the sixth nerve nucleus, forming the facial colliculus in the floor of the fourth ventricle. It makes its exit from the lower part of pons between the olive and restiform body. Fibres for voluntary and reflexive facial movements are different. The sensory root (nervus intermedius of Wrisberg) contains bipolar neurons in geniculate ganglion, the distal axons of which supply taste fibres to the anterior two-thirds of the tongue and the proximal axons terminate in the nucleus solitarius. Visceral fibres from superior salivatory nuclei course in nervus intermedius and course along the greater superficial petrosal nerve to synapse in the sphenopalatine ganglion. The postganglionic fibres from sphenopalatine ganglion, in turn, supply lacrimal and palatine glands. After leaving the pons, motor and sensory roots course in the cerebellopontine angle for about 24 mm, entering the internal auditory canal where it lies anterosuperior to the vestibulocochlear nerve. From the internal auditory canal to the stylomastoid foramen, the facial nerve has a tortuous course which is nearly 33 mm long. Facial nerve has six segments; intra-cranial (24 mm), in the internal auditory canal, labyrinthine, tympanic (12 mm), mastoid (15 mm to 20 mm), and intraparotid. After it leaves the internal auditory canal, the facial nerve travels the fallopian canal (labyrinthine segment), running at a right angle to the petrous pyramid. Here the nerve is most susceptible to vascular and traumatic insults. The tympanic portion courses behind the cochlea and semicircular canal and ends at the beginning of the stylomastoid segment. Stylomastoid segment gives branches to stapedius muscle and the chorda tympani. Facial nerve exits through the stylomastoid foramen entering the parotid gland where it divides in upper and lower trunks. Upper trunk gives rise to frontal, zygomatic and buccal branches. Lower trunk has mandibular and cervical branches. Upper face has bilateral representation, while the lower face has contralateral representation.

Causes of Facial Nerve Lesion

Congenital

This is frequently associated with other birth defects including limb deformity, pectoral aplasia, microtia and external auditory canal atresia. Craniofacial syndrome and Möbius' syndrome are some of the examples of congenital facial palsies.

Toxins

Thalidomide embryopathy causes peripheral facial palsy. Exposure to chlorocresol and ethylene glycol may cause facial palsy.

Traumatic

Peripheral facial palsy in the context of trauma should raise suspicion of basilar skull fracture. Sphenoid electrode insertion for long term video EEG monitoring can cause facial palsy in about 20% cases.

Pregnancy

Facial palsy occurs three times more often in pregnant women as compared to non-pregnant women. Most cases of facial palsy occur in the third trimester. Neonatal outcome is unaffected.

Bilateral facial palsy

Guillain-Barre syndrome, Lyme's disease, sarcoidosis, HIV seroconversion phase, acute lymphoblastic leukaemia, CIDP and leprosy are some of the common causes of bilateral facial palsy.

Bell's palsy

It is an acute, acquired, nontraumatic, unilateral, infranuclear facial palsy. There is flaccid paresis of all facial mimetic muscles on the involved side. Affected side is smooth, the brow droops, and the cheek balloons on expiration. There is lagophthalmos and Bell's phenomenon (on attempted closure, the globe turns

up and out). Lower lid is everted with excess tearing. Various facial reflexes are lost. Lesions proximal to the geniculate ganglion affect taste sensation, lacrimation and stapedial reflex, while distal lesions cause only muscle weakness. Bell's palsy is most common in the third decade; it's incidence in the general population is about 20 cases per 1, 00,000 population. A typical patient complains of facial palsy which evolves over 24 to 48 hours, preceded by retroauricular pain. Herpes simplex virus is often blamed as the culprit. About 80% to 85% patients recover completely within three months.

Clinical Testing

Assessment of facial nerve involves five important functions: (1) functions of facial expression; (2) taste function with sugar or salt solution. Protruded tongue is touched using a stick soaked in sugar or salt solutions on one side, and patient was asked to point out at the appropriate taste written on paper before he returns his tongue into mouth. Rinsing with water between testing two different applications is a must; (3) somatic sensation from the external ear; (4) function of Stapedius muscle (hyperacusis); (5) secretomotor innervation of the lacrimal and salivary glands (Schirmer's test).

VESTIBULOCOCHLEAR NERVE

Anatomy and Physiology

The nerve is unique in that it subserves two entirely distinct sensory functions, i.e. hearing (cochlear component) and balance (vestibular component). The acoustic and vestibular systems via the eighth nerve and their diverse central connections in the brainstem, cerebellum, reticular formation, and cortex allow localisation and interpretation of the body with respect to gravity, motion, and posture. The sensory receptors for both components of cranial nerve VIII are hair cells and they are situated on the inner wall of the membranous labyrinth, which is a coiled delicate tubular structure containing endolymph. The membranous labyrinth lies inside the bony labyrinth which consists of interconnected tunnels within the petrous temporal bone.

The hair cells of the vestibular apparatus and cochlea are connected through the primary sensory neurons to the nerve cell bodies in the Scarpa's (vestibular) and spiral ganglia respectively. The central processes form the eighth cranial nerve that travels through the internal auditory meatus accompanied by the VII cranial nerve and enters medulla at its junction with pons.

The Vestibular System

The vestibular apparatus consists of the utricle, the saccule, and the three semicircular canals. Fibres are projected to the vestibular nuclei, which lie in the floor of the fourth ventricle. These nuclei consist of four separate nuclear groups viz. superior, lateral nucleus of Deiter, the medial nucleus of Schwalbe, and the descending nucleus. The superior and medial vestibular nuclei receive efferent fibres primarily from the cristae and cerebellum. Cerebellar afferents primarily synapse on the lateral vestibular nucleus.

The Cochlear System

The cell bodies of the afferent auditory neurons lie in the spiral ganglion in Rosenthal's canal, which follows the pathway of the bony spiral shelf from the apex of the cochlea towards its base. The fibres are arranged in a tonotopic manner throughout their extent till the brainstem. The cells synapse with the inner hair cells of organ of Corti. The cochlear efferent supply originates in the superior olivary complex of brainstem. The fibres of the auditory nerve bifurcate in the brainstem, and enter both the dorsal and ventral cochlear nuclei. From here, fibres are projected tonotopically, via the three striae, to inferior colliculus, medial geniculate body and auditory cortex.

Clinical Evaluation

Specialised books should be consulted for a detailed account of the following tests.

1. Function of vestibular nerve is assessed by examination of eye and postural movements. It is important to assess movements of all extraocular muscles and look carefully for nystagmus.
2. Caloric test: A caloric test can be conducted by irrigation of the external auditory canal with warm (44°C) and cold water (30°C). The head has to be elevated and should form an angle of 30 degrees from the horizontal plane, irrigation should be done for 20 seconds and after a latent period of 1.5 minutes to 2 minutes nystagmus is observed which is towards the opposite side with cold water irrigation and towards the same side after irrigation with warm water (COWS—cold opposite and warm same side).
3. Hearing test: Rinne's and Weber'.
4. Electro-oculography (EOG).
5. Electronystagmography.
6. Computerised dynamic positionography.
7. Auditory function: Pure tone audiometry, speech audiometry, tympanometry, BAER, etc.

Sensorineural Deafness

This term refers to a deficit in perceiving either tones or speech that is due to a lesion central to the oval window. This is therefore due to lesion of cochlea (sensory), cochlear nerve, nuclei (neural), or the central auditory pathways.

Tinnitus

Tinnitus and head noises are common complains which bring a patient to audiologists and otolaryngologists. The patient experiencing tinnitus may describe the sound as ringing, roaring, hissing, whistling, and rustling.

Vertigo

Vertigo refers to hallucination of movement. The most common complaint is of dizziness, a term that represents a wide range of symptoms. Peripheral causes of vertigo are peripheral vestibulopathy (labyrinthitis, vestibular neuronitis), benign positional vertigo, post-traumatic vertigo, vestibulotoxic drug-induced vertigo, Meniere's disease, other focal peripheral diseases (e.g. bacterial infections, degeneration of hair cells, genetic anomalies of labyrinth, cupulolithiasis, tumours of eighth nerve, otosclerosis, fistula of labyrinth and rarely focal ischaemia etc.).

GLOSSOPHARYNGEAL AND VAGUS NERVES

Glossopharyngeal nerve carries visceral and general sensation from the pharynx, carries subconscious sensation from the carotid sinus and body, and innervates the stylopharyngeus

muscle and the parotid gland. Vagus nerve carries visceral sensation from the larynx, pharynx, and thoracic and abdominal viscera and sends motor signals to pharyngeal, laryngeal and visceral muscles. Both these nerves mediate the complex interplay between upper aero-digestive tract functions. Dysfunction of these two nerves may lead to dysphagia, dysphonia, dyspnoea, or a combination of these symptoms.

Anatomy and Physiology

The glossopharyngeal nerve is comprised of general somatic afferent, general visceral efferent, special visceral afferent, and parasympathetic fibres that supply the tongue and pharynx.

The vagus nerve contains motor, sensory, and parasympathetic fibres. It emerges from the posterolateral sulcus of the medulla, in close association with the glossopharyngeal nerve.

Clinical Evaluation

Motor function

Pure glossopharyngeal motor paralysis may be negligible. Mild dysphagia may occur and the palatal arch may be somewhat lower on the affected side. The striated muscles of the pharynx, soft palate, and larynx are innervated by the vagus nerve. The soft palate and the uvula are examined at rest and with phonation. Pharyngeal function is evaluated by noting the character of the voice, ease of respiration and cough, and observing pharyngeal contractions during phonation. Unilateral palsy results in ipsilateral flattening of the palatal arch on phonation, ipsilateral palate fails to elevate, and uvula is retracted to the nonparalysed side. Nasal twang to speech and dysphagia may occur. Ipsilateral cord may assume cadaveric position. With bilateral vagal lesions, the palate droops bilaterally with no palatal movement on phonation. Voice is of nasal quality. There is profound dysphagia, more for liquids. Nasal regurgitation and respiratory embarrassment are other features.

Sensory function

In glossopharyngeal nerve dysfunction assessment, taste sensation is tested over posterior third of the tongue and is lost ipsilaterally in nerve lesions. Pain and soft touch is ipsilaterally lost over posterior third of the tongue, soft palate, tonsils and pharyngeal region. The vagus nerve sensory dysfunction cannot be tested adequately, as the area of supply overlaps with other cranial nerves, and some of the structures are inaccessible.

Reflex function

Pharyngeal and palatal reflexes are absent on the side of the lesion. In cases of vagus nerve dysfunction, ipsilateral gag reflex is depressed as the efferent fibres are carried in the vagus nerve.

The gag reflex prevents the entry of foreign objects into the alimentary and respiratory passages. Both cranial nerves IX and X are assessed by testing the gag reflex. The right and left side of the pharynx should be lightly touched with a tongue depressor. The IX nerve acts as the sensory afferent and the X nerve as the motor efferent.

LESIONS OF THE IX AND X NERVES

Nuclear and Intramedullary Lesions

This may occur in syringobulbia, demyelination, vascular disease, motor neuron disease and malignancy. These lesions cause involvement of other cranial nerves and brainstem structures.

Extramedullary Lesions

Cerebellopontine angle syndromes: Acoustic tumours may involve the nerve here. The involvement is associated with tinnitus, deafness, and vertigo. Lesions within the posterior fossa like primary or metastatic tumours, infections, carcinomatous meningitis, sarcoidosis and Guillain-Barre syndrome are some of the causes of lower cranial nerve dysfunction.

Jugular Foramen (Vernet's) Syndrome

This syndrome consists of ipsilateral sternomastoid and trapezius weakness, dysphonia, dysphagia, impaired gag reflex, palatal droop and vocal cord paresis on the affected side, with loss of sensation over the posterior tongue and palate. Unilateral, dull aching pain, localised behind the ear is often associated. Glomus jugulare tumours, skull base fractures, and metastasis can involve the glossopharyngeal, vagus, and accessory nerves which travel through this foramen.

Lesions within the Retropharyngeal and Retroparotid Space

Neoplasms, vascular compression, abscesses, adenopathy, trauma can involve the nerve in these spaces. This results in Collet-Sicard's syndrome (involvement of 9th, 10th, 11th, and 12th cranial nerves) and Villaret's syndrome (involvement of 9th, 10th, 11th, and 12th cranial nerves, sympathetic chain and occasionally 7th cranial nerve).

Lesions of the Vagus Nerve

Tumours, aneurysms, trauma and enlarged lymph nodes can injure the vagus nerve in the neck and in the thorax. This results in complete vocal cord paralysis with unilateral pharyngeal anaesthesia.

Lesions of the Superior Laryngeal Nerve

Trauma, surgery, and tumour may damage this nerve. This results in mild hoarseness of voice.

Lesions of the Recurrent Laryngeal Nerve

Aneurysm, enlarged lymph nodes, mediastinal lymph nodes and surgical intervention can damage this nerve, more so on the left side. Unilateral insult causes transient hoarseness of voice, while bilateral palsy results in severe bilateral approximation of the cord resulting in airway limitation, stridor, and severe limitation of voice.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is characterised by severe sharp, lancinating pain in the region of the tonsil, radiating to the ear. Patient usually describes an abrupt pain in the throat or ear that lasts for a few seconds and is triggered by chewing, swallowing, yawning etc.; occasionally the pain may be associated with syncope (bradycardia and hypotension causing the fall). This is often idiopathic, and occasionally tumour, vascular compression, trauma and demyelination may cause this syndrome.

ACCESSORY NERVE

The spinal accessory nerve, primarily a motor nerve, innervates two major muscles, the sternocleidomastoid and the trapezius, in the neck and back. The lower motor neuron cell bodies are located within the rostral spinal cord. The accessory nucleus is a column of cells located in the anterolateral grey area of

the upper cervical spinal cord segments, which anatomically correlate the location of the nucleus ambiguous above and the dorsolateral part of the ventral horn of the spinal cord below.

Clinical Evaluation

Sternomastoid muscle

This muscle flexes the head and turns it from side to side. When one muscle contracts, the head is rotated and drawn to the ipsilateral shoulder so that the occiput is pulled toward the side of the contracting muscle. When both sternomastoids contract simultaneously, it results in flexion of neck.

Trapezius muscle

The muscle retracts the head and also elevates, rotates and retracts the scapula. It also assists in raising the abducted arm above the horizontal.

HYPOGLOSSAL NERVE

Anatomy and Physiology

The hypoglossal nerve is the motor nerve of the tongue. Its fibres arise from the hypoglossal nucleus, situated in the paramedian medulla, beneath the hypoglossal trigone of the floor of the fourth ventricle.

Clinical Evaluation

Observe the tongue at rest, after protrusion, and assess the strength while the tip of tongue is pushed against the cheek and rapidity of tongue movements. Unilateral lower motor neuron lesions cause paresis, atrophy, furrowing, and fasciculation. The tongue deviates to the paretic side on protrusion due to unopposed action of the normal contralateral genioglossus muscle. Dysphagia and dysarthria are minimal. Protrusion of tongue requires the action of the extrinsic muscles, whereas lateral movements of the nonprotruded tongue are accomplished by the intrinsic muscles. Bilateral lower motor neuron lesions of the tongue result in bilateral atrophy, weakness and fasciculation. The tongue cannot be protruded voluntarily. Marked dysarthria, dysphagia, and breathing difficulties may be associated.

20.8 Ischaemic Cerebrovascular Diseases

PM Dalal

INTRODUCTION

'Stroke' is defined as rapid onset of focal neurological deficit, resulting from diseases of the cerebral vasculature and its contents. The term 'transient ischaemic attacks' (TIA) implies complete recovery of such a deficit within 24 hours. Cerebral or subarachnoid haemorrhage is consequent to rupture through some acquired or inherent weakness of the vessel wall (see chapter on Haemorrhagic Cerebrovascular Diseases). Stroke represents third most common cause of death in developed nations. For India, community surveys have shown a crude prevalence rate for 'hemiplegia' in the range of 200 per 100,000 persons, nearly 1.5% of all urban hospital admissions, 4.5% of all medical and around 20% of neurological cases.

PATHOGENESIS

The normal functions of the brain are dependent upon a relatively constant supply of oxygen and glucose derived from the blood perfusing it (55 mL to 70 mL of blood/100 g of brain/min). The principal source of energy is almost exclusively oxidation of glucose. If the blood flow is critically reduced below 15 mL/100 g/min, the resulting ischaemia with hypoxia, when sufficiently prolonged, may cause death of neurons and glia (cerebral infarction).

The mean arterial blood pressure, cerebrovascular tissue resistance, local metabolic products (pH, PaO_2, $PaCO_2$), together with several known and unknown factors, help to maintain the critical threshold of blood flow for energy metabolism. Furthermore, the blood flow varies in different areas of the brain and a self-regulatory mechanism ('autoregulation') determines the regional flow to meet local metabolic needs.

In regions of cerebral ischaemia, there is 'paralysis of autoregulation' and the microvasculature is non-reactive to pressure changes, to vasoactive agents and to other forms of stimuli. The cerebral vasculature in this ischaemic zone becomes permeable to protein and fluid leaks in the vicinity (extracellular cerebral oedema). Such vascular events also lead to local haemoconcentration and vascular stasis.

To protect the brain from ischaemia, several collateral pathways exist. The four major extra-cranial arteries (carotid and vertebral arteries) form good-calibre, low-resistance anastomoses at the base of brain ('Circle of Willis'). In addition, extra-cranial anastomoses exist between the cervical branches of the ipsilateral external carotid, subclavian and vertebral arteries. Such arterial anastomoses help to maintain cerebral blood supply even with occlusion of major extra-cranial arteries or various intra-cerebral arteries. These post-Willisian anastomoses further protect the brain tissue from the effects of occlusion of single cortical branches (**Figure 1**). However, in the presence of generalised arterial disease or multiple skipped stenotic lesions (atherosclerosis), anomalous or congenital variations, these collateral pathways may prove inadequate and predispose to cerebral ischaemia resulting in brain infarction.

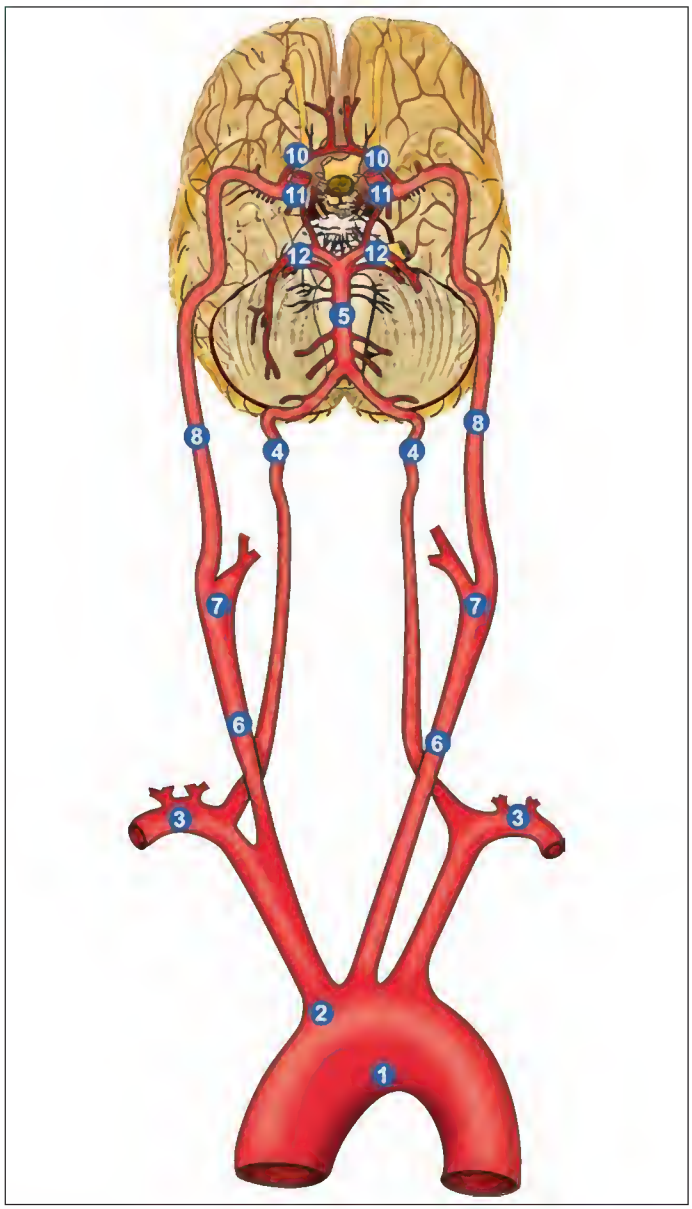

Figure 1: Cerebral collateral circulation. Aortic arch (1), Brachiocephalic artery (2), Subclavian artery (3). The four major cerebral vessels, i.e. the carotid system (6,7 and 8), and the vertebro-basilar system (4 and 5), unite at the base of the brain to form a hexagonal 'Circle of Willis'. These vessels form a network of extensive anastomoses between themselves, in the neck (pre-Willisian anastomoses). Their cerebral branches: the anterior cerebral (10), the middle cerebral (11), and the posterior cerebral arteries (12) anastomose with themselves distal to the circle of Willis (post-Willisian anastomoses).

GENERAL CLASSIFICATION

Table 1 outlines the classification of cerebrovascular diseases. Three types of major strokes are now recognised. These are ischaemic, haemorrhagic and lacunar strokes. Ischaemic variety with cerebral infarction results from atherothrombosis or brain embolism to cerebral vessels. The term transient ischaemic attack implies cerebral ischaemia with complete recovery of focal neurologic deficit within 24 hours, resulting from platelet-fibrin microemboli ('embolic hypotheses) or 'haemo-dynamic crisis.' Haemorrhagic stroke with bleeding within the central nervous tissue occurs due to ruptured cerebral aneurysm in the young and hypertensive intra-cerebral bleeding in the elderly. Lacunar strokes are deep, small cerebral infarcts located in basal ganglia or deep white matter, resulting from diseases of small penetrating vessels.

Table 1: Classification of Cerebrovascular Diseases

Ischaemic strokes
- With cerebral infarction
  - Cerebral thrombosis with or without atherosclerosis
  - Cerebral embolism (congenital heart disease and acquired valvular disease, cardiomyopathy, myocardial infarction, endocarditis, prolapsed mitral valve, etc.)
  - Lacunar strokes (deep, small cerebral infarcts)
  - Cerebral venous thrombosis and cortical thrombophlebitis
  - Arteritis (syphilitic, tuberculous, rheumatic, Takayasu's disease, collagen diseases, etc.)
  - Blood diseases (polycythaemia, sickle cell anaemia, procoagulant states like protein C and protein S deficiency, raised anticardiolipin antibodies or circulating lupus anticoagulants, hyperproteinaemia, etc.)
  - Arterial hypotension and anoxic encephalopathy
  - Dissecting aneurysms of brachiocephalic vessels
  - Angiographic complications
  - Infarction of undetermined cause (e.g. AIDS-related syndromes)
- With cerebral ischaemia
  - Transient ischaemic attacks (platelet-fibrin microemboli associated with atheroma or cardiac diseases, etc.)
  - Local embolism from proximal atheromatous plaques and paradoxical embolism
  - With cardiac arrhythmias (atrial fibrillation, complete heart block, sick-sinus syndrome, etc.)
  - Arterial hypotension or haemodynamic crisis (e.g. massive gastrointestinal bleeding)
  - Vasospasm with migraine or subarachnoid haemorrhage
  - Undetermined source

Idiopathic and rare types
- Drugs and oral contraceptives, disseminated intravascular coagulopathy, consumption coagulopathy, cerebral malaria, Behcet's syndrome, cerebral amyloid angiopathy, hyper-homocysteinaemia/homocystinuria, hyperviscosity syndrome, paraproteinaemia, etc., cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL)

Haemorrhagic stroke
- Discussed in Chapter on Haemorrhagic Cerebrovascular Diseases

Stroke of undetermined origin
- Multi-infarct dementia in lacunar syndromes or leucoaraiosis
- Moyamoya disease
- Fibromuscular dysplasia
- Binswanger's subcortical arteriosclerotic encephalopathy
- Winiwarter-Buerger disease (thromboangitis obliterans - cerebral form)
- Aortic arch syndrome (non-inflammatory)
- Unclassified syndromes

ISCHAEMIC CEREBROVASCULAR DISEASES (CEREBRAL ISCHAEMIA AND INFARCTION)

General Considerations

If, for any reason, such a cardiac arrest or prolonged hypotension [systolic blood pressure (BP) falls below 70 mm Hg] occurs, brain tissue is significantly deprived of its nutrition for more than three minutes, ischaemic-hypoxic cerebral injury or infarction results. Such infarcts are either pale (ischaemic infarction in thrombosis) or may show petechial haemorrhages in the cortical mantle (haemorrhagic infarction in brain embolism). The sylvian region is commonly involved in middle cerebral artery occlusion (mid-field infarct) whereas with internal carotid artery lesions; the cerebral infarction is mostly located in the distal territory (end-field infarction).

A mid-field infarct is produced by occlusion of a small penetrating vessel, and if located in the territory of major anatomical pathways, it may prove catastrophic. On the other hand, an end-field infarct resulting from occlusion of a major vessel in the neck with good collateral circulation may be asymptomatic. Obstruction to venous return can also result in haemorrhagic infarction (e.g. cortical cerebral venous thrombosis). Acutely infarcted brain tissue is soft and swollen, frequently herniates downwards and may compress the vital centres within the brainstem, with fatal outcome. Like infarction elsewhere in the body, cerebral infarcts heal by gliosis leaving a firm scar or a cystic cavity.

Aetiopathology and Pathophysiology

Cerebral infarction is usually attributed to partial or total occlusion of its regional microvasculature by thromboembolism (**Figure 2**). Cerebral atheroma is by far the most common underlying intimal vascular pathology, whereas thrombosis associated with arteritis (syphilitic, rheumatic, tuberculosis) is not an uncommon aetiology for 'strokes in the young' in India.

Experimental studies on pathophysiological events leading to infarction have shown that there is a dense central core, surrounded by a less dense zone of ischaemia ('penumbra') and neuronal death occurs in this central focus unless perfusion is quickly restored. On the other hand, cells in the zone of penumbra remain viable for about three hours ('therapeutic window') and can be salvaged by reperfusion or neuro-protective agents. Major factors, which enhance neuronal injury, are an increase in intra-cellular cytosolic calcium concentration from failure of ionic-pump functions or 'leaks', changes in Na^+/K^+ gradients, acidosis, release of free radicals and other unknown factors, which in turn disrupt the blood-brain barrier (BBB) and microvascular function. Energy depletion from brain hypoxia is one of the key events that fails to maintain normal concentrations of cellular adenosine triphosphate (ATP), leading to delay in re-synthesis of macromolecular proteins essential for endothelial cell structure and function. Energy failures also induce proteolysis and lipolysis, production of arachidonic acid and platelet activating factors, cell adhesion molecules, nitric oxide and free radicals, post-ischaemic hypo-perfusion or hyper-perfusion injuries resulting in further neuronal damage ('ischaemic cascade hypothesis'). Thus, development of cerebral infarct is not merely the result of ischaemia but the end-result of several highly complex 'ischaemia-modifying factors.' For

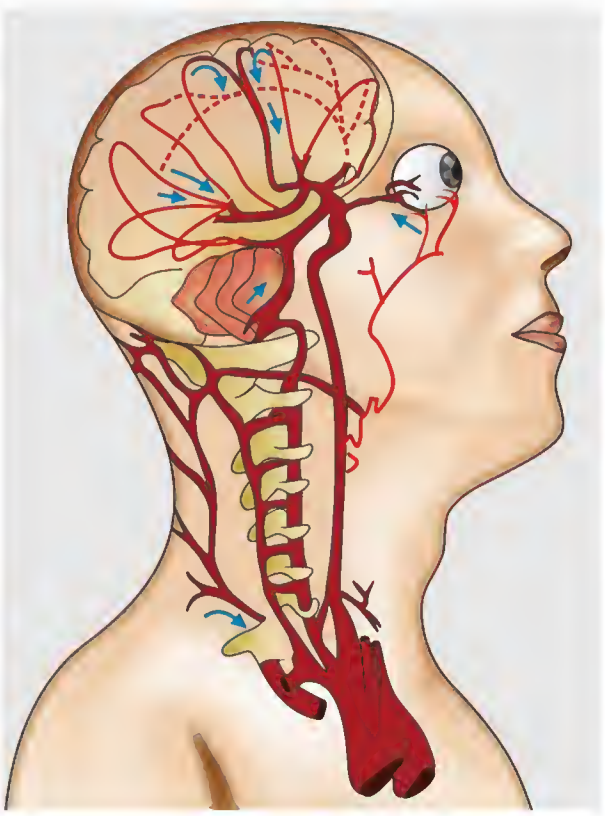

Figure 2: Arrows denote the alternative route of blood supply in the event of a major block in the neck vessels (e.g. carotid or the vertebral arteries), via costo-cervical and the thyrocervical anastomoses. Likewise, leptomeningeal anastomoses over the cerebral hemispheres (arrows) will try and limit the size of an infarct from an isolated branch occlusion (Diagrammatic presentation).

example, exposure of vascular endothelium to raised homocysteine (>100 µmol/L) levels leads to reduced nitric oxide, increased levels of adhesion molecules and expression of procoagulant factors like plasminogen activator inhibitor (PAI-1), tissue plasminogen activator (tPA), protein C (PC) and thrombomodulin (TM), which in turn promote platelet aggregation, leucocytes adhesion and thrombosis.

Clinical Features

Obesity, feeble or absent peripheral arterial pulsations, vascular bruits, unequal or raised blood pressure, postural hypotension and retinopathy may be detected during general physical examination.

In about 60% of the patients, prodromal warning symptoms of TIA may precede. Such episodes of TIA are usually brief (lasting for a few minutes to less than an hour) and may come singly or in successive spells over a number of hours or days or months, and leave no significant residual signs. TIAs may not be always related to posture or the level of BP, and may disappear altogether. However, in some cases (10% to 15%), an evolving or a full-blown stroke may follow the last ischaemic spell.

When the stroke evolves in a stepwise manner, ('thrombosis in evolution') the symptoms may appear in each limb in succession or simultaneously. This stuttering or intermittent progression is typical of atherothrombosis. Not infrequently, the stroke may announce itself abruptly as a single major catastrophic event (accomplished infarction or completed stroke). The other clinical manifestations depend on the site of arterial occlusion. The specific neurovascular syndromes, which result from there, are described below.

Internal carotid syndrome

The cervical portion of the internal carotid artery near the carotid sinus is a common site for athero-stenosis (**Figures 1 and 2**) and about 60% of all thrombotic lesions are located here. Often, these lesions may be asymptomatic because of collateral anastomoses (external carotid-ophthalmic anastomoses or from superficial and deep cervical anastomoses or from the opposite carotid artery through the anterior segment of the Circle of Willis). Warning symptoms precede a major ictus in nearly 50% of the subjects. Such symptoms include brief episodes of confusion, with speech difficulty (aphasia, dysarthria, dyslexia), sensory paraesthesia with or without motor weakness of the opposite side. Ipsilateral amaurosis fugax (transient monocular blindness), fleeting or semi-permanent, alternating with or accompanied by a contralateral hemiplegia or sensory deficit, is pathognomonic of carotid artery syndrome; however, these events occur in only 15% to 20% of the patients.

The clinical manifestations of acute carotid artery occlusion are almost indistinguishable from those of middle cerebral syndrome. Feeble internal carotid or superficial temporal artery pulsations, dilated pupil and poorly pulsating retinal vessels on the side of the suspected carotid lesion and ocular or cervical bruits on the ipsilateral side may suggest the correct diagnosis. Carotid duplex Doppler sonography and angiography are helpful in defining the extent and degree of stenosis.

In patients with an old or silent occlusive carotid artery lesion on one side, a new lesion on the opposite side may prove catastrophic. Here, the physical finding of bilateral hemiplegia (quadriplegia) with coma can be mistaken for basilar artery syndrome.

Asymptomatic cervical bruit

A carotid bruit may be heard in the neck in about 5% of asymptomatic elderly patients (55 years to 80 years). Unless haemodynamically significant, it is very difficult to correlate the mere presence of a bruit with a subsequent TIA or stroke in that territory. The role of prophylactic endarterectomy to prevent a future stroke (estimated at 6% within next 3 years) has not been established by clinical trials. In such cases antiplatelet therapy may be prescribed.

Middle cerebral syndrome

The cortical branches supply lateral surface of the cerebral hemisphere, except for the regions supplied by the anterior and posterior cerebral arteries. The areas of supply include the sensory-motor cortex, the motor and sensory speech centres, auditory area and optic radiation. The penetrating branches (lenticulo-striate arteries) supply the putamen, globus pallidus, genu and posterior limb of the internal capsule.

The clinical picture of middle cerebral artery occlusion is variable. Contralateral hemiplegia, hemianaesthesia with or without homonymous hemianopia and aphasia (dominant hemisphere) are common manifestations. Occlusion of the superior division presents as contralateral hemiparesis with sensory deficit and expressive aphasia (Broca's aphasia), whereas Wernicke's aphasia

(sensory aphasia) is frequent with lesions of the inferior division of dominant side. Monoplegic symptoms with lesion of single cortical branches are not uncommon.

Occlusion of penetrating branches (lenticulo-striate arteries) has been repeatedly blamed for a dense sensorimotor hemiplegic syndrome ('capsular-hemiplegia'), but significant sensory loss seldom occurs with such a lesion and 'pure motor hemiplegia' is common.

Anterior choroidal syndrome

This artery supplies the posterior limb of the internal capsule, which carries the corticospinal and sensory fibres for the contralateral limb. This syndrome, which represents a true 'capsular-hemiplegia' (dense hemiplegia, hemianaesthesia and homonymous hemianopia), is rare.

Anterior cerebral syndrome

The cortical branches mainly supply the medial superior surface of the frontal lobe and the parietal lobe up to the paracentral lobule. The penetrating branches supply the anterior limb of the internal capsule and part of the head of caudate nucleus.

An anterior cerebral artery occlusion proximal to the anterior communicating artery, in subjects with a symmetrical Circle of Willis, is frequently asymptomatic. Occlusion, distal to the anterior communicating artery, manifests itself by a sensorimotor paralysis of the opposite lower extremity with mild weakness of the opposite shoulder. Mental changes, ictal and urinary incontinence, gait disturbances, apraxia, grasp and sucking reflexes may accompany the above findings.

Occlusion of an unpaired anterior cerebral artery (supplying both the hemispheres) results in a cortical type of paraplegia, with sphincter incontinence and a mental state in which the patient is alert but mute (akinetic mutism). Aphasia and hemianopia are never seen.

Occlusion of the penetrating branches and of the Heubner's artery is frequently blamed for ataxic tremors of the contralateral limbs (frontal ataxia). Apraxias, idiomotor dyspraxia of the limbs and gait may also be present.

Posterior cerebral syndrome

This artery supplies the medial and inferior aspects of the occipital and temporal lobes. Its branches also supply the midbrain, cerebral peduncle, most of the thalamic and sub-thalamic regions.

Embolic occlusion of the posterior cerebral arteries is not uncommon. Contralateral homonymous hemianopia is a significant finding and this results from infarction of the primary visual area (calcarine cortex); the central vision is frequently spared, even in cases with bilateral disease (gun-barrel vision). Other manifestations of visual dysfunction include illusory or distorted vision, visual-object agnosia and various forms of dyslexia without dysgraphia. The pupillary reflexes are well preserved. Contralateral hemiplegia from lesion of the cerebral peduncle (peduncular hemiplegia) and thalamic syndrome (Dejerine-Roussy syndrome) may also be present. In the thalamic syndrome, there is varying degree of sensory loss to all modalities and spontaneous burning or agonising pains are frequent (analgia dolorosa). Memory loss (amnesia) suggests lesion of the medial temporal cortex. Contralateral involuntary choreoathetosis or ataxic tremors are rarely observed.

Vertebro-basilar syndrome

After traversing through the bony vertebral canals both vertebral arteries unite intra-cranially to form the basilar trunk. Their short paramedian and long circumferential branches supply the entire brainstem, cerebellum and the vestibular apparatus. TIA manifest as episodes of vertigo, dizziness, diplopia, dysarthria, dysphasia, incoordination of gait and limbs and bilateral signs of sensorimotor deficit. Occipital headaches may be present. Ipsilateral 3rd nerve palsy with contralateral hemiplegia (Weber's syndrome) or with crossed cerebellar ataxia (Claude's syndrome) is diagnostic of midbrain localisation. Homolateral paralysis of the 7th nerve with contralateral hemiplegia and hemianaesthesia (Millard-Gubler syndrome) is suggestive of a pontine lesion. Palatal paralysis and ataxia of limbs, with impairment of posterior column sensation on same side of the body accompanied by diminution of pain and thermal sense on the opposite limbs (Wallenberg's syndrome) indicate lateral medullary infarction from a distal vertebral artery lesion.

Quadriplegia with bilateral conjugate, lateral gaze palsy and 'mute state' with fully preserved consciousness has been described ('locked-in syndrome') in infarction of the basis pontis (sparing the tegmentum), from a mid-basilar occlusion.

Occlusion of isolated cerebellar branches may produce dizziness, nausea, vomiting, nystagmus and appendicular or truncal ataxia without sensorimotor deficit in any limb. Such a syndrome should be differentiated from cerebellar haemorrhage where emergency surgical decompression may prove life-saving.

Aortic arch syndrome

The intriguing clinical syndrome is characterised by diminution or absence of the arterial pulsations in the vessels of the arms and the neck; the seat of the disease, irrespective of its aetiology, being located near the origins of the great vessels arising from the aortic arch.

Several aetiological factors like congenital anomalies, trauma with or without aneurysm, chronic dissecting aneurysm, mediastinal tumours, thrombophilia syphilitic aortitis and atheromatosis appear to be one of the causes of this syndrome, and that an arteritis of undetermined origin is responsible for a good number of female cases. Likewise, it has been a prevalent impression that nearly all the cases of aortic arch syndrome reported from India are a form of arteritis of rheumatic, syphilitic or undetermined origin. It has now been appreciated that the primary lesion in such cases, particularly in men, may not always be an arteritis.

Laboratory and Other Investigations

Complete haemogram with platelet count, erythrocyte sedimentation rate, bleeding, clotting and prothrombin time are routine screening tests for the diagnosis of anaemia, polycythaemia and bleeding diathesis. Tests for sickle cell, anticardiolipin antibodies, or circulating lupus anticoagulant, C-reactive protein are performed when indicated. Blood sugar, urea, lipids, uric acid and electrolytes are other baseline

investigations. In thrombotic strokes, at any age, where common risk factors are not present, protein C and protein S deficiency and homocysteinaemia should be looked for. Genetic and chromosomal studies are rarely indicated.

Chest radiograph and serial electrocardiograms are essential. In cardioembolic studies, two-dimensional echo (transthoracic or trans-oesophageal) is of great value whereas Holter monitoring should be done when indicated.

Electroencephalography (EEG) is not of diagnostic value but examination of cerebrospinal fluid (CSF) within 7 days of the ictus is helpful in the diagnosis of cerebral haemorrhage (80%) and in nearly 90% of subarachnoid haemorrhagic (SAH) cases. Red cell and leucocyte counts per mm^3 of CSF in three citrate bulbs will differentiate a traumatic tap. VDRL of blood and CSF, fluorescent treponemal antibody absorption tests (FTA-ABS) and HIV test are necessary for the diagnosis of syphilis and AIDS-related vascular syndromes.

Duplex sonography and transcranial Doppler studies have assumed significant role in evaluation of extra-cranial and intra-cranial carotid arteries, in assessing the degree of narrowing (stenosis) and location of superimposed thromboemboli, if any. This is an investigator-oriented test and individual variations in defining degree of stenosis are common. Nonetheless, serial evaluation by same investigator using well standardised diagnostic set up is useful. The nature of lesions (stenosis, etc.) may need to be verified by magnetic resonance (MR) or computed tomography (CT) angiography. If surgical intervention is planned, it would be more meaningful to define available collateral circulation and precise degree of narrowing by digital subtraction angiography (DSA). There is a correlation between intima-media thickness (? early athero lesions) and elevated lipid levels and here serial follow-up evaluation to judge regression by statin therapy is often recommended.

Computerised cranial tomography is the single-most important non-invasive investigation to distinguish an ischaemic infarction and cerebral haematoma from other conditions simulating strokes (e.g. subdural haematoma, tumour). It also provides an estimate of the extent and location of supratentorial cerebral infarction, including small (0.5 cm) lacunar infarct. It can also detect surrounding oedema and haemorrhagic infarction. However, it may not differentiate early (within 1 to 3 hours) ischaemic lesion from normal tissue. Brainstem lacunaes are difficult to detect by conventional CT.

In subjects having TIA or reversible ischaemic neurologic deficit (RIND), carotid Doppler sonography helps to detect carotid artery lesion, but magnetic resonance angiography (MRA) or DSA will clearly define the cerebral vasculature, the extent and degree of ulcerated atheromatous lesions, and will help in eventual medical or surgical management. The hazards of DSA in comatose patients with dense neurologic deficit and decompensated cardiac status should be carefully weighed.

Magnetic resonance imaging (MRI) (T2 weighted, diffusion and perfusion weighted studies) of brain, and visualisation of cerebral arteries by MRA in hyperacute (within 1 to 3 hours) ischaemic strokes defines the extent and severity of arterial and cerebral lesions, which are usually not well seen on routine CT evaluation. Thus, MRI with MRA helps a great deal in taking therapeutic decisions like thrombolytic therapy. The DSA is performed when surgical intervention is contemplated. SPECT of brain with specific radio-pharmaceutical agent can be performed to study cerebrovascular reactivity in regions of hypoperfusion.

Course and Prognosis

In subjects who survive stroke, some degree of recovery is the rule. Chances of significant recovery are remote when no improvement is noted within first 6 weeks to 8 weeks. About 20% to 25% of the patients with massive cerebral infarction and brain swelling die during the acute phase. Here, old age, presence of severe neurological deficit with coma and pyrexia, intercurrent infections, poorly controlled hypertension, diabetic states and basilar artery thrombosis are of grave prognostic significance.

Recurrent episodes are frequent but there is no way to predict the same in a given subject. However, control of 'risk-factors' is beneficial (*see stroke prevention*).

Differential Diagnosis

The principal hallmarks of cerebral infarction resulting from thromboembolism include prodromal warning symptoms with rapid onset of focal neurologic deficit, stuttering or intermittent progression, a constellation of symptoms and signs diagnostic of a well-defined neurovascular syndrome, relative preservation of consciousness, clear CSF, some degree of recovery, and evidence of vascular disease elsewhere in the body.

In distinguishing cerebral haemorrhage from cerebral infarction, the following collective criteria may prove helpful: moderately severe to intense headache (throbbing, pulsating or pounding) in a known hypertensive subject, accompanied by nausea and vomiting; altered state of consciousness (drowsiness progressing to deepening coma) with irregular respirations; neck stiffness accompanied by dissociated eye movements, or forced gaze deviation; blurred disc margins or pre-retinal haemorrhage, with changes suggestive of hypertensive retinopathy and hemiparesis on one side with shivering movements or even frank convulsions on the non-paralysed side or quadriparesis (paucity of withdrawal movements to pinch stimuli in each limb), with an extensor plantar response on both sides. Presence of blood in the CSF will settle the diagnosis in majority. It should be noted that nearly 30% survive a small intra-cerebral bleed. However, haemorrhagic cerebral infarction in a hypertensive subject and occult intra-cerebral bleed (haematoma or slit haemorrhage) may show a clear CSF at the onset. Here, CT scanning is invaluable in arriving at a diagnosis.

Subdural haematoma and other mass lesion may mimic a stroke. A history of headache or seizures, papilloedema, raised spinal fluid pressure and xanthochromia with elevated protein content, midline shift of a calcified pineal gland on skull radiograph, or shift of midline on echoencephalography, suppressed alpha activity or high-voltage slow waves on EEG and abnormally high local concentrations of radioisotope in brain scan, all point to the true nature of the lesion. CT or cerebral angiography helps to settle the diagnosis, but isodense subdural haematoma can often be misdiagnosed as an infarct.

A history of head injury, careful cranial examination for marks of injury, blood-stained CSF and characteristic radiographic

findings like fracture easily differentiate post-traumatic conditions from strokes.

Post-epileptic hemiplegia (Todd's paralysis) with complete recovery may simulate transient cerebral ischaemia. Clinical history suggestive of seizure disorders with EEG abnormalities in a young subject proves helpful in arriving at a correct diagnosis.

Posterior fossa tumours, the administration of sedatives or tranquillisers, multiple sclerosis, vestibular disorders and hysteria may simulate vertebro-basilar artery disease, but seldom present diagnostic problems. Here, meticulous history with serial clinical observations proves more helpful.

Transient Ischaemic Attack (TIA Syndrome)

The term transient ischaemic attack implies complete recovery of focal neurologic deficit in stroke syndrome within 24 hours. In RIND, the paresis may persist for more than 24 hours with nearly complete recovery within a week. During a follow-up of nearly five years 30% of TIA patients develop a full-fledged stroke.

Among proposed theories for TIA, the 'embolic hypothesis' and 'haemodynamic crisis' are gaining support. It is suggested that platelets begin to adhere over exposed collagen of denuded intimal surface and triggers the release of phospholipids and arachidonic acid, cyclooxygenase enzyme converts arachidonic acid into a potent platelet aggregator (thromboxane-A_2). Acetylsalicylic acid (aspirin) blocks this enzyme activity and thereby helps in prevention of TIA. Dipyridamole blocks enzyme phosphodiesterase to achieve effect similar to aspirin. Furthermore, endothelial cells release prostacyclin (PG_2), which also prevents aggregation of platelets.

Repetitive (5 to 10 attacks/day), short-lived (<15 min), typical spells of hand and arm weakness suggest proximal arterial narrowing with poor collateral circulation producing transient focal ischaemia. On the other hand, a single spell of speech difficulty with or without arm involvement lasting for about 12 hours suggests embolic ischaemic attack with some degree of infarction. The specific type of TIA points to the particular artery involved.

Treatment of Ischaemic Cerebrovascular Disease

An outline of diagnostic evaluation and the emergency management of an acute stroke case (acute hemiplegic syndrome) are described in **Figure 3**.

Medical Management

The goal of therapy is to avoid development of cerebral infarction and, if already present, to restrict its progression or recurrence. Treatment is divided into three phases: phase I—saving life and speedy recovery; phase II—rehabilitation to achieve adaptation (physical, occupational, social) for a gainful employment; and in phase III—emphasis is laid on prevention of the recurrence of stroke.

Phase I

General measures and intensive care: In acute stage of cerebral ischaemia (ASCI), maintenance of vital signs (temperature, pulse, respiration, BP), patency of airway, fluid and electrolyte balance, and prevention of complications like pulmonary aspiration, seizures, thrombophlebitis, and bedsores are mandatory. Here, general medical and meticulous nursing care is of paramount importance. Hyperglycaemia or hypoglycaemia should be appropriately treated. Acute stroke is now recognised as a medical emergency and specialised care in intensive stroke units is generally recommended.

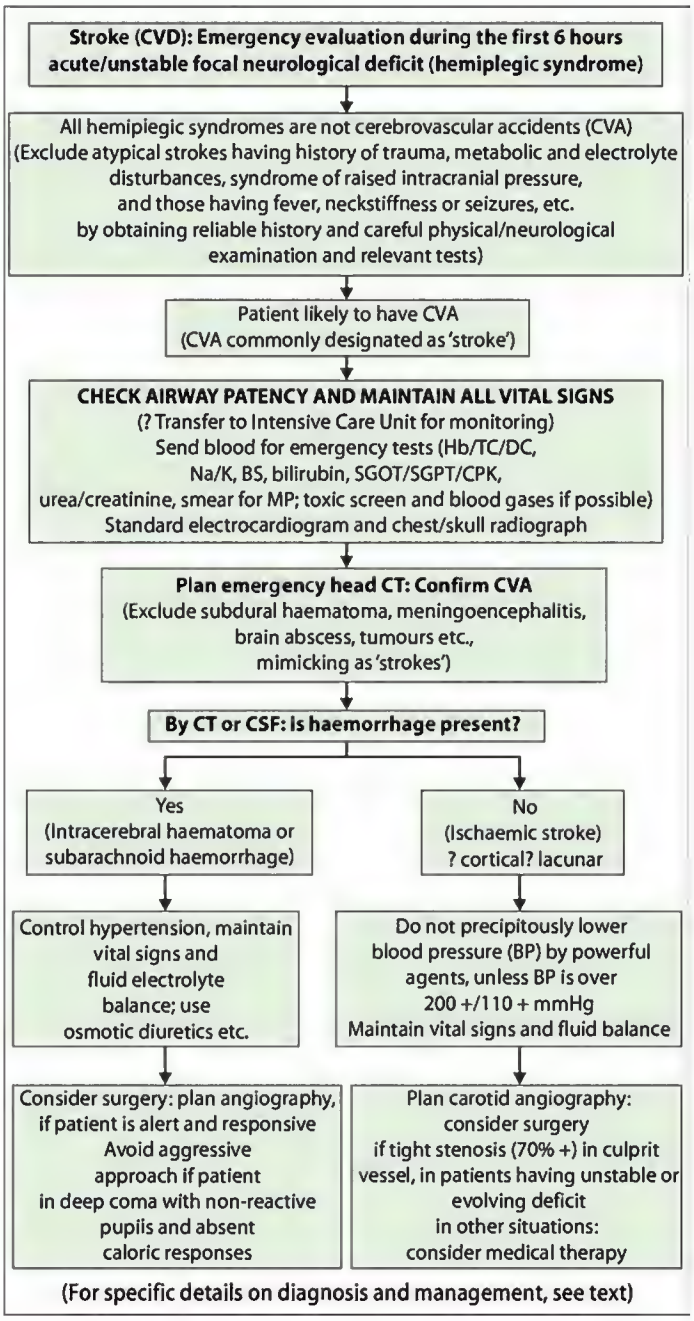

Figure 3: Diagnostic evaluation and emergency management of an acute stroke.
Courtesy: Modified from US National Stroke Association recommendations for the emergency evaluation and treatment of stroke.

CVD = Cerebrovascular disease; Hb = Haemoglobin; TLC = Total leucocyte counts; DLC = Differential leucocyte counts; Na = Sodium; K = Potassium; BS = Blood sugar.

Ventilation: Cerebral hypoxia in ischaemic and haemorrhagic strokes carries grave prognosis because it predisposes to cerebral oedema and raised intra-cranial pressure (ICP) and may precipitate brain herniation. Therefore, every effort should be made to keep the airway patent by preventing accidental aspirations and gentle care of pulmonary secretions with utmost sterile precautions. Here, administration of oxygen (4 to 6 litres/minute) preferably through an oxygen tent, is now routinely advocated. Ventilator support is indicated with O_2

saturation less than 90% or raised $PaCO_2$ or in comatose subjects having signs of cerebral hypoxia secondary to hypoventilation. Ear oximetry monitoring is helpful.

Blood pressure control: In acute stroke, 'cerebral autoregulation' is lost and blood flow in the infarcted areas is solely dependent on mean arterial BP. In the presence of severe hypertension (e.g. BP over 220/120 mm Hg) parenteral therapy with titratable agents such as intravenous (IV) labetalol or enalapril which reduce BP smoothly are recommended. Calcium channel blockers are best avoided because they produce marked fall in BP in some patients. On the other hand, raised BP levels in patients with hypertensive and non-hypertensive stroke often falls unpredictably within 24 hours to few days, worsening perfusion in ischaemic penumbra leading to irreversible injury. Therefore, any significant hypotensive episode should be promptly treated to prevent extension of cerebral infarction.

Fluids, electrolyte balance and blood glucose: Ischaemic tissue with break in the 'blood-brain barrier' (BBB) retains fluid, predisposing to cerebral oedema. Thus, a phenomenon of 'cerebral squeeze' sets in and this compresses the adjacent viable neuronal tissue; the swollen brain may also herniate transtentorially onto the vital brainstem areas and thereby impair level of responsiveness and increase the neurological deficit. Irrespective of stroke subtype, hyper-glycaemia (plasma glucose more than 200 mg/dL or 10 mmol/L) is associated with increased mortality or reduced functional outcome, and insulin therapy may be desirable. Likewise, IV 5% dextrose in water is best avoided in early stages of massive cerebral infarction with brain swelling. Judicious restriction of fluid intake (parenteral) in first 48 hours is often advocated. On the other hand, excessive use of diuretics may precipitate cerebral hyponatraemia.

Measures to improve cerebral blood flow: Haematocrit is one of the chief determinants of whole-blood viscosity. It is postulated that lowering the haematocrit value to 30% to 33% with haemodilution therapy improves cerebral blood flow and oxygenation of infarcted tissues. However, results of recent randomised trials have failed to show consistent beneficial effects of haemodilution therapy.

Reduction of increased intra-cranial pressure and cerebral oedema: With raised ICP, the head should be elevated by 30°. If associated with increasing drowsiness, intubation and hyperventilation to keep partial pressure of carbon dioxide (PCO_2) at 25 to 30 mm Hg would be helpful. In hypertensive crisis (BP more than 240/130 mm Hg), sodium nitroprusside is often used but parenteral use of labetalol or enalapril and frusemide are preferred. The BP should be carefully monitored and lowered gradually. In the first week of massive cerebral infarction with evidence of cerebral oedema hyperosmolar solution (e.g. intravenous mannitol) is prescribed to reduce vasogenic brain oedema but its effect is short-lasting and rebound cerebral oedema may prove harmful. Furthermore, in patients with incipient left ventricular failure, pulmonary oedema may be precipitated. Here, IV infusion of 10% glycerol may be helpful. On the other hand, restriction of IV fluids and frusemide induced diuresis are more effective in brain oedema with signs of herniation. High dose of corticosteroids can reduce cerebral oedema but their role in the treatment of vasogenic oedema is doubtful. Decompressive craniotomy, in massive cerebral or cerebellar infarction causing brainstem compression, is often advocated.

Specific therapy

Antiplatelet drugs: Acetylsalicylic acid (aspirin) prevents platelet aggregation by blocking production of platelet-derived thromboxane-A_2 but it also suppresses release of prostacyclin from vascular endothelium. It is widely used in primary and secondary prevention of strokes. In the treatment of TIA, RIND and in secondary prevention of strokes, the optimal dose is still debated. Low-dose therapy (100 mg/day or less) may be as effective as higher dose (325 mg/day or more). Other antiplatelet drugs like sulphinpyrazone or dipyridamole used alone do not offer any specific advantage. However, in female 'non-responders' aspirin combined with dipyridamole (up to 200 mg twice a day) may prove more effective on account of its synergistic activity.

Ticlopidine (a thienopyridine derivative) inhibits platelet aggregation by interfering with ADP-induced transformation of glycoprotein IIb/IIIa receptors on platelet membrane. It has shown more than 30% reduction in 'stroke risk' when compared to aspirin therapy. It is equally beneficial to men and women. Patients with diabetes mellitus, those on anti-hypertensives and those with elevated creatinine levels benefit more with ticlopidine (250 mg b.i.d.) than aspirin. However, the drug is relatively toxic (i.e. reversible neutropaenia, diarrhoea). Clopidogrel (75 mg/day) is reported to be safer than ticlopidine. In a recent trial (MATCH study), combination of clopidogrel (75 mg) and aspirin (75 mg) showed no real benefit in outcome of vascular end-points. Newer antiplatelet agents like abciximab are potent antagonists of platelet glycoprotein IIb/IIIa receptors but hazards like symptomatic intra-cranial bleeding are a major concern.

Anticoagulants: Parenteral heparin and long-term oral anticoagulants have been extensively tried in acute ischaemic strokes, particularly in elderly subjects having non-rheumatic atrial fibrillation (NRAF) or from cardioembolic source. Though such treatments can prevent extension of thrombus, its value in completed stroke is doubtful and its use is often fraught with dangers. Judicious use in recurrent TIAs, thrombosis in-evolution, cardiogenic embolisation to the brain in patients not responding to anti-platelet therapy, and in patients who are not fit for carotid surgery has been suggested.

To minimise the risk of haemorrhagic complications, it is necessary that the ischaemic infarction is confirmed by investigations like CT scan and CSF and not on the basis of clinical acumen alone. If a subject worsens under anticoagulant therapy, diagnostic re-evaluation should be done and even a second CT with or without CSF examination (under manometric control) may have to be carried out to ascertain the cause of worsening (extension of infarct *versus* intra-cranial bleeding due to anticoagulation).

During the stage of heparinisation activated partial thrombo-plastin time is kept up to two times the control, and 3000 to 5000 units of heparin are often given on 6 to 8 hourly basis. In practice, an IV bolus of 100 units/kg followed by continuous infusion (1000 units/hour for 24 hours), under constant supervision for bleeding parameters, preferably in an acute care unit is advocated. Of the many oral anticoagulant drugs, coumarin sodium (2 to 5 mg/day) is generally well tolerated. Prothrombin index (ideally INR) of 2.0 to 3.0 is usually maintained for months or longer, keeping

a close watch on haemorrhagic complications. Newer synthetic short-chain (low molecular weight) heparins or heparinoids are safer and effective but expensive. In the presence of actively bleeding ulcers, malignant hypertension, hepatic failure and poor patient compliance, anticoagulant treatment is contraindicated.

The current evidence suggests that aspirin is the treatment of choice when compared to anticoagulants for patients with non-cardioembolic stroke. However, anticoagulant therapy significantly benefits high-risk patients with atrial fibrillation in the elderly subjects, whereas aspirin may still be the drug of choice in stroke prevention in low risk group in the younger age.

Thrombolytic therapy

Intravenous thrombolytic therapy: Spontaneous recanalisation with better survival by intrinsic thrombolysis is well documented. Increasing experience with several 'clot-selective' thrombolytic agents have demonstrated significant and sustained neurological improvement when treatment is initiated within the first four and half hours of ictus, in MRI-positive and CT-negative ischaemic infarcts (i.e. when 'window of therapeutic opportunity' is open).

Intra-arterial thrombolytic therapy: Recent advances in superselective microcatheter (Tracker-18 or Microsoft stream catheter) techniques permit the investigator to reach at exact site of occlusive lesion and infuse a thrombolytic agent directly on to the clot surface thereby achieving higher rate of successful recanalisation.

Neuroprotective agents: Cerebral ischaemia induces release of excitatory aminoacid neurotransmitters like glutamate and glycine, which promote calcium entry into neurons through receptor-mediated membrane channels or by voltage-dependent calcium channels. Cell destruction most likely occurs from production of nitric oxide and subsequent formation of other free radicals. Clinical trials with several neuroprotective agents, including dihydropyridine compound (nimodipine), have not shown overall beneficial effects. Results of other trials are awaited.

Managing raised homocysteine (tHcy) level: Elevated levels of tHcy have been reported as significant and an 'independent risk factor' for myocardial infarction and stroke, though precise mechanisms linking raised tHcy to vascular disease have not been established. It has been suggested that raised tHcy harms endothelial cell functions, increases oxidative stress and thereby risk to thrombosis. Treatment with vitamins (B6, B12, folic acid) reverses the raised levels of tHcy and thereby possibly prevents progression of vascular disease.

Statins and stroke: Hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statins have also been considered beneficial in prophylaxis against myocardial infarction, stroke and other vascular events.

Data from SPARCL study (Stroke Prevention by Aggressive Reduction in Cholesterol Levels) suggest that statins reduce a risk of recurrence of stroke and that stroke prevention may be independent of their effects on lowering low-density lipoprotein.

Surgical management: Thromboendarterectomy with or without reconstructive vascular surgery within a few hours or days after an acute ischaemic brain infarction is considered risky, because early reperfusion may convert pale infarct into a haemorrhagic one.

Recent well-designed controlled studies (NASCET—North American Symptomatic Carotid Endarterectomy Trial) have confirmed beneficial results of carotid artery endarterectomy (CAE) in tight cervical stenosis (70% to 99%). Patients who benefit the most from surgery are those with highest risk-factors. During immediate post-operative period higher doses of aspirin and control of all risk-factors are mandatory. The benefit by carotid endarterectomy in symptomatic lesions with mild stenosis (30% to 69%) or in asymptomatic cases is controversial.

Stenting and angioplasty in symptomatic carotid stenosis: Though CAE appears well established in tight symptomatic carotid stenosis (>70%), stenting with or without embolic protection devices are getting accepted as alternative mode of treatment in cases with CAE is not feasible or difficult. It has been reported that fewer complications occur with stenting as compared to CAE (e.g. neck haematoma, cranial neuropathy, etc.).

Stem cell therapy in acute stroke: Ethical and moral issues have prevented experimental trials on stem cell therapy in humans with acute ischaemic stroke. Animal experiments in various models do suggest that this avenue of therapy needs to be explored. However, reliable and verifiable reports are yet not available.

Phase II

Neurorehabilitation: As soon as the subject shows signs of neuronal recovery with some volitional movements, active physiotherapeutic measures should be started for early rehabilitation.

Phase III

Stroke prevention: In 80% of stroke-survivors, the chances of recurrence are high during the first few weeks and nearly 10% in the first year. Modification of risk-factors has shown decline in stroke morbidity and mortality. The prevention strategies are: control of hypertension, stop smoking or tobacco use, antiplatelet anticoagulants, CAE, treating hyperlipidaemia and diabetes mellitus, correcting all other treatable or modifiable risk-factors, and regular physical exercise and keeping ideal body weight. The risk of stroke doubles for every 7.5 mmHg rise in diastolic BP and a 25% relative risk reduction in stroke risk is reported in patients who are able to lower their diastolic BP by more than 6 mmHg.

CEREBRAL EMBOLISM

General Considerations

Local occlusion of an intra-cranial artery by a circulating fragment, which may be composed of broken bits of thrombi, platelet-fibrin masses, cholesterol debris, tumour cells, fat globules, gas bubbles, bacteria and parasites or other foreign bodies, is known as cerebral embolism.

Aetiopathology and Pathophysiologyc

Detachment of intra-cardiac thrombi or vegetations during atrial fibrillation is most frequent source of cerebral embolism. Atheromatous debris from aortic arch is another common source. Thrombosed pulmonary veins in bronchiectasis, lung abscess and such infections may be a source of embolisation. Paradoxical embolism is not uncommon. Recurrent embolism can occur from unidentifiable source and here subacute bacterial endocarditis, non-bacterial marantic endocarditis and atrial myxoma should be considered.

Twenty-five per cent of all systemic emboli reach the brain and 60% of them lodge in the middle cerebral arterial territory. In urban centres cerebral embolism accounts for 25% to 30% of all ischaemic strokes; young subjects of either sex are frequently affected. Acute carotid embolism in the neck with fluctuating paresis (RIND) has also been described.

On account of sudden impaction of an embolic plug, sufficient time is not available for compensatory mechanisms to protect the cerebral cortex from ischaemia; hence, the ictus announces instantaneously with varying degree of neurological deficit. The embolic plugs frequently break and migrate distally and thereby restore circulation in its ischaemic territory; haemorrhagic (red) cerebral infarction is, thus, the consequence of reperfusion of blood in an ischaemic (pale) area. If the circulation is restored within an hour, before the death of nerve cells the neurological recovery may be equally dramatic.

Clinical Features

Cardiac arrhythmia and obvious heart disease may be noted on general physical examination. Ophthalmoscopy may reveal embolic fragments with sludging or stasis of blood in the retinal veins. Ipsilateral carotid arterial pulsations may be feeble.

There are no warning prodromal symptoms but in some subjects focal seizures may precede the ictus. The stroke develops fully within few seconds or minutes; stuttering or intermittent progression is rare. The clinical manifestations depend on the site of occlusion, and the specific neurovascular syndromes resulting therefrom are in no way different from those described for thrombotic arterial disease. Coma indicates massive cerebral infarction.

The presence of severe neurological deficit with coma at the onset of the ictus, fever and other intercurrent infections, cardiac failure, uncontrolled hypertension or diabetes mellitus, advanced age and basilar artery embolism, all carry a grave prognosis. Nearly 30% of all patients with acute brain embolism die from the initial ictus and around 80% of comatose patients succumb to the illness. In those who survive an acute insult some degree of recovery is common. If no improvement is noted in the first 6 to 8 weeks, chances of subsequent or significant recovery are remote. Recurrence of a cerebral embolic episode is reported in 40% of patients, and nearly 40% of them die from a second embolic stroke.

Laboratory Findings

In general, the findings are similar to those outlined under atherothrombosis. In septic infarcts, the white cell count may be very high; in haemorrhagic cerebral infarction, the CSF is often blood-stained. Atrial fibrillation, tachyarrhythmia and other ECG abnormalities are frequently detected. In early stages (within hours), cerebral angiographic findings are characteristic and may show migratory occlusive lesions of isolated branches in absence of atheromatous disease. A repeat arteriography after a few days may be entirely normal and this suggests, 'vanishing emboli'. two-dimensional echo or transoesophageal echocardiography helps to define myocardial infarction or valvular lesions or vegetations. Holter monitoring may document cardiac dysrhythmia.

Diagnosis

The following points should help to arrive at the correct diagnosis; history of abrupt onset of a full-blown neurologic deficit without intermittent progression, developing within a few minutes; absence of warning symptoms; presence of potential source of embolism; evidence of previous or concurrent episodes of embolism to other parts of the body; and clear spinal fluid (in almost all cases).

CT or MRI may show hyperdense arterial occlusive lesion and also helps to settle the diagnosis by excluding atherothrombotic brain infarction, intra-cerebral haemorrhage and subdural haematoma and other non-stroke conditions.

Treatment

General nursing and intensive medical care, as outlined for cerebral thrombosis, are the sheet-anchor of therapy. Vasodilator drugs do not help. Current enthusiasm for infusion of thrombolytic agents to lyse an embolus has not been very encouraging as haemorrhagic complications far outweigh the potential benefits. Since the stroke is complete, anticoagulant medication is of little help. Furthermore, in massive cerebral infarction or in the presence of severe hypertension, anticoagulant therapy may convert pale infarct to a haemorrhagic one. On the other hand, long-term anticoagulant treatment (keeping INR around 2.0) is routinely advocated to prevent recurrent embolism in elderly subjects with irregular cardiac rhythm. Specific treatment for the underlying cardiac or similar disease should be given (e.g. bacterial endocarditis). An active rehabilitation programme is initiated as soon as some volitional movement is noted.

Prophylaxis in Cardioembolic Stroke

Cardioembolic strokes are common in subjects having non-valvular atrial fibrillation, post acute coronary syndrome (e.g. mural thrombi, ruptured chordae tendinae, ventricular aneurysm, etc.), valvular rheumatic heart disease, cardiomyopathy, septal defects and patent foramen ovale (PFO). In atrial fibrillation, the stroke recurrence risk is as high as 12% per year. To prevent recurrent brain embolism, long-term oral anticoagulant therapy keeping INR around 2.0, is advocated in elderly patients having irregular cardiac rhythm. Thus, choice of antithrombotic therapy depends upon the aetiology of stroke. Oral anticoagulation treatment is the preferred choice for inferred cardioembolism in setting of atrial fibrillation, while the varying rates of haemorrhage with oral anticoagulants continue to favour antiplatelet therapy in other setting of inferred aetiology. Insufficient data exist to determine whether antithrombotic therapy combined with antihypertensives, statins or other agents will further reduce the risk of stroke in synergistic or supplemental fashion.

LACUNAR STROKES

When exposed to chronic hypertension, the small cerebral vessels and penetrating vessels in particular, show thickening and fibrosis of their walls leading to luminal narrowing, lipohyaline changes (lipohyalinosis) and microinfarction (lacunar infarcts). The weakness in the vessel wall segment may predispose to formation of microaneurysms, which may bleed or become occluded by thrombosis.

Lacunae are deep, small (150 mm to 300 mm), multiple wedge-shaped infarcts in the subcortical white matter seen mostly in hypertensive, diabetic and elderly subjects. These are commonly located in the basal ganglia, thalamus, corona radiata, internal capsule, brainstem, cerebellum and mainly in the territory of

small penetrating vessels. Cortical grey matter, hypothalamus, midbrain and medulla oblongata are relatively spared.

Lacunae can be asymptomatic, but may produce dense neurological deficit if located in the regions of major pathways. On the basis of clinico-pathological studies, Fisher described many lacunar syndromes, i.e. pure motor hemiplegia (infarction in the posterior limb of the internal capsule or basis pontis), pure hemisensory syndrome (thalamic infarct), homolateral ataxia and crural paresis, clumsy-hand dysarthria syndrome and other brainstem symptom complexes. Earlier, these syndromes were considered pathognomonic of ischaemic cerebrovascular disease but these have also been described with small cerebral bleed; here, CT is often desirable to rule out such micro-bleeds. It is not uncommon to have TIA or RIND precede lacunar stroke. Some degree of recovery is always common. Progressive intellectual deterioration and loss of cognitive functions (dementia) in association with slow hesitant gait and pseudobulbar signs may result from multiple lacunae (multi-infarct dementia) and should be differentiated from Alzheimer's disease and similar conditions. Here, CT or MRI is important diagnostic test where lacunar infarcts are often visible as small, punched out, hypodense areas.

Aspirin is commonly prescribed. Treatment of underlying diseases like hypertension, diabetes mellitus and hyper-lipidaemia is essential. Anticoagulant therapy is considered controversial.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is a syndrome characterised by recurrent ischaemic attacks with subcortical microinfarcts (non-arteriosclerotic, non-amyloid angiopathy) associated with subcortical dementia and migraine in young adults. Here, MRI shows widespread white matter disease and genetic dysfunction is presumably located on chromosomes 19q12. Similar syndrome where gene polymorphism is associated with specific cerebral small vessel pathologies is under investigation.

Arteritis

The clinical features of syphilitic and other forms of arteritis involving various cerebral arteries are in no way different from the neurovascular syndromes described under cerebral thrombosis. With specific serological tests, the diagnosis of meningovascular syphilis is not difficult. Specific treatment with antisyphilitic drugs is advocated.

STROKES OF UNDETERMINED ORIGIN

Strokes in Young in India

Several reports suggest that in about 20% of non-cardioembolic strokes in young (<45 years), the commonly believed risk-factors (e.g. hypertension, diabetes mellitus, tobacco use, etc.) are absent. Here, altered haematocrit level and disturbed equilibrium in coagulation and fibrinolysis have been postulated. Among procoagulant states: protein C/protein S deficiency, hyperhomocysteinaemia, raised anticardiolipin antibody or circulating lupus anticoagulant factor, etc. should be checked for. The possibilities of subacute central nervous system infection and autoimmune vasculitis need critical evaluation. Thus, strokes in young demand meticulous evaluation and specific tests to ascertain its aetiology for correct diagnosis and long-term management. Comprehensive cardiovascular evaluation should not be ignored. CT, MRI of brain and imaging of extra-cranial and intra-cranial vessels often helps to define the anatomical lesion and possibly its pathology. General medical management of ischaemic stroke in the young is similar to strokes in elderly and specific therapies should be prescribed for specific aetiologies. However, despite extensive investigations in 10% of cases the underlined aetiopathology remains uncertain or speculative.

Moyamoya Disease

It is an angiographic entity characterised by an unusual combination of progressive occlusive lesion at the intra-cranial carotid bifurcation with an extensive or profuse abnormal anastomotic network of dilated arterioles and capillaries at the base of the brain. The characteristic angiographic appearance is often described as puff of cigarette smoke drifting in the air. The carotid occlusion is non-inflammatory subintimal fibroplasia near arterial cushions. It is mostly reported in children and young adults among Japanese and other Asians. Headaches, convulsions and SAH are frequent clinical manifestations. As yet, there is no specific treatment.

Fibromuscular Dysplasia

Fibromuscular dysplasia is a segmental, non-atheromatous, non-inflammatory angiopathy of unknown cause. It involves the intima, media and sometimes the adventitia of renal, aorto-iliac, splenic and internal carotid arteries and vascular bruits are usually present. It has a characteristic angiographic appearance where irregular beading on stenotic areas alternate with dilated aneurysmal segments. Young or middle-aged women, taking contraceptive pills, may present with migraine type headache or TIA. Surgical dilatation of the narrowed segments reduces these symptoms in many.

Other Cerebrovascular Diseases

Binswanger's subcortical arteriosclerotic encephalopathy, leucoaraiosis, Winiwarter-Buerger disease are some other causes of strokes. Cerebral venous thrombosis during pregnancy and puerperium is commonly seen throughout India and will need special evaluation and demands acute intensive medical management. Recent studies have shown a significant decline in the incidence of stroke mortality, through the relative distribution of cerebrovascular disease lesions (ischaemic and haemorrhagic) in hospital cases has not changed over the years. Thus, a higher percentage of stroke survivors with varying degree of residual disability will pose major socio-economic challenge in occupational rehabilitation of these victims. Stroke prevention needs no emphasis.

20.9 Haemorrhagic Cerebrovascular Diseases

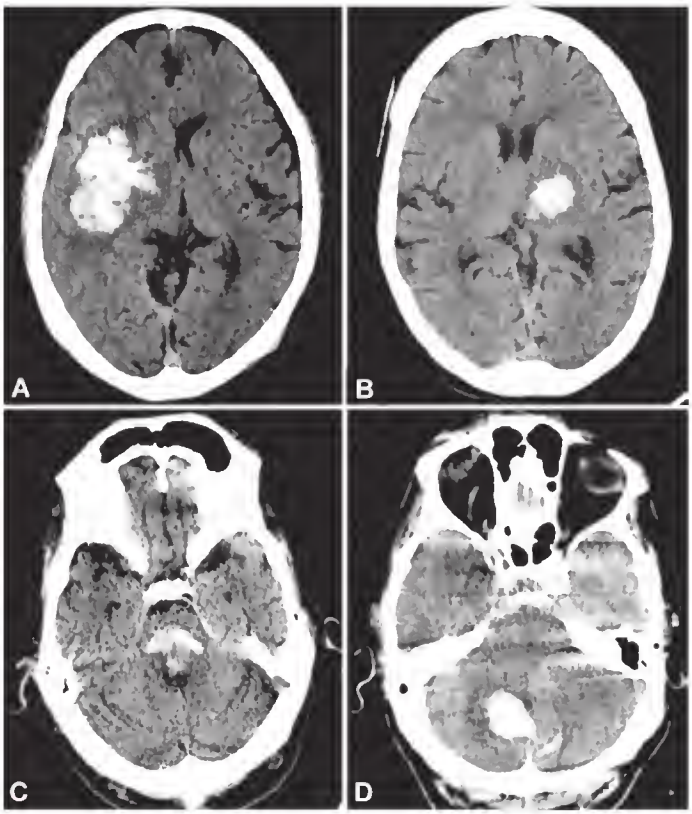
MV Padma Srivastava, Ajay Garg

INTRODUCTION

Spontaneous intra-cerebral haemorrhage (ICH) is the deadliest most disabling and least treatable form of stroke. Following a major haemorrhage, 35% to 52% are dead within a month and less than 20% were living independently after 6 months. The hospital mortality rates of ICH who are comatose and mechanically ventilated is 60%. ICH constitutes 15% of all strokes in the West and 20% to 30% in Asian populations. The lack of proven and accepted medical or surgical treatment for ICH leads to great variation among physicians concerning both surgical and medical management.

The percentage of haemorrhagic strokes may vary between different regions within India and there is increasing literature suggesting higher percentage of haemorrhagic strokes (30% to 40% of all strokes), in North-Eastern regions including Kolkata, Death at 1 year for ICH varies by location of ICH, 50% for deep haemorrhage; 57% for lobar; 42% for cerebellar and 65% for brainstem bleeds. The most important risk factor for ICH is poorly controlled chronic hypertension. Advanced age is an additional risk factor for ICH, with the rate doubling with each decade of life until 80, when the incidence plateaus at nearly 25 times that of previous decade

AETIOLOGY



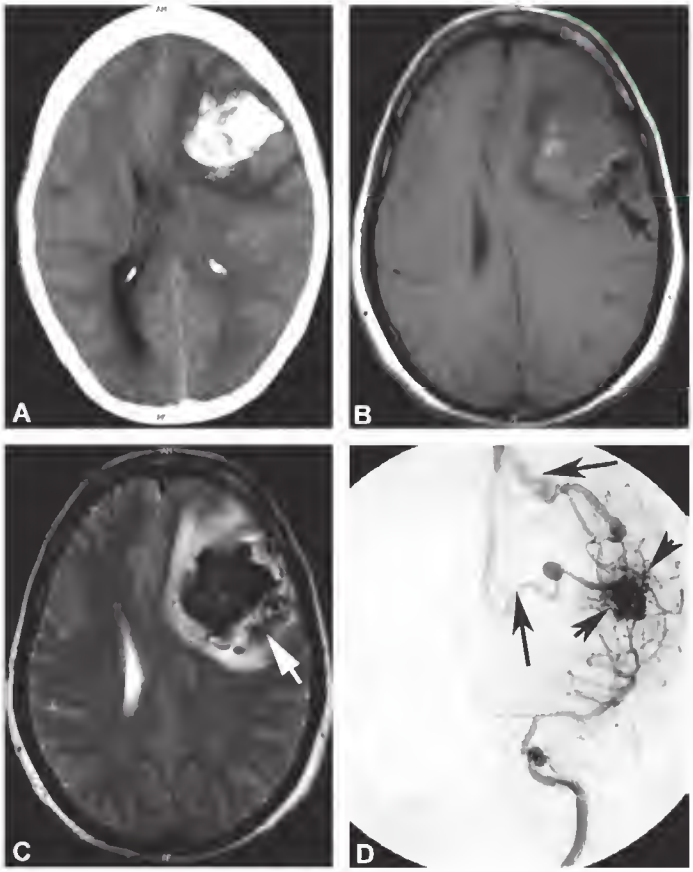
The various aetiological factors for ICH are listed in **Table 1**.

Table 1: Causes of Intra-Cerebral Haemorrhage

- **Abnormal blood vessels**
  - Vascular malformations
    - Arteriovenous malformations
    - Saccular aneurysms
    - Cavernous angiomas
    - Septic and mycotic aneurysms
  - Lipohyalinosis and microaneurysms
  - Amyloid angiopathy
  - Cerebral tumours
  - Cerebral venous thrombosis
  - Vasculitis
  - Moyamoya syndrome
  - Haemorrhagic transformation
- **Sytemic bleeding tendency**
  - Haemophilia
  - Leukaemia
  - Thrombocytopaenia
  - Anticoagulants
  - Antiplatelet agents
  - Thrombolytic agents
- **Illicit drugs**
  - Amphetamines
  - Cocaine
- **Hyperperfusion syndrome**
- **Trauma**

CHRONIC HYPERTENSION

The most common sites of hypertensive haemorrhage are deep grey matter (putamen, globus pallidus, and thalamus) (65%), subcortical white matter (10% to 20%), pons (10% to 15%), and cerebellum (8% to 10%) (**Figures 1A to D**). Haemorrhages have been associated with microscopic changes in blood vessels, but the exact mechanism is debated. Miliary aneurysms (Charcot-Bouchard aneurysms) are found on the lenticulostriate branches of the middle cerebral artery and paramedian branches of the basilar artery in nearly 50% of hypertensive patients over 66 years of age. Destruction of the tunica media through a process variably described as lipohyalinosis and fibrinoid necrosis on the other hand, is found in vessels within the area of ICH. An anatomic factor that may contribute to hypertensive ICH is that perforating vessels are small perpendicular branches directly off major arteries that are subject to much higher shear stress than cortical feeders, which reside at the end of the circulatory tree. It is likely that hypertension-induced ICH is the result of some combination of altered flow dynamics and histopathologic changes within the vasculature.



Figures 1A to D: Hypertensive haematomas. (A) Axial non-contrast CT scans show hyperdense acute intra-cerebral haematomas in the region of right external capsule/lentiform nucleus, (B) left thalamus, (C) pons and (D) right cerebellar hemisphere.

VASCULAR MALFORMATIONS

Up to 25% of ICH are attributable to bleeding from rupture of aneurysms and arteriovenous malformations (AVMs). Rupture of an aneurysm produces ICH in 5% to 25% of cases. If the aneurysm is adherent to the brain parenchyma, haemorrhage may be directed into the substance of the brain rather than purely into the subarachnoid space. In some cases the bleeding is actually limited to the parenchymal component, and no subarachnoid blood is found on computed tomography (CT) scan. Anterior communicating aneurysms may produce flame-shaped haemorrhages in the base of the frontal lobes.

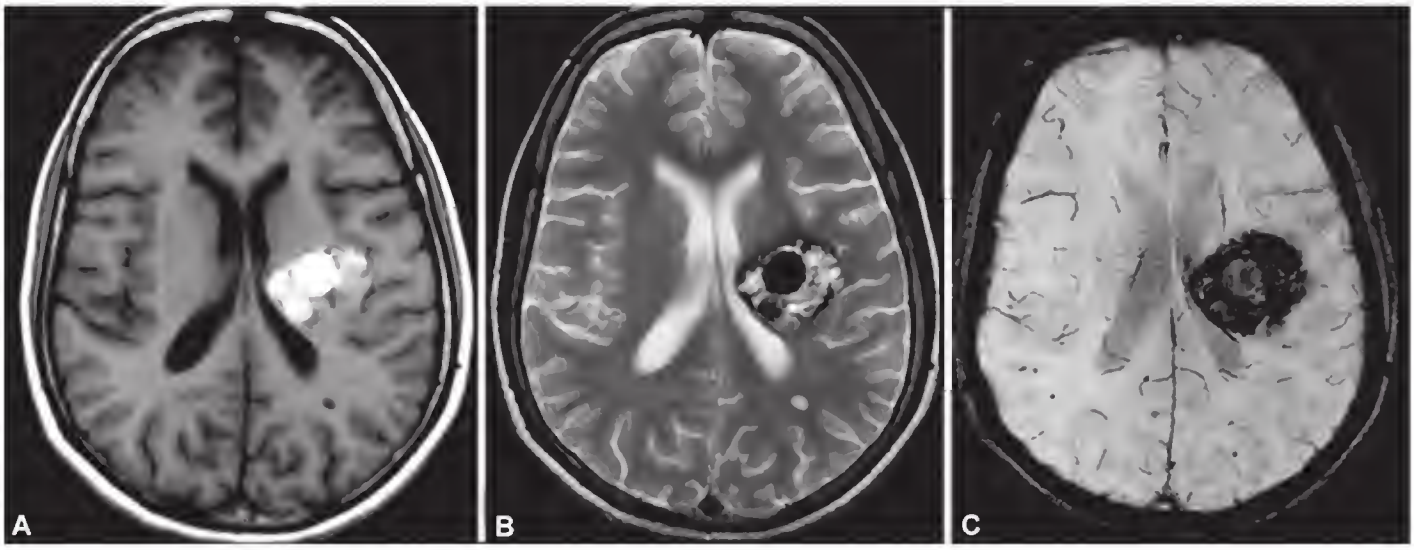
Over half of patients with AVMs present with some type of haemorrhage; 60% of which are parenchymal in location. Lesions are found throughout the cerebrum, brainstem, or cerebellum. AVMs characteristically rupture during the 2nd to 4th decades of life. Symptoms of AVM-induced ICH depend on location. Multiple calcified vascular channels may be seen within a haematoma on CT scan, suggesting the presence of an underlying AVM (**Figure 2A**). Magnetic resonance imaging (MRI) (**Figure 2B and C**) and four-vessel cerebral digital subtraction angiography are useful adjuncts in diagnosis and planning management (**Figure 2D**).

Figures 2A to D: (A) Axial non-contrast CT scan show hyperdense acute intra-cerebral haematoma in the left frontal lobe with surrounding hypodense oedema. (B) The haematoma is iso-hyperintense on T1-weighted image and (C) hypointense on T2-weighted image suggesting acute-early subacute stage. Note that hypointense flow-voids on the posterolateral aspect of haematoma on both T1-WI and T2-WI (short arrows in B and C), pointing to arteriovenous malformation as cause of haematoma. In intra-arterial digital substraction angiography, (D) left internal carotid angiogram show nidus of the arteriovenous malformation (short arrows in D) with early draining veins into superficial and deep venous systems (long arrows in D).

CEREBRAL AMYLOID ANGIOPATHY

This is characterised pathologically by the deposition of amyloid in cerebral vessels, primarily small and medium-sized arteries of the cortex and leptomeninges. The classical birefringent amyloid material is seen on histological examination in the media and adventitia, which stains positive for Congo red. The incidence of these histopathological changes at post-mortem increases steadily with age, occurring in as many 60% of unselected autopsies of individuals older than 90 years. The incidence of haemorrhage secondary to amyloid angiopathy also increases with age and is rare before the age of 55 years. The mechanism of rupture of affected arteries is thought to be either a weakening of the vessel wall or the formation of microaneurysms at the sites of amyloid deposition. It is strikingly restricted to vessels of the leptomeninges and grey matter, and usually stops abruptly when a penetrating vessel reaches a junction of the cortex and subcortical white matter. Haemorrhages in cerebral amyloid angiopathy are almost exclusively lobar and often superficially close to the surface, with the site of rupture usually being at the grey-white matter junction.

CAVERNOUS ANGIOMAS (CAVERNOMAS)



These are of unknown aetiology, but it has been suggested that at least part of the lesion forms as a localised reaction to small haemorrhages. These are mainly diagnosed from the characteristic MRI appearance of a central nidus of irregular bright signal intensity on T2-weighted imaging, surrounded by a peripheral hypointense ring resulting from haemosiderin deposition due to previous episodes of bleeding (**Figures 3A to C**). No abnormalities are seen on angiography. Cavernomas are predominantly supratentorial, most commonly affecting the temporal, frontal and parietal lobes. The most frequent infratentorial site is the pons. Cavernomas may present with seizures, intra-cerebral haemorrhage or progressive neurological deficit. The last of these is more likely to occur in brainstem cavernoma. The majority of cavernous angiomas are asymptomatic and are frequently found on MRI performed for other reasons. The outlook in the vast majority of asymptomatic cases is benign.

OTHER CAUSES

Approximately 10% of ICHs are attributable to coagulopathies, resulting from anticoagulation, platelet inhibition, thrombolytic therapy or underlying systemic disease (**Figure 4**). Warfarin, heparin, aspirin, dipyridamole, tissue plasminogen activator, streptokinase, and urokinase have all been implicated as causes of ICH. Additionally, ICH occurs in 1% to 2% of patients receiving anticoagulants for systemic indications. Systemic disease such as renal and hepatic failure, thrombocytopaenia and the leukaemias produce coagulopathic states that may also result in ICH. Haemorrhage from an underlying neoplasm is rare. This occasionally appears in malignant tumours, including glioblastoma multiforme, lymphoma, and metastatic tumours such as malignant melanoma, choriocarcinoma, renal cell and bronchogenic carcinoma. Benign tumours are almost never associated with ICH.

Infections may also result in ICH. Fungal infections predispose to cortical and subcortical haemorrhage by direct infiltration of the vessel wall by the organism. In its extreme form, herpes simplex may produce acute, necrotising encephalitis that preferentially affects the temporal and frontal lobes.

ICH may occur following reperfusion (e.g. following carotid endarterectomy or acute thrombolysis), 1 or 2 days after head

Figures 3A to C: Cavernoma. (A) Axial T1-weighted image show a iso-hyperintense lesion in the left corona radiata. (B) The lesion is of mixed signal intensity with hypointense rim in T2-weighted image and (C) blooms in susceptibility-weighted image, suggesting cavernoma.

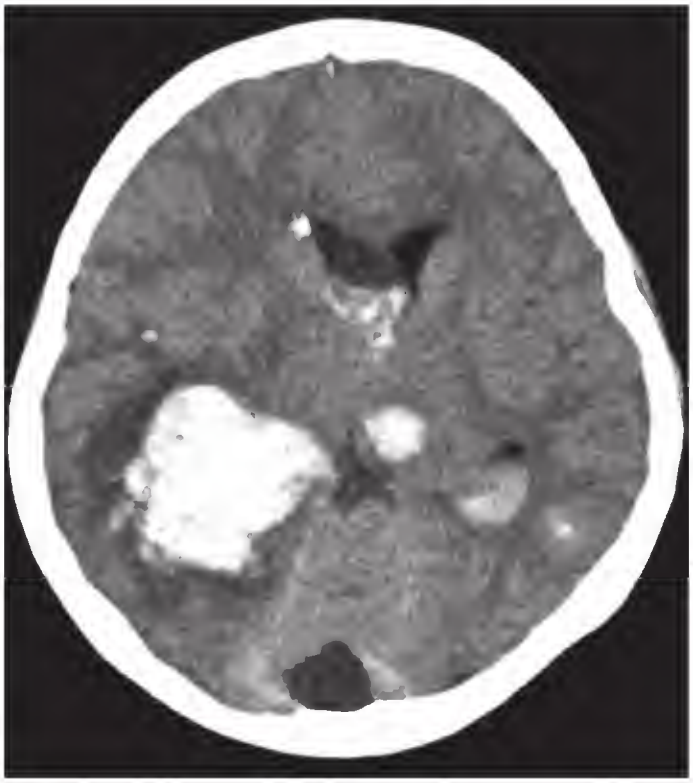


Figure 4: Haemophilia. Axial non-contrast CT scan show multifocal hyperdense acute haematomas of different sizes in both cerebral hemispheres with intraventricular extension.

trauma as a result of venous sinus occlusion, and consequent to the use of drugs such as cocaine, amphetamines, pseudoephidrine and phenylpropanolamine. Sinus thrombosis is associated with a variety of medical conditions, including pregnancy, dehydration, local or systemic infection, sickle cell trait, oral contraceptive use and hypercoagulable states.

CLINICAL FEATURES

The focal signs and symptoms accompanying ICH reflect the location of the haemorrhage and are indistinguishable from ischaemia occurring in the same vascular territory. Lobar haemorrhages frequently produce contralateral weakness or sensory loss, language disturbance, hemianopia or lesser field disorders, and parietal lobe signs. Their relationship to the cortex makes them more likely to be complicated by seizures. Seizure are more frequent in ICH, occurring in as many as a quarter of individuals, although they are also seen in about 5% of patients with ischaemia, particularly early after onset.

Occasionally, very small haematomas present with symptoms indistinguishable from transient ischaemic attacks (TIAs). However, majority of ICHs cause complete stroke.

Putaminal haemorrhages typically cause contralateral hemiparesis with variable degrees of sensory loss, ataxia and with larger haematomas, a homonymous hemianopia.

Thalamic haemorrhages can result in contralateral sensory loss and weakness, while if they extend to or compress the superior midbrain, they may result in depressed signs. Pontine haemorrhages often result in reduced consciousness, pinpoint pupils, bilateral weakness and pontine cranial nerve dysfunction, and may be severely disabling.

Cerebellar haemorrhages are particularly important to identify clinically as they may require surgical intervention, which can be life-saving. The onset can be deceptive, with initial non-specific brainstem symptoms (e.g. vertigo or double vision), followed a few hours or even days later by progressive clinical features, including gait, trunk or limb ataxia, nystagmus, headache, vomiting and coma from brainstem compression. Hemiparesis will be rare. The clinical course of cerebellar haemorrhage can be difficult to predict at onset. An abrupt deterioration may occur after a period of clinical stability. Moderate degrees of quadrigeminal cisternal compression predicts poor outcome unless the haematoma is evacuated early in the course. Severe mass effect on the cistern carries a poor prognosis.

INVESTIGATIONS

Plain CT scan of the brain remains the mainstay of diagnosis of ICH. Blood is easily seen and appears hyperdense on non-contrast enhanced CT scans. MRI is also very sensitive investigation to ICH provided the appropriate sequences are used. However, interpretation of haemorrhage on images is more complicated than with CT. Following haemorrhage, a

series of events occurs that can be detected using MRI; these include initial deoxygenation of the blood within the haemorrhage; its subsequent chemical breakdown from haemoglobin into methaemoglobin, and finally the formation of iron-containing haemosiderin deposits. Therefore, MRI can be used to distinguish between previous cerebral infarction and haemorrhage at a time when the appearances on CT are identical.

Certain radiological features characterise particular underlying causes of ICH. An AVM may be seen on MRI as a cluster of vascular channels with flow voids (**Figures 2B and C**). Cavernous angiomas appear as small areas of high signal on T2-weighted images surrounded by a ring of low intensity due to haemosiderin deposition (**Figure 3C**). Haemorrhage secondary to tumours can contain complex mixtures of increased and decreased signals related to the presence of viable tumour, necrotic tissue, calcification and haemorrhage occurring at various time points. Cerebral vasculitis may be suggested by the concurrent appearance of both ischaemic and haemorrhagic lesions. Angiography (conventional four vessel; magnetic resonance angiography (MRA) or CT angiography) will be required to exclude a treatable source of recurrence, such as aneurysm, AVM, etc.

TREATMENT

Treatment of Acute ICH

1. Potential treatments of ICH include stopping or slowing the initial bleeding during the first few hours after the onset.
2. Removing blood from the parenchyma or ventricles.
3. Management of raised intra-cranial pressure (ICP) and decreased cerebral perfusion.
4. Good general supportive management.

Patients with ICH require considerable attention to the ABCs of resuscitation and rapid correction of deranged parameters. Up to 50% of these patients may require mechanical ventilation. Recent evidence indicates that many haematomas undergo enlargement over the first few hours suggesting that aggressive correction of coagulopathies might be helpful.

Consensus on Managing Blood Pressure

Early after ICH, there appears to be no compelling need to treat hypertension aggressively unless there are signs of systemic complications especially in the setting of large bleeds with raised ICP. However, new data suggest that modest (15%) reduction of blood pressure (BP) does not lower cerebral blood flow (CBF) in patients within 24 hours of ICH. Thus, modest reduction in blood pressure of very hypertensive patients (MAP >130 mm Hg) is indicated. Further studies to validate the level of BP lowering are in progress.

Choice of Antihypertensives

The most appropriate antihypertensive agent to use in ICH patients is one that has a short half-life and moderate efficacy with minimal cerebrovascular effects. Drugs should be administered so as to avoid sudden large drops in blood pressure. Vasodilators, especially those that dilate veins, can raise ICP by increasing cerebral blood volume and should be avoided. Sodium nitroprusside and nitroglycerin increase. ICP and lower cerebral blood flow in patients with reduced intra-cranial compliance. Labetalol, a combined alpha blocker and beta blocker, does not alter ICP or CBF; thus making it a popular agent making it a popular agent. However, large doses may be required to counteract the sympathetic nervous system stimulation associated with ICH. Other useful agents include hydralazine, and the calcium channel blockers, nicardipine and angiotensin converting enzyme inhibitors, enalapril.

Management of Increased Intra-Cranial Pressure

ICP is considered a major contributor to mortality after ICH. ICP may be managed through osmotherapy, controlled hypertension and barbiturate coma. Elevated ICP is defined as intra-cranial pressure more than or equal to 20 mm Hg for more than 5 minutes. A therapeutic goal of all treatments of raised ICP is less than 20 mm Hg and cerebral perfusion pressure (CPP) of more than 70 mm Hg. Patients with suspected elevated ICP and deteriorating level of consciousness are candidates for invasive ICP monitoring. Intraventricular ICP monitors and intrapare-nchymal fiberoptic ICP devises are two commonly used methods of monitoring ICP.

The CPP-guided therapy focuses on maintaining a CPP of more than 70 mm Hg to minimise reflex vasodilation or ischaemia. Despite long standing debates, no controlled trial has demonstrated the superiority of approaches. A balanced approach begins with simple and less aggressive measures, such as head positioning, analgesia and sedation and then progresses to more aggressive measures.

Head of bed elevation

Elevation of the head of the bed to 30 degress improves jugular venous outflow and lowers ICP.

Osmotic therapy

The most commonly used agent is mannitol, an intravascular osmotic agent, that can draw fluid from both oedematous and non-oedematous brain tissue. It also decreases ICP through cerebral autoregulation. Mannitol decreases blood viscosity that results in reflex vasoconstriction and decreased cerebrovascular volume. The first medical line of defence is osmotherpay. However, it should not be used prophylactically. Mannitol 20% (0.25 to 0.5 g/kg every 4 hours) is reserved for patients with type B ICP waves, progressively increasing ICP values, or clinical deterioration associated with mass effect. Due to rebound phenomenon, mannitol is recommended for only few days to a week. To maintain an osmotic gradient, frusemide (10 mg 2 to 8 hourly) may be administered simultaneously with osmotherapy. Serum osmolarity should be measured twice daily in patients receiving osmotherapy and targeted to less than or equal to 310 mOsm/L.

Hypertonic saline

Solutions have been shown to reduce ICP in some cases of refractory raised ICP to mannitol and hyper-ventilation. Exact dose, concentration and mode are not clarified.

Cerebrospinal fluid (CSF) drainage

When an intraventricular catheter is used to monitor ICP, CSF drainage is an effective method for lowering ICP, particularly in the setting of hydrocephalus. The principal risks associated with ventriculostomy are infection and haemorrhage. In addition to the mass effect of the haematomas, secondary hydrocephalus may contribute to elevated ICP. Ventricular drains should be

used in patients with or at risk for hydrocephalus. Use prophylactic antibiotics and preferably remote catheter early but not later than 7 days.

Neuromuscular blockade

Muscle activity may further raise ICP by increasing intrathoracic pressure and obstructing cerebral venous outflow. If the patient is not responsive to analgesia and sedation alone, neuromuscular blockade is considered.

Hyperventilation

Hyperventilation is one of the most effective methods to reduce raised ICP. However, it has fallen out of favour primarily because of the simultaneous effect of lowering CBF. And it is also transient in its effect. In fact, after a patient has been hyperventilated for more than 6 hours, rapid normalisation of arterial partial pressure of carbon dioxide can cause a significant rebound increase in the ICP.

Barbiturate coma

High-dose barbiturate treatment acts by depressing cerebral metabolic activity. This results in reduction in CBF, which is coupled to metabolism, and a fall in ICP. The use of barbiturates in the treatment of refractory ICP requires intensive monitoring and is associated with a significant risk of complications.

Surgery

Evacuation of haematoma; VP shunts, etc.

MANAGEMENT OF GLUCOSE LEVELS

Evidence indicates that persistent hyperglycaemia (>140 mg/dL) during the first 24 hours after stroke is associated with poor outcomes, and thus, it is generally agreed that hyperglycaemia should be treated in patients with acute stroke. The management for ICH and ischaemic strokes are similar.

Fluid Management

The goal is euvolaemia. If hypovolaemia is thought to contribute to hypotension, central venous pressure (CVP) should be maintained between 5 mm Hg and 12 mm Hg. Electrolytes should be checked and substituted; acidosis and alkalosis should be corrected according to blood gas analysis.

Prevention of Seizures

Seizure activity can result in neuronal injury and destabilisation of an already critically ill patient and must be treated aggressively. Additionally, non-convulsive seizures may contribute to coma in less than or equal to 10% of neurocritical care patients. In patients with ICH, prophylactic AED may be considered for a month and then tapered and discontinued if no seizure activity occurs during treatment.

Management of Body Temperature

Normothermia should be maintained. Acetaminophen or cooling blankets may be used to treat hyperthermia. Use antibiotics if infection is suspected.

Other Medical Management Issues

Pulmonary embolism is a common threat during the recovery period, particularly for bedridden patients with hemiplegia. Pneumatic devices decrease the risk of pulmonary embolism during hospitalisation. Randomised trials of medical therapy for ICH comparing steroid versus placebo, haemodilution versus best medical therapy and glycerol versus placebo did not reveal significant benefit for the use of these agents. Depending on the patients clinical state, physical therapy, speech therapy and occupational therapy should be instituted as soon as possible.

Recommendations for Initial Medical Therapy

Class I evidence

1. Monitoring and management of patients with ICH should take place in an intensive care unit setting because of the severity and complexity of the condition.
2. Appropriate anti-epileptic therapy should be used for treatment of clinical seizures in patients with ICH.
3. Sources of fever should be treated and antipyretic medications should be administered to lower temperatures in febrile patients with stroke.
4. Early mobilisation and rehabilitation are recommended in patients with ICH who are clinically stable.

Class II evidence

1. Treatment of elevated ICP should include a balanced and graded approach that begins with simple measures such as elevation of the head of the bed and analgesia and sedation and followed by aggressive treatment as outlined above.
2. Evidence indicates that persistent hyperglycemia (>140 mg/dL) should be treated in patients with acute stroke.
3. Blood pressure management: The blood pressure has to be lowered by 10% to 15% and rather slowly.
4. A brief period of prophylactic anti-epileptic therapy soon after ICH onset may reduce the risk of early seizures in patients with lobar haemorrhage.

Recommendations for Prevention of Deep Vein Thrombosis and Pulmonary Embolism

Class I

1. Patients with acute primary ICH and hemiparesis should have intermittent pneumatic compression for prevention of venous thromboembolism.
2. Treatment of hypertension should always be part of long-term therapy because such therapy decreases the risk of recurrent ICH.

Class II

1. After documentation of cessation of bleeding, low-dose subcutaneous low-molecular weight heparin or unfractionated heparin may be considered in patients with hemiplegia after 3 to 4 days from onset.
2. Patients with an ICH who develop an acute proximal venous thrombosis, particularly those with clinical or sub-clinical pulmonary emboli, should be considered for acute placement of a vena cava filter.
3. The decision to add long-term anti-thrombotic therapy several weeks or more after placement of a vena cava filter must take into consideration the likely cause of the haemorrhage, associated conditions with increased arterial thrombotic risk and the overall health and mobility of the patient.

Potential New Treatments for ICH

Potential new treatments for ICH include stopping or slowing the bleeding during the first several hours, removing the

bleeding during the first several hours, removing the blood after the bleeding has stopped and delivering agents that limit the effects of blood.

HOW OFTEN DOES ICH GROW?

Before the 1990, the accepted wisdom was that bleeding in ICH occurred over minutes and then remained stable.

In a study where repeated CT scans were done was surprisingly seen, the haematomas continued to grow significantly) an increase of more than 33% in volume), after the first CT in 38% of patients; 26% within 1 hour and 12% between 1 and 20 hours. This growth occurred in all locations and was associated with clinical deterioration on the NIH stroke scale (NIHSS) and Glasgow coma scale (GCS) scores.

The only consistently identified risk factor for early haematoma growth is the interval between symptom onset and the initial CT; the earlier the CT, the more likely it is that a follow-up CT will show enlargement. Other risk factors that have been identified include liver disease, a history of cerebral infarction, hypertension, hyperglycaemia, irregular haematoma shape, depressed level of consciousness, alcohol use, and reduced fibrinogen levels, but these have not yet been confirmed.

The pathogenesis of early haematoma growth is poorly understood. The reasonable and conventional notion is that haematoma growth results from persistent bleeding or re-bleeding from a single arterial or arteriolar rupture. Several lines of evidence also suggest that early haematoma enlargement may also result from secondary bleeding into perilesional tissue in the periphery of the clot.

RATIONALE FOR ULTRA-EARLY HAEMOSTATIC THERAPY FOR INTRA-CEREBRAL HAEMORRHAGE

The three most consistently identified predictors of poor outcome after ICH are haematoma volume, the presence of intra-ventricular haemorrhage and depressed level of consciousness. Of these, haematoma volume has been identified as the single most powerful predictor of 30-day mortality after ICH. Given the evidence that ongoing bleeding can occur for several hours after onset, it is plausible that ultra-early haemostatic therapy might minimise haematoma volume and improve outcome.

In patients with normal coagulation, the most feasible haemostatic agents for ultra-early ICH therapy include the antifibrinolytic amino acids, aminocaproic acid and tranexamic acid, aprotinin and activated recombinant factor VII (rFVIIa).

Since these drugs primarily inhibit fibrinolysis, these are more suitable for clot stabilisation than for the promotion of clot formation. Clinical trials indicate that these agents reduce the frequency of rebleeding after aneurysmal sub-arachnoid haemorrhage but increase the frequency of delayed cerebral ischaemia and other thrombotic complications resulting in no overall benefit on the outcome.

Aprotinin is a polypeptide that inhibits the action of several serine proteases including plasmin and kallikrein. Aprotinin primarily inhibits the initiation of both coagulation and fibrinolysis induced by contact of blood with a foreign surface but it has no effect on platelet function. Its main indication is for reducing peri-operative bleeding including cardiac surgery rather than treating spontaneous internal bleeding.

FVIIa is an important natural initiator of haemostasis and exerts its primary effects locally in regions of endothelial disruption and vascular injury. Pharmacological doses of rFVIIa amplify this process. In 9 years of clinical use for the treatment of haemophilic patients with inhibitors, rFVIIa has been associated with a low risk of systemic coagulation or thromboembolic complications and has a good record for treating intra-cranial haemorrhages. Preliminary clinical trials indicate that rFVIIa also promotes haemostasis in patients with normal coagulation systems. It is rapidly acting and has a relatively short half-life of 2.5 hours which corresponds well with the duration of high risk for continued bleeding in the acute stage of ICH.

Trials of recombinant activated factor VII were not contributory or at best inconclusive.

SURGICAL THERAPY

The four recognised surgical procedures to evacuate an ICH are simple aspiration, craniotomy with open surgery, endoscopic evacuation and stereotactic aspiration. Their use in clinical practice is inconsistent. In some countries, e.g. the Netherlands, these are rarely performed; in others, e.g. in USA, these are undertaken in about 20% of patients with ICH and in others, e.g. some centres in Germany and Japan, they are offered to 50% or more of patients. Such wide variation in practice reflects uncertainty about the effectiveness and risks of surgery due to lack of appropriate evidence.

CEREBELLAR HAEMATOMA

Indications of surgery are less controversial than supratentorial ICH. The selection criteria include, impaired consciousness with preserved brainstem reflexes, and perhaps large haematomas (>3 cm to 4 cm in diameter) and vermis haematomas distorting the quadrigeminal cistern even in alert patients, because delayed decline in consciousness and death can be extremely rapid. Trials in cerebellar haematoma showed benefit in small haematomas, in patients put on less invasive surgical procedures like endoscopic aspiration and stereotactic aspiration. Over a period the consensus has been developed as below.

Consensus Guidelines

Surgery for Primary Intra-cerebral Haemorrhage

Recommendations for surgical approaches

Class I:

Patients with cerebellar haemorrhage more than 3 cm who are deteriorating neurologically or who have brainstem compression and/or hydrocephalus from ventricular obstruction should have surgical removal of the haemorrhage as soon as possible.

Class II:

1. Although stereotactic infusion of urokinase into the clot cavity within 72 hours of ictus apparently reduces the clot burden and risk of death, re-bleeding is more common, and functional outcome is not improved; therefore, its usefulness is unknown.
2. Although theoretically attractive, the usefulness of minimally invasive clot evacuation utilising a variety of

mechanical devices and/or endoscopy awaits further testing in clinical testing; therefore, its current usefulness is unknown.

3. For patients presenting with lobar clots within 1 cm of the surface, evacuation of supratentorial ICH by standard craniotomy might be considered.

Class III:

The routine evacuation of supratentorial ICH by standard craniotomy within 96 hours of ictus is not recommended. Possible exception is for patients presenting with lobar clots within 1 cm of the surface.

Recommendations for timing of surgery

Class II:

No clear evidence at present indicates that ultra-early craniotomy improves functional outcome or mortality rate. Operative removal within 12 hours particularly when performed by less-invasive methods, has the most supportive evidence, but the number of subjects treated within this window is very small.

Class III:

Delayed evacuation by craniotomy appears to offer little if any benefit with a fairly high degree of certainty. In those patients presenting in coma with deep haemorrhages, removal of ICH by craniotomy may actually worsen outcome and is not recommended.

Recommendations for decompressive craniectomy

Class II:

Too few data currently exist to comment on the potential of decompressive craniectomy to improve outcome in ICH.

THE ICH SCORE

In an attempt to develop a standard clinical grading scale for ICH analogous to those for traumatic brain injury, SAH or ischaemic stroke, Hemphil *et al* developed the ICH score. The factors included for ICH score were:

GCS score—3 to 4 (2 points), 5 to 12 (1 point), 13 to 15 (0 point); age >80 years—yes (1 point), no (0 point); infratentorial origin of ICH—yes (1 point), no (0 point); ICH volume >30 cm^3 (1 point), <30 cm^3 (0 point), and intraventricular extension—yes (1 point); no (0 point). All 26 patients with an ICH score of 0 survived and all 6 patients with an ICH score of 5 died. Thirty-day mortality increased steadily with ICH score ($p < 0.005$). The ICH score is a simple clinical grading scale that allows risk stratification on presentation with ICH. The use of a scale such as the ICH score could improve standardisation of clinical treatment protocols and clinical research studies in ICH.

The time is nearing when ICH will join ischaemic stroke and SAH as a cerebrovascular disease with scientifically proven therapies.

20.10 Cerebrovenous Thrombotic Disorder

D Nagaraja, N Karthik

Cerebral veno-sinous thrombosis (CVT) involves the thrombosis of the cortical veins and the draining venous sinuses, either alone or in combination. This distinct cerebrovascular condition frequently affects young adults and children. About 75% of the adult patients affected by CVT are women, but this trend is not seen among children or elderly persons. CVT is an important cause of maternal morbidity and mortality in India. Puerperal CVT has been reported to be about 10 to 12 times more frequent in India than in the West.

AETIOLOGY AND PATHOGENESIS

There are a number of causes of CVT. In about 80% to 85% of patients with CVT in developed countries, a direct cause or pro-thrombotic risk factor can be identified. In a patient with such an underlying risk, a precipitating factor such as delivery, dehydration, infection or injury may result in CVT. In all these situations, the common underlying pathogenetic mechanisms include hyper-coagulable state, decreased fibrinolytic activity, slowing of circulation, damage to the endothelium and other unknown mechanisms

Despite new diagnostic technologies, the exact cause of puerperal CVT is still unclear and several predisposing factors are being continuously described. Observational studies have shown a higher platelet adhesive index, platelet adhesive number, serum triglyceride, phospholipids, fatty acid level and elevated plasma fibrinogen levels compared to controls. Elevated Factor VIII:C independently increases thrombotic risk. A population based case control study showed that FVIII:C of greater than 150% is associated with an adjusted odds ratio of 4.8 for a first episode of CVT compared to levels under 100%. In addition, the presence of moderate to severe anaemia has been observed in most patients, with about 56% having haemoglobin less than 10 g/dL. Various genetic thrombophilic conditions such as those associated with factor V Leiden, prothrombin variant G20210A and MTHFR C677T mutations have been identified as risk factors for venous thrombosis. Factor V Leiden mutation resulting in resistance to activated protein C is the most common genetic risk factor for venous thrombosis in Caucasian population. It has been reported to be present in about 4% to 5% of the normal white population, but absent from the indigenous populations of Asia, Africa, America and Australia. The second commonest genetic polymorphism in Caucasians is a variant in the prothrombin (factor II) gene comprising a G to A transition in the 32-untranslated region at nucleotide position 20210. In the European general population, with CVT its frequency is seen as high as 50%. Another polymorphism involves the gene that encodes methylene tetrahydrofolate reductase enzyme (MTHFR) (677C >T) which results in substitution of alanine to valine and produces a thermolabile enzyme with reduced activity. With regard to venous thrombosis, a meta-analysis showed that the MTHFR 677TT genotype was associated with a 20% higher risk of venous thrombosis compared to the 677CC genotype.

Oral contraceptives, especially third-generation contraceptives that contain gestodene or desogestrel have an increased risk of CVT. However, it plays an insignificant role in developing countries. Anti-phospholipid antibody syndrome has been recognised as an important cause of CVT. Anti-cardiolipin antibodies have been detected in 23% of patients with CVT compared to controls from India suggesting it to be an important risk marker. CVT can occur after trauma, neurosurgical procedures. Local infections in the head and face area are notorious to cause sinus thrombosis (cavernous, transverse and sigmoid sinus thrombosis). Meningitis can predispose to more generalised thrombosis of the veins/sinuses.

Recently hyper-homocysteinaemia has been identified as independent risk factor for CVT. Over 50% of the patients with CVT are observed to have elevated homocysteine. Various genetic mutations involving homocysteine have been studied. Only MTHFR C677T mutation has been found to influence homocysteine levels in 5% to 10% of patients and controls. Folate deficiency and to lesser extent B12 deficiency was found to influence high levels of homocysteine in over 50%. Unlike in Caucasians, factor V Leiden, factor V A4070G, prothrombin G20210A, factor VII G353A gene mutations do not have any significant role in Indian patients with CVT. Elevated factor VIII elevated anti-phospholipid antibodies are the other common risk factors associated with increased CVT risk. Often, more than one risk factor may co-exist in CVT.

CLINICAL FEATURES

The presenting features of CVT usually depend upon the sinuses involved, speed of occlusion, involvement of the cortical veins and the presence of collaterals. The common symptoms of CVT include headache, seizures, vomiting, focal deficit and fever. The most frequent but least specific symptom of sinus thrombosis, present in over 90% of adult patients, is severe headache. It is gradual in onset, usually increasing over a period of days to weeks, severe in intensity and often bilateral with associated vomiting. However, it can also be catastrophic such as in sub-arachnoid haemorrhage. Seizures, the next commonest symptom, occur in about 40% to 70% of patients. They may be focal but more commonly generalised. Life-threatening status epilepticus or clusters may be seen in 20% patients. Neurological signs develop in 50% of patients with sinus thrombosis and include monoparesis, hemiparesis or paraparesis. At times, patients may show only extensor plantar response. Unlike puerperal CVT, symptoms develop less rapidly in the non-puerperal group.

Based on the clinical symptoms and signs, the following distinct syndromes can be seen in patients with CVT:

1. Syndrome of dural sinus and cortical vein thrombosis (commonest)
2. Syndrome of deep venous system occlusion
3. Syndrome of cavernous sinus thrombosis

4. Syndrome of increased intra-cranial tension without motor weakness.

INVESTIGATIONS

Cranial Computed Tomography

It is a useful initial technique to diagnose CVT and rule out other acute cerebral disorders. However, it can be entirely normal in 10% of patients. The findings include 'direct signs', i.e. primarily caused by the thrombosis of veins and sinuses and 'indirect signs' when they are secondary to the effects of thrombosis.

1. Direct signs of CVT

a. *Cord sign:* In a non-contrast enhanced computed tomography (CT), the fresh clot in the cerebral veins and sinuses appears hyperdense; and is referred to as cord sign. It is commonly seen in cortical veins, straight sinus and vein of Galen. False positive cord sign may be in children and in conditions with haemo-concentration (**Figure 1A**).

b. *Dense delta sign:* It is seen in non-contrast enhanced CT. In the axial section, the superior sagittal sinus appears as a hyperdense triangle (**Figure 1B**).

2. Empty delta sign

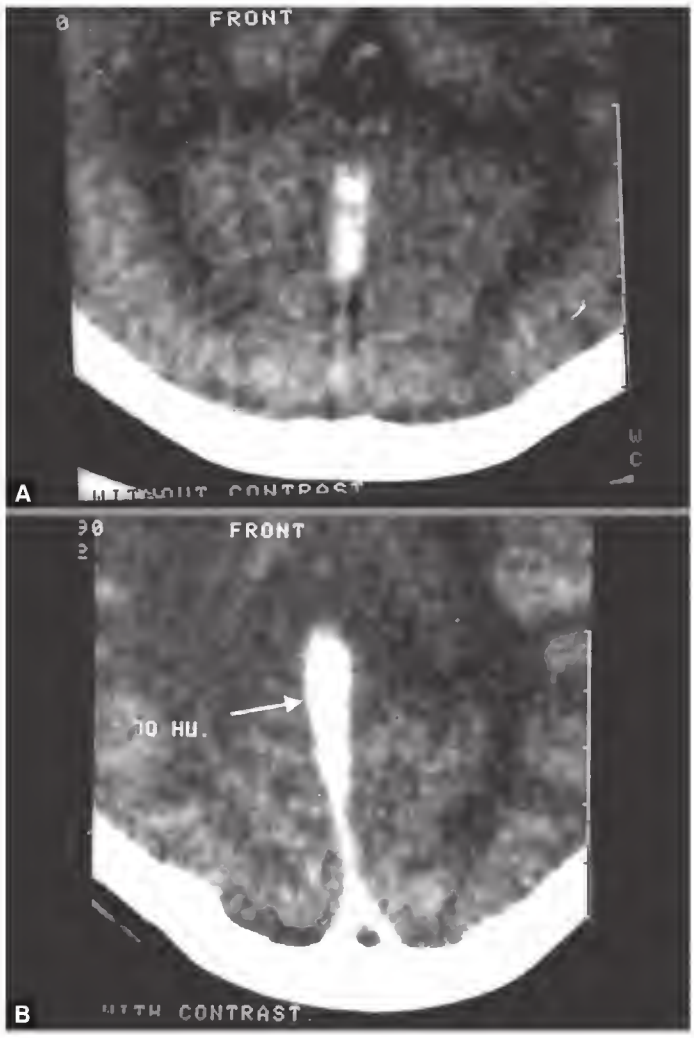
In contrast enhanced CT, a triangular shaped hypodensity surrounded by hyperdense rim is observed. This is most commonly seen in the posterior part of the superior sagittal sinus, straight sinus and transverse sinus. It is the most frequent direct sign of CVT.

3. Indirect signs of CVT

Indirect signs are more frequent. Venous stasis and hyperaemia caused by occlusion of the straight sinus and superior sagittal sinus may lead to intense enhancement of the falx cerebri and tentorium. Non-contrast enhanced CT may show irregular hyperdense or mixed density lesions suggestive of haemorrhagic infarctions which are either small or large, single or multiple. These may not confirm to known arterial territories. Non-haemorrhagic infarctions are also common. In addition, diffuse oedema of the brain may be seen.

CT venography is a promising technique for creating images of the cerebral venous system using helical CT technology. The appearance of dural sinus thrombosis at CT venography is that of a filling defect within the thrombosed dural sinus, alone or in association with a venous infarct.

Magnetic Resonance Imaging



The introduction of magnetic resonance imaging (MRI) has made the diagnosis of CVT possible non-invasively. The following are the changes seen in the MRI.

1. Thrombosed sinus with occlusion

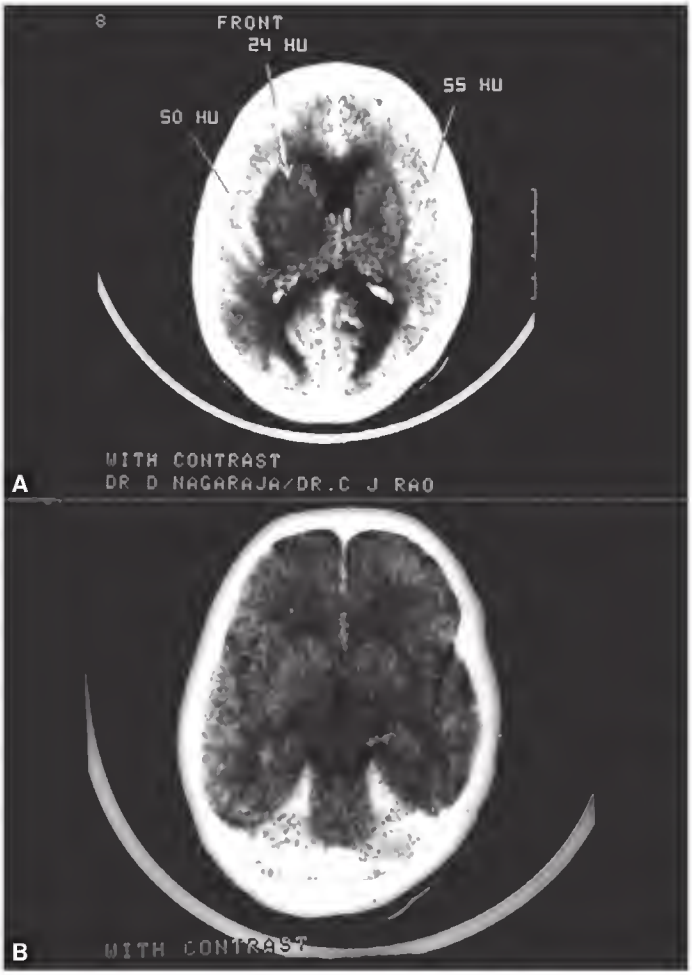
Early thrombus, which contains deoxyhaemoglobin is isointense on T1-weighted and hypointense on T2-weighted image. This is usually seen during the first five days of CVT. Subacute thrombus, which contains methaemoglobin, shows a hyperintense signal on T1-weighted and T2-weighted MRI.

2. Venous infarct

Acute venous infarcts may often be haemorrhagic and appear iso- to mildly hyperintense on T1-weighted and hypointense on T2-weighted image.

Figures 1A and B: (A) Cord sign CT scan without contrast; (B) Delta sign CT scan with contrast.

3. Diffuse cerebral oedema



Venous congestion of the brain leads to sulcal effacement and slit-like ventricles.

Magnetic Resonance Venography

It shows either reduction in rate of flow from the involved sinus which is not aplastic or hypoplastic on source images, presence of frayed appearance of flow signal from the sinus after recanalisation. The combination of an abnormal signal in a sinus and a corresponding absence of flow on magnetic resonance venography confirms the diagnosis of thrombosis (**Figures 2A and B**).

Digital Subtraction Angiograph (DSA)

DSA is the gold standard for the diagnosis of CVT. It provides better details of the cerebral veins and hence is useful in the diagnosis of rare cases of isolated thrombosis of the cortical veins without sinus thrombosis. The characteristic angiographic signs are non-filling of the cortical veins or dural sinuses (**Figure 3**), slowing of circulation and stagnation of the contrast medium in the capillary and venous phases. Angiography also shows dilated and tortuous ('corkscrew') veins, which are evidence of thrombosis downstream in the sinuses.

Figures 2A and B: (A) Contrast scan—Bilateral deep venous infarction with peripheral enhancement; (B) Contrast scan—Intense tentorial enhancement.

Other Laboratory Investigations

Other studies include a complete haematological profile, coagulation work-up including prothrombin time, activated partial thromboplastin time, pro-coagulant profile (antiphospholipid antibody, serum homocysteine, Protein C/Protein S, antithrombin III), blood sugar, liver and renal function tests, cardiac evaluation and systemic screening for malignancy.

MANAGEMENT

Combination of acutely increased intra-cranial pressure and large venous infarcts is potential for cerebral herniation. But, these patients can make a remarkable recovery. The priority of treatment in the acute phase is to stabilise the patient's condition and to prevent or reverse cerebral herniation. Raised intra-cranial pressure should be tackled with aggressive osmotic agents such as mannitol with supportive ventilation as and when required. Surgical removal of the infarct or decompressive hemicraniectomy may be attempted in patients not responding to the above regime as a last resort. In addition, it is imperative to evaluate and treat possible causes of sinus thrombosis, such as infections. Anti-epileptic medications should be given to all patients of CVT irrespective of the occurrence of seizures as convulsions can further worsen the intra-cranial hypertension.

Anticoagulation

Prior to the introduction of heparin therapy, the outcome of CVT was uniformly poor with a high mortality. The most obvious rationale is that heparin may arrest the progression of thrombotic process and prevent pulmonary embolism. The ideal dose of heparin that would be beneficial without increasing the risk of intra-cranial haemorrhage is still debated. There is no increased risk of cerebral haemorrhages after treatment with heparin with conventional doses of heparin at 1,000 units per hour, but regular monitoring of APTT is required. Medium dose (5,000 units 8 hourly) and low dose (2,500 units 8 hourly) have been found to be effective (medium better than low) with better safety profile. As such, there is no necessity of monitoring of APTT with low and medium dose regimens. As per recent guidelines, patients with CVT without contraindications for anticoagulation should be treated either with body weight-adjusted subcutaneous low molecular weight heparin or dose-adjusted heparin. Concomitant intra-cranial haemorrhage related to CVT is not a contraindication for heparin therapy. The optimal duration of oral anticoagulant treatment after the acute phase is unclear. Oral anticoagulation may be given for 3 to 6 months. If CVT was idiopathic or secondary to transient risk factor, hereditary thrombophilia with a target INR of 2.5 for 6 to 12 months in patients with mild hereditary thrombophilia with a target INR of 2 to 2.5. In puerperal CVT, anti-coagulation is recommended for a period of 6 to 12 weeks as the recurrence of CVT beyond this period is rare. Recurrent sinus thrombosis occurs in 2% of patients, and about 4% of patients have an extra-cranial thrombotic event within one year. Indefinite anticoagulation should be considered in patients with two or more episodes of CVT or in those with 'severe' hereditary thrombophilia.

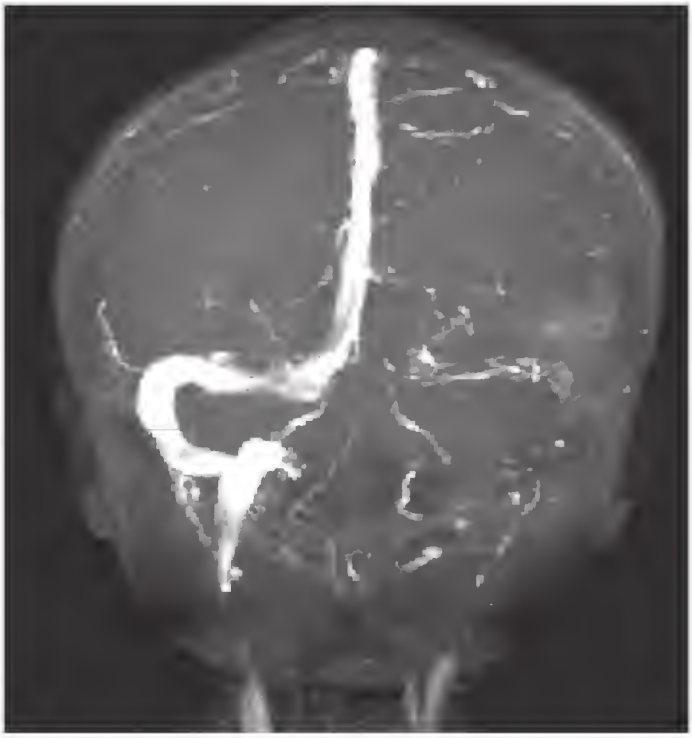


Figure 3: Digital subtraction angiogram showing non-visualisation of left transverse and sigmoid sinus.

Thrombolysis

Rationale of thrombolytic therapy is to obtain a rapid recanalisation of vessels affected and thereby stop the clinical deterioration. Endovascular thrombolysis can be attempted with instillation of thrombolytic enzyme, usually urokinase, into the sinus, sometimes in combination with mechanical thrombo-aspiration. Thrombolysis may be used systemically. The results are not well validated.

COURSE AND PROGNOSIS

More than 80% of all patients now have a good neurologic outcome. In the present era, mortality has fallen from 20% to 50% in the pre-CT period to less than 10%. Puerperal CVT has poorer outcome than non-puerperal cases. Similarly, the symptomatic CVT group has a less favourable outcome. Poor prognostic factors include prolonged deep coma, massive haemorrhagic infarction with midline shift and brainstem compression, rapidly progressive course and involvement of the deep venous system. Deaths in CVT are usually caused by mass effect with herniation. With low morbidity only a small proportion is left with neurological sequelae. Recurrence of CVT is also rare unless associated with inherited pro-thrombotic state.

20.11 Bacterial Meningitis and Brain Abscess

Ravindra Kumar Garg

BACTERIAL MENINGITIS

Bacterial meningitis is defined as bacterial invasion and subsequent inflammation of pia-arachnoid matter and exudation in cerebrospinal fluid (CSF) of the subarachnoid space. Bacterial meningitis is a potentially life-threatening condition if left untreated. The grave potential for severe neurological damage or even death necessitates prompt medical attention and evaluation.

Epidemiology

Bacterial meningitis has an annual incidence of 4 to 6 cases per 100,000 adults. At present about 1.2 million sporadic cases of bacterial meningitis occur annually worldwide with approximately 135,000 deaths. Bacterial meningitis is much more common in developing and poor countries than developed nations. In developed countries, previously *Haemophilus influenzae* was the most common cause of community-acquired meningitis; following the introduction of effective vaccination, the frequency of meningitis caused by this organism has declined by 82%. At present *Streptococcus pneumoniae* and *Neisseria meningitidis* are responsible for approximately 80% of all cases. In India *Salmonella* species have also been reported to cause meningitis.

Pneumococcal meningitis is often associated with distant infection, such as pneumonia, otitis media, mastoiditis, sinusitis or endocarditis. The triad of pneumococcal pneumonia, meningitis, and endocarditis is a rare but serious condition, known as Austrian syndrome. Predisposing conditions include splenectomy or asplenic state, multiple myeloma, hypogammaglobulinaemia, alcoholism and liver cirrhosis.

Meningococci are transmitted through respiratory droplets. Most cases of invasive disease occur in children and young adults. Meningococcal infection is possibly the most common cause of bacterial meningitis in India and vast majority of cases are sporadic.

Listeria monocytogenes is associated with exceptionally high mortality. *Listeria* meningitis is more frequently seen in neonates, the elderly, alcoholics, diabetics, and in patients with immunocompromised states. Meningitis due to Gram-negative bacilli is unusual except at the extremes of life. *Escherichia coli* are cultured from 30% to 50% neonatal patients of bacterial meningitis. *Klebsiella* species, *Escherichia coli*, and *Pseudomonas aeruginosa* may be isolated in CSF following head trauma or neurosurgical procedures.

Pathogenesis

The common bacteria causing meningitis are transmitted via air-borne route. Bacteria after colonising the nasopharyngeal mucosa secrete immunoglobulin (Ig)A protease enzymes that breakdown the protective mucous barrier allowing bacterial attachment to the epithelium. The outer adhesive bacterial pili (finger-like projections) also play an important role in the attachment of the encapsulated bacteria to the nasopharyngeal mucosa. After attachment bacteria invade the adjacent intravascular space and gain access to the blood stream and finally enter into the CSF through the choroid plexus of the lateral ventricles, and other points where blood-brain barrier is weak. Once bacteria reach the CSF these rapidly multiply because host humoral defence mechanisms in CSF are deficient. Alternatively, bacterial meningitis can occur by haematogenous spread of bacteria, through congenital neuroectodermal defects, craniotomy sites, middle ear diseases, paranasal sinus infections and skull fractures (**Table 1**).

Table 1: Six Stages in the Pathogenesis of Community-acquired Bacterial Meningitis

Nasopharyngeal colonisation
Nasopharyngeal epithelial cell invasion
Invasion of meningeal vessels
Intravascular multiplication and bacteraemia
Crossing of blood-brain barrier; bacterial entry into CSF
Survival and multiplication in CSF

The innate inflammatory immune response of the host is of crucial importance for the early containment of bacterial infection. The innate immune responses are mediated by toll-like receptors which are pattern recognition receptors that are expressed in microglia (the resident macrophages of the brain). When Toll-like receptors interact with bacterial antigens, an intense inflammatory immune response starts which has the potential to cause immunopathological changes in the host tissue. Experimental studies demonstrated that Toll-like receptors-2 deficient mice were highly susceptible to *Streptococcus pneumoniae* meningitis because of reduced bacterial clearing.

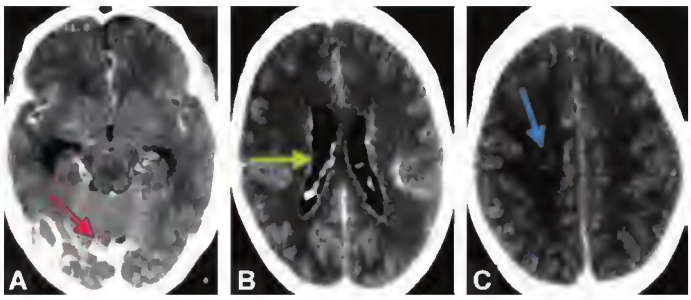
In central nervous system (CNS), in addition to multiplication, bacteria expose microbial antigens to host cells, which subsequently trigger an inflammatory response. This inflammatory response is mediated by cytokines such as tumour necrosis factor-alpha (TNF-α), interleukins (IL), and prostaglandins. Secretion of IL-1 family of cytokines along with TNF-α leads to excessive production of several other pro-inflammatory mediators. Under influence of these chemicals, a large number of neutrophils are recruited in to the subarachnoid space. Activated neutrophils and other inflammatory cells release many potentially cytotoxic agents including oxidants and matrix metallo-proteinases that cause extensive damage to the brain tissue. Matrix-metallo-proteinases, in fact, lead to degradation of components of the blood-brain barrier. This in turn results in several acute complications of bacterial meningitis like cerebral oedema formation, increased intra-cranial pressure and ischaemia.

Pathology

The important pathological feature of bacterial meningitis is a purulent exudate which is present in the basal cisterns and extends throughout the subarachnoid space. The underlying brain (although not invaded by bacteria) becomes congested, oedematous and ischaemic because of extensive disruption of blood-brain barrier. The inflammatory exudates may affect vascular structures crossing the subarachnoid space producing an arteritis or venous thrombophlebitis with resultant cerebral infarction. Similarly, cranial nerves passing through the purulent basal exudates may suffer direct damage. Hydrocephalus can result from obstruction of CSF flow in the ventricles and subarachnoid space. Transtentorial herniation is caused by diffuse swelling of the brain parenchyma, or hydrocephalus.

Clinical Features

The characteristic symptoms and signs of bacterial meningitis are headache, fever, nuchal rigidity, photophobia, vomiting and lethargy or an altered level of consciousness. The sensitivity of the classic triad of fever, neck stiffness, and altered mental status is low, but almost all such patients present with at least two of four symptoms: headache, fever, neck stiffness, and altered mental status. Other signs of meningeal irritation (Brudzinski's and Kernig's signs of the neck and legs) are also present in majority of the patients. Seizures occur in approximately 23% to 40% of patients, typically in the first week of illness. Focal neurological signs complicate bacterial meningitis in 15% to 28% of patients, and are caused by cortical vein thrombosis, cerebral artery spasm, subdural empyema or rarely brain abscess. In the elderly and in the immunocompromised or neutropaenic patients, classical signs and symptoms of meningitis may be minimal or absent. These patients may present with a mild confusional state.



The most frequent cranial nerve abnormality is the involvement of the 8th cranial nerve, which results in hearing loss. Sensorineural deafness, unilateral or bilateral can appear early or late in the course of illness, and is usually permanent. Involvement of the 6th and 7th cranial nerves occurs early or late in the course of the disease and is probably never persistent. The presence of bilateral 6th nerve palsies suggests raised intracranial pressure. Papilloedema is rare (less than 1% of patients), its presence usually suggests another diagnosis such as intracranial space-occupying lesion. Abnormalities of 7th and 8th cranial nerves may also develop even in a few adequately treated individuals. The incidence of hearing loss is greater in patients with *Streptococcus pneumoniae* meningitis than in patients with *Neisseria meningitidis* infection.

Other clinical signs indicative of elevated intra-cranial pressure and cerebral herniation are coma, unilateral or bilateral fixed and dilated pupils, decorticate or decerebrate posture, abnormal respiration (Cheyne-Stokes breathing, hyperventilation, apnoea or respiratory arrest) and loss of oculo-cephalic reflex. These signs are often of ominous prognostic significance.

Diagnosis

If bacterial meningitis is suspected, lumbar puncture is an essential procedure. CSF changes are characteristic of bacterial meningitis. Opening CSF pressure is often elevated usually in the range of 200 mm Hg to 500 mm H_2O. The CSF appearance may be turbid because of the presence of blood cells, bacteria, and protein. In untreated bacterial meningitis, the white blood cell count is markedly elevated, usually in the range of 1,000 cells/mm^3 to 5,000 cells/mm^3. Bacterial meningitis usually leads to a neutrophil predominance in CSF. The CSF glucose concentration is less than 40 mg/dL in approximately 50% to 60% of patients. A ratio of CSF to serum glucose of less than or equal to 0.4 is 80% sensitive and 98% specific. The CSF protein concentration is invariably elevated. Gram's staining of CSF sediment is extremely important as it permits rapid and accurate identification of the causative micro-organism. The CSF culture is positive in approximately 70% to 85% of patients. The probability of CSF culture being negative is increased if patient has received prior antimicrobial therapy. Blood culture is also performed and can be positive in 80% of cases of *Haemophilus influenzae* meningitis and less than 50% of patients with pneumococcal and meningococcal meningitis. Polymerase chain reaction (PCR) has been utilised to amplify deoxyribonucleic acid (DNA) from patients with meningitis caused by the common meningeal pathogens. A rapid aetiologic diagnosis is possible with the use of counter-current immunoelectrophoresis and such other serological techniques. These tests detect capsular antigen in CSF and are useful if CSF microscopy is negative, especially, if patient has already received antibiotics.

Neuroimaging, before lumbar puncture, should be performed if patient has focal neurological deficit, seizures, papilloedema, coma, or in immunocompromised state. CNS complications of bacterial meningitis detectable by neuroimaging are: meningeal enhancement, cerebral oedema, transient dilatation of ventricles, ventriculitis, hydrocephalus, subdural effusion or empyema, cerebral infarct, brain abscess, and cerebral venous sinus thrombosis (**Figures 1A to C**). Neuroimaging in uncomplicated bacterial meningitis is often normal.

Figures 1A to C: Cranial contrast-enhanced computed tomography of brain in a patient with pneumococcal bacterial meningitis showing: (A) meningeal inflammation (red arrow); (B) ventriculitis (green arrow); and (C) a small brain abscess (blue arrow).

Differential Diagnosis

Several infective and non-infective CNS disorders, presenting with headache, fever, focal neurological deficit and with an altered state of consciousness, are included in the differential diagnosis of acute bacterial meningitis. These conditions include cerebral malaria, heat stroke, viral encephalitis and viral meningitis. In India and other endemic countries distinction between cerebral malaria and acute bacterial meningitis is often difficult, particularly in children. If a patient of suspected bacterial meningitis is HIV-positive, the differential diagnosis should also include cryptococcal meningitis, tuberculous meningitis, and toxoplasma meningoencephalitis.

Treatment

Antibiotic therapy should be immediately started soon after diagnosis is suspected or confirmed with characteristic CSF findings, without waiting to determine the aetiological organism. Delay in initiation of antimicrobial therapy can result in poor outcome.

Empirical antibiotic therapy

Choice of empirical antibiotic is determined on the basis of the patient's age and underlying health status. With the worldwide increase in the occurrence of penicillin-resistant pneumococci, combination therapy with vancomycin plus a third-generation cephalosporin (either ceftriaxone or cefotaxime) has become the choice of empirical antimicrobial therapy. For patients with penicillin or cephalosporin hypersensitivity, the recommended treatment is chloramphenicol plus vancomycin. In young infants (less than 3 months old) and older adults, in whom *Streptococcus agalactiae* and *Listeria monocytogenes* are prevalent, treatment with broad-spectrum cephalosporins is supplemented with ampicillin. Patients who have had recent neurosurgery, head trauma and immunosuppressed patients with or without nosocomially acquired infection need broader antibiotic coverage such as combination of ceftazidime and vancomycin (**Table 2**).

Table 2: Empirical Antimicrobial Therapy in Bacterial Meningitis

	Likely Organisms	Choice of Antimicrobials
Children less than 3 months	*Streptococcus agalactiae*, *Escherichia coli*, *Listeria monocytogenes*	Ampicillin + Cefotaxime *or* Ampicillin + Aminoglycoside
3 months to less than 18 years	*Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*	Vancomycin + Third-generation Cephalosporin
18 to 50 years	*Streptococcus pneumoniae*, *Neisseria meningitidis*	Vancomycin + Third-generation Cephalosporin
Above 50 years	*Streptococcus pneumoniae*, *Listeria monocytogenes*	Vancomycin + Third-generation Cephalosporin + Ampicillin
Immunocompromised adults	*Listeria monocytogenes*, Gram-negative bacilli	Ampicillin + Ceftazidime
Penetrating head trauma, ventricular shunt, neurosurgical trauma	*Streptococcus pneumoniae*, *Staphylococcus*, *Listeria monocytogenes*, Gram-negative bacilli, *Pseudomonas aeruginosa*	Vancomycin + Ceftazidime *or* Vancomycin + Cefepime

Pathogen-specific therapy

Once a bacterial pathogen is isolated and *in vitro* susceptibility testing is performed, antimicrobial treatment should be modified. As a result of increase in penicillin-resistant *Streptococcus pneumoniae*, adult patients with pneumococcal infection should receive ceftriaxone plus vancomycin unless organism is demonstrated to be cephalosporin-sensitive. Penicillin-sensitive species can be treated with continued cefotaxime, ceftriaxone, or chloramphenicol, or even switched to penicillin-G. For penicillin-resistant species, vancomycin is continued and rifampin may be added. Penicillin is the drug of choice for meningococcal meningitis. Generally, high-dose intravenous penicillin-G should be administered every 4 to 6 hours for patients with invasive meningococcal disease. Acceptable alternatives to penicillin-G are ampicillin, cefotaxime and ceftriaxone. Most reported strains of *Neisseria meningitidis* are moderately susceptible to high-dose penicillin-G, cefotaxime, and ceftriaxone. Chloramphenicol is indicated for patients with anaphylactic allergic reactions to penicillin. Chloramphenicol has also been used routinely in under-developed countries, but single-dose ceftriaxone is an efficacious, easy to use, and low-cost alternative (**Table 3**).

Role of corticosteroids

Theoretically, control of inflammatory changes with the help of corticosteroids may prove effective in decreasing many of the pathophysiologic ill-effects of bacterial meningitis. Several clinical studies have demonstrated the benefit of adjunctive dexamethasone in infants and children with *Haemophilus influenzae* meningitis, and adults with pneumococcal meningitis, in which mortality and incidence of adverse outcome have found to be declined. In children, administration of corticosteroids led to reduction in incidence of severe hearing loss in *Haemophilus influenzae* bacterial meningitis. However, a recent meta-analysis of existing data suggests that the benefit of dexamethasone for all or any subgroup of patients with bacterial meningitis remains unproven and dexamethasone does not seem to significantly reduce death or neurological disability. Use of adjunctive dexamethasone in adults with meningitis caused by other bacteria, and in infants and children with pneumococcal meningitis, is controversial.

To be effective, dexamethasone should be administered concomitant with or just prior to the first antimicrobial dose for maximal effect on the subarachnoid space inflammatory response. In adults, the dexamethasone was administered in dosage schedule of 0.15 mg/kg every 6 hours for 2 to 4 days with the first dose administered 10 to 20 minutes before, or at least concomitant with the first dose of antimicrobial therapy. Dexamethasone was usually given for four days regardless of microbial cause or clinical severity.

Table 3: Pathogen-specific Antibiotic Therapy for Bacterial Meningitis in Adults

Pathogen	Antimicrobials	Dosage	Duration (Days)
Streptococcus pneumoniae	Ceftriaxone *or* Cefotaxime + Vancomycin	4 g/day (12 hourly) 12 g/day (4 hourly) 2 g/day (6 hourly)	10 to 14
Neisseria meningitidis	Penicillin-G *or*	20 to 24 million U/day (4 hourly)	5 to 7
	Ceftriaxone	4 g/day (12 hourly)	
Haemophilus influenzae	Ceftriaxone *or* Cefotaxime	4 g/day (12 hourly) 12 g/day (4 hourly)	7
Listeria monocytogenes	Ampicillin + Gentamycin	12 g/day (4 hourly) 6 mg/kg/day (8 hourly)	14 to 21
Gram-negative bacilli	Ceftriaxone *or* Cefotaxime	4 g/day (12 hourly) 12 g/day (4 hourly)	21
Pseudomonas aeruginosa	Ceftazidime + Intraventricular Gentamycin	8 g/day (8 hourly)	21

Other supportive management

Careful management of fluid and electrolyte balance is an important supportive therapy. Both over- and under-

hydration are associated with adverse outcomes. The patient requires analgesics for headache and backache and careful nursing in a darkened room if photophobia is prominent. Symptomatic treatment of pyrexia is appropriate in majority of the patients. In children, prophylactic anticonvulsant can also be used. In patients with signs of raised intra-cranial pressure, an intracranial pressure measuring device may be inserted. Intravenous mannitol may be required to reduce the elevated intra-cranial pressure. In a few patients treatment of shock or disseminated intravascular coagulation may be needed.

Duration of antibiotic therapy and response to treatment

Usually, 5 days of antibiotic therapy is sufficient for most of the immunocompetent patients of bacterial meningitis. However, authorities on the subject suggest at least 7 days treatment for *Haemophilus* and meningococcal meningitis. Patients with pneumococcal meningitis require antibiotic therapy for at least 10 to 14 days. A prolonged antibiotic therapy is worthwhile in patients with persistent fever, seizures, coma, and in patients who are immunocompromised. In *Listeria monocytogenes* and streptococcal meningitis, antibiotics should be given for 14 to 21 days. For Gram-negative bacilli a minimum treatment of three weeks is needed. In a responsive patient, the CSF becomes sterile 1 to 2 days after antibiotic treatment. The fever usually disappears within few days but may persist for several weeks. Dead bacteria may be seen on Gram's stain of CSF for several days. In bacterial meningitis which has responded well to antimicrobial therapy, repeated lumbar puncture is not routinely required. Repeat CSF analysis should be performed if patient has not responded after 48 hours of appropriate antimicrobial therapy.

Prognosis and Complications

Mortality from bacterial meningitis varies from 5% to 25%, depending on the causative organism, age of the patient, and the predisposing illness. The mortality rate is higher among patients with pneumococcal meningitis than among those with meningococcal meningitis (30% versus 7%). Risk factors for an unfavourable outcome are advanced age, presence of otitis or sinusitis, absence of rash, a low score on the Glasgow Coma Scale on admission, tachycardia, a positive blood culture, an elevated erythrocyte sedimentation rate, thrombocytopaenia, and a low CSF white-cell count. The case fatality rate for *Haemophilus influenzae* meningitis has been reported about 5%. *Listeria monocytogenes* meningitis is associated with a high mortality rate.

A study (in adults with pneumococcal meningitis) reported meningitis-associated intra-cranial complications in 75% of patients, and systemic complications in 38%. Diffuse brain oedema and hydrocephalus were the most frequent intra-cranial complications. The incidence of arterial thrombosis and cerebral venous thrombosis were also very high. Approximately 10% of cases developed spontaneous intra-cranial haemorrhages. Few patients developed acute spinal cord dysfunction due to myelitis. Hearing loss was reported in 20% of all patients and 26% of survivors. Sterile subdural effusion is a common complication of *H. influenzae* meningitis but is relatively uncommon in other bacterial infections of the meninges. In up to 30% of meningitis survivors, long-term neurologic sequelae develop, including hearing loss and other focal neurologic deficits.

Meningococcal meningitis may be characteristically associated with prominent purpuric or petechial rash affecting extremities in about 50% of patients. Neurological and other systemic complications are relatively infrequent. The most important non-neurological complication of meningococcal meningitis is disseminated intravascular coagulation induced by the endotoxins liberated by the bacteria.

Prophylaxis

During an outbreak of meningococcal disease, individuals at risk should be treated by administration of antibiotics known to eradicate meningococcal carriage. Rifampicin is used for the prevention of secondary cases of meningococcal meningitis. The recommended dose is 600 mg every 12 hours for 2 days in adults. Prophylactic treatment is given to close household contacts and hospital personnel. Ciprofloxacin can also be used for prophylaxis in single oral dose of 500 mg daily in adults.

Recurrent Bacterial Meningitis

Three factors, that play an important role in the predisposition of recurrences of bacterial meningitis, include tears in the dura, fracture of the cribriform plate or paranasal sinuses and a nasal meningocoele. These lesions produce a connection between the external environment and the subarachnoid space. Through these defects, bacterial pathogens can readily gain access to meninges and brain, leading to recurrent meningitis. About 50% of patients with repeated attacks of bacterial meningitis have persistent CSF rhinorrhoea for months to years. Abrupt cessation of nasal discharge of CSF followed by global headache and fever suggest recurrence of meningitis. In patients with recurrent bacterial meningitis, *Streptococcus pneumoniae* is the usual pathogen. CSF rhinorrhoea can be diagnosed by measuring glucose concentration of nasal secretions. Usually nasal mucus secretion contains little glucose but in case of CSF rhinorrhoea, the glucose amount of nasal secretion approximates that in CSF. Treatment of recurrent bacterial meningitis consists of use of the pneumococcal vaccine, along with prophylactic oral penicillin. Fistulous connection between subarachnoid space and nasal sinuses requires surgical repair. The prognosis of recurrent meningitis is better as mortality is much lower than in other forms of bacterial meningitis.

BRAIN ABSCESS

Definition

A brain abscess may be defined as localised suppurative necrosis of the brain parenchyma and a circumscribed collection of purulent exudate in the brain, due to bacterial and other infections.

Incidence

The advent of antibiotics and improved treatment of ear and sinus infections has led to a reduction in intra-cranial abscess formation, but incidence in western world still lies at 2 to 3 patients per million per year.

Pathogenesis

In brain abscess, bacteria reach the brain parenchyma by spreading from a contiguous cranial site of primary infection. These sites most often are in the middle ear, mastoids or

paranasal sinuses. Infection may spread either directly through the skull bone (osteomyelitis), or through emissary vein producing a suppurative thrombophlebitis. The area of brain involved is usually adjacent to the area of primary infection. For example, infection from frontal sinusitis can extend to frontal lobes and infection originating from middle ear or mastoid air cells can lead to either temporal lobe or cerebellar abscess. There may also be direct extension of infection from a contaminated compound skull fracture or other deep penetrating head injury. Occasional cases are associated with osteomyelitis of skull or dental infections. Brain abscess may also be a complication of neurosurgical procedure.

About one-third of all brain abscesses are haematogenous in origin and primary septic focus is either acute bacterial endocarditis or pyogenic infections of lung or pleura. Pulmonary infections commonly associated with this disease are lung abscess and bronchiectasis. Haematogenous spread of bacteria to the brain may occur in patients with congenital cyanotic heart diseases or with pulmonary right-to-left shunt. Fallot's tetralogy is the commonest congenital heart disease responsible for brain abscess. Metastatic or haematogenous brain abscess are often multiple and found at grey and white matter junctions in the territory of middle cerebral artery. *Listeria* abscesses tend to involve brainstem.

Pathology

Formation of brain abscess is usually preceded by the development of a small area of infarct secondary to occlusion of a small vessel or because of thrombophlebitis of surface vessels. Infarcted or necrotic brain tissue favours bacterial invasion and multiplication. Thus, formation of brain abscess begins with an area of focal cerebritis with subsequent focal softening and liquefaction. As the process continues there is formation of an encapsulated abscess cavity along with variable amount of oedema surrounding the abscess.

Improved anaerobic and aerobic bacteria culture techniques enable us to identify the causative organism in over 80% of patients. Mixed infection is seen in approximately 30% to 60% of patients. Microaerophilic and anaerobic organisms are the main pathogens isolated from brain abscess, the most common being the bacteria of *Streptococcus intermedius* group especially *Streptococcus milleri*, and anaerobic *Bacteroides* species. Methicillin-resistant *Staphylococcus aureus* is of increasing concern as an aetiological organism. Isolates from brain abscesses in immunocompromised patients frequently differ from those recovered from abscesses in immunologically intact individuals. *Enterobacteriaceae*, *Pseudomonas aeruginosa*, or *Listeria monocytogenes* may be isolated from brain abscess in immunosuppressed patients. Fungi including *Cryptococcus neoformans*, *Candida*, *Mucor*, *Aspergillus* species and *Cladophialophora bantiana* may be associated with brain abscess in diabetics and other immunocompromised patients, as well as in patients abusing intravenous drugs. *Nocardia asteroides*, although most commonly isolated from immunocompromised patients, may cause brain abscess in patients without known impairment of immune function. The most common cause of focal intracranial infection in patients with AIDS is *Toxoplasma gondii*, followed by *Cryptococcus neoformans* and *Mycobacterium tuberculosis* (**Table 4**).

Table 4: Most likely Pathogen Depending on Primary Source of Infection in Brain Abscess

Site	Likely Pathogen
Middle ear	*Streptococcus milleri, Bacteroides fragilis, Escherichia coli, Proteus, Streptococcus pneumoniae,* often mixed
Paranasal sinuses	*Streptococcus pneumoniae Streptococcus milleri*
Haematogenous	*Streptococcus pneumoniae Streptococcus milleri, Staphylococcus aureus*
Head trauma	*Staphylococcus aureus, Pseudomonas*
Lung abscess	Anaerobic bacteria
Immunocompromised patients	*Toxoplasma, Streptococcus pneumoniae, Aspergillus, Candida, Nocardia, Listeria monocytogenes*

Clinical Features

Symptoms and signs of brain abscess usually develop over 2 to 3 weeks. Infrequently, the onset is more gradual, but features may develop acutely in the immunocompromised patient. Early symptoms include headache, lethargy, intermittent fever and focal or generalised seizures. Fever is present in less than 50% of patients. Focal neurological deficit may develop depending on the site of lesion. For example, lesions in the frontal cortex may produce hemiparesis or monoparesis while lesions in the occipital cortex cause homonymous visual field defects. Patients with cerebellar abscess may present with dysarthria, nystagmus and limb incoordination. Nuchal rigidity is present in 25% patients. Papilloedema and 6th cranial nerve palsy are infrequent. As the abscess expands increased intra-cranial pressure becomes more pronounced producing headache, vomiting, psychomotor slowing, lethargy and increasing confusion. If untreated, eventually, brain herniation and death may occur as a result of expanding mass.

Diagnosis

The diagnosis of brain abscess is established with the help of neuroimaging. The CT scan usually demonstrates a lesion with a low-density necrotic centre, a well developed contrast-enhancing capsule (in the form of 'ring' enhancement) and surrounding cerebral oedema (**Figure 2**). The enhancing lesions caused by pyogenic abscesses are commonly located at the grey-white matter junction. Frequently, the capsule of abscess is difficult to visualise via conventional imaging techniques, and double contrast CT is needed to clearly define the capsule of the abscess. CT, in addition, may also reveal opacification of the mastoids and sinuses. On non-contrast magnetic resonance imaging, pyogenic abscess show an isointense-to-slightly hyperintense capsule on T1-weighted images and is hypointense on T2-weighted images. The ring enhancement on post-contrast images is usually thin, smooth, and often thinner along the medial margin. However, a greater thickness, irregularity, and nodularity of the wall of the lesions are often suggestive of tumour or a fungal infection. Magnetic resonance diffusion-weighted imaging along with apparent diffusion coefficient and proton magnetic resonance spectroscopy can provide additional information for differentiation of brain abscess from other necrotic lesions. Differential diagnosis of ring enhancing lesions on CT is tabulated in **Table 5**.

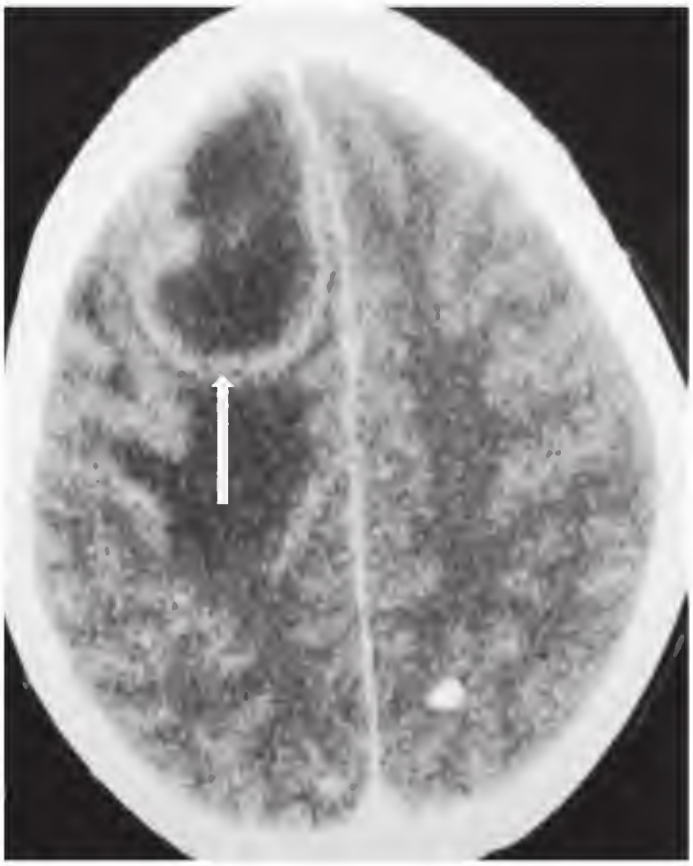


Figure 2: Cranial contrast-enhanced computed tomography of brain showing a brain abscess (white arrow) and marked perilesional vasogenic oedema in the right frontal region.

Table 5: Differential Diagnosis of Ring Enhancing CT Lesions

Large (>20 mm)
Brain abscess
Brain tumours (e.g. gliomas, secondaries)
Tuberculous abscess
Fungal abscess
Small (<20 mm)
Common
Cysticercus granuloma
Tuberculoma
Uncommon
Old infarct
Focal encephalitis
Sarcoidosis
Microabscesses
Vasculitis
In Immunocompromised Patients
Toxoplasmosis
Primary CNS lymphoma
Fungal granuloma
Tuberculoma and tuberculous abscess

Treatment

The treatment of brain abscess usually requires appropriate antibiotic therapy and surgical drainage. Broad-spectrum antibiotic treatment is started as soon as clinical diagnosis is made. Empirical antibiotic therapy should provide coverage against staphylococci (usually with vancomycin to cover methicillin-resistant *Staphylococcus aureus*) and Gram-negative bacilli (with a third-generation or a fourth-generation cephalosporin, such as ceftazidime or cefepime, respectively). Because vancomycin is less active against methicillin-susceptible *Staphylococcus aureus*, nafcillin or cefazolin is preferred for the treatment of documented methicillin-susceptible *Staphylococcus aureus* infection. Ceftazidime should be used in place of ceftriaxone or cefotaxime if *Pseudomonas aeruginosa* infection is suspected. Once bacteria are cultured, therapy should be changed according to the antibiotic sensitivities. Antibiotics should be administered intravenously and treatment is continued for 6 to 8 weeks.

Because the most immediate threat from brain abscess is the mass effect, surgical aspiration of pus often diminishes the risks of increased intra-cranial pressure. Burr-hole aspiration of pus is a simple and safe method. Persistent reaccumulation of pus despite repeated aspiration may require surgical excision of the abscess. Mannitol or corticosteroids may be essential, at least, initially to control cerebral oedema. Corticosteroids should be used cautiously if at all and should be tapered off rapidly as they may interfere with capsule formation and host defence against organisms.

Prognosis

Mortality from brain abscesses ranges from 30% to 65%, mortality is lower in patients who receive dual treatment with antibiotics and surgery. About 50% of survivors have neurological sequelae like recurrent seizures and focal neurological deficit.

20.12 Neurotuberculosis

Shyamal Kumar Das, Deb Sankar Guin

INTRODUCTION

Tuberculosis is one of the oldest known diseases affecting almost every organ system of the human body. Despite worldwide infection control programmes and powerful antibiotics, tuberculosis of the central nervous system (CNS) is still more than a historical relic. There is increasing prominence of extrapulmonary infection, worrying prevalence of drug-resistance mycobacteria and there is increasing association of acquired immunodeficiency syndrome (AIDS) epidemic with tuberculosis. All these facts suggest that CNS tuberculosis will remain a significant clinical entity in coming years.

Tuberculosis can affect any part of the nervous system including the meninges, brain and spinal cord. Tuberculous meningitis (TBM) is by far the most common manifestation, accounting for 70% to 80% of all cases of neurotuberculosis. Various forms of neurotuberculosis that are commonly encountered in clinical practice are given in **Table 1**.

Table 1: Spectrum of Neurotuberculosis

Tuberculous meningitis	Basal Spinal
Tuberculoma	Intra-cranial Parenchymal Extraparenchymal Spinal
Tuberculous abscess	
Tuberculous encephalopathy	With meningitis Without meningitis
Spinal affection secondary to skeletal tuberculosis	

EPIDEMIOLOGY

Neurotuberculosis is not distributed uniformly around the world. In the less developed countries, the disease remains a common disease of childhood. The epidemiological data regarding prevalence of neurotuberculosis is very scarce in the developing countries. It accounts about 15% of extrapulmonary tuberculosis and 0.7% of all clinical tuberculosis. Neuro-tuberculosis is the most serious form of tuberculosis; even with prompt and adequate treatment, mortality rate goes up to 27%.

In the developed countries, the rates of extrapulmonary tuberculosis declined only minimally in spite of reduction of incidence of pulmonary tuberculosis, and rates of CNS infection remained similarly constant, representing approximately 5% of extrapulmonary cases reported.

Since the epidemic of HIV infection, there are increased occurrences of both reactivated and newly-acquired infections. Extrapulmonary tuberculosis including CNS tuberculosis, is considerably more frequent in the setting of HIV infection than otherwise. In parts of Africa and Asia, more than 50% of HIV-infected patients have tuberculosis during the course of their illness. Thus, HIV-infected individuals with active disease may come to serve as reservoir for the spread of primary tuberculous infection into their community.

AETIOLOGY

Virtually all tuberculous infections of the CNS are caused by the human tubercle bacillus, *Mycobacterium tuberculosis*. Infections caused by *M. bovis* acquired from the ingestion of contaminated milk are now quite rare, as are infections caused by other non-tuberculous mycobacteria (NTM) pathogenic for human, except in immunocompromised patients, where infection of *M. avium* and *M. intercellulare* are common.

PATHOGENESIS

Like all other forms of tuberculosis, CNS infection begins with inhalation of infectious particles. On reaching the alveoli, airborne droplet nuclei, each containing small number of organisms, multiply either within the alveolar space or within the alveolar macrophages. For first 2 to 4 weeks, when there is virtually no inflammatory response, haematogenous dissemination of the organism is believed to occur in every case.

Two to four weeks following infection, cell-mediated immunity to bacteria develops. A tubercle is formed, consisting of macrophages, lymphocytes and other cells surrounding a necrotic caseous centre. Fate of these tubercles and subsequent course of infection are a function of both the immunologic capacity of the host and other incompletely understood genetic factors. When there is robust immunity, minute caseous foci are formed only to be eliminated completely by the surrounding macrophages leaving no residua. Less efficient but still effective immune response results in larger caseous foci which, despite fibrous encapsulation, continue to shelter viable mycobacteria, which may cause reactivated disease if host's immune vigilance lessens. In the presence of profound immunodeficiency, primary tubercle continues to grow, the caseous centre may liquefy, organisms proliferate and tubercle ultimately ruptures, discharging organisms into the surrounding tissue.

When these events occur within the brain and meninges and the so-called Rich's foci ruptures discharging the organism in the subarachnoid space, tuberculous meningitis results. The vascular choroid plexus are common sites for tubercle formation and also common site for rupture of a tubercle as also foci located on the surface of the brain. Those tubercles located deep in the brain or spinal cord parenchyma will enlarge to form tuberculoma or tuberculous abscesses.

PATHOLOGY

Meningeal Exudate and Meningitis

The primary pathological event is the formation of thick tuberculous exudates within the subarachnoid space. These exudates diffuse with particular prominence at the base of the

brain irrespective of the location of the discharging focus. The exudates accumulate around the interpeduncular fossa, enveloping the optic nerves at the chiasma and extending over the pons and cerebellum, often into the sylvian fissures and rarely up along the cerebral hemispheres. Thus, other cranial nerves such as III, IV, VI, VII, and VIII may be involved in the subarachnoid space in varying degrees.

In appearance, the exudate is gelatinous and frequently nodular. Microscopically, it consists of polymorphonuclear leucocytes, red blood cells, macrophages and lymphocytes within a fibrin network. Typical tubercles, occasionally with large zones of caseation necrosis develop within the exudate. In untreated cases, a large number of tubercle bacilli can be detected at the margins of caseous necrosis. With treatment fibroblasts and elements of connective tissues replace the exudates.

Vasculopathy

Accompanying the tuberculous exudate is a characteristic inflammation affecting the medium and small sized blood vessels traversing it. The adventitial layer of vessels develops changes similar to those of the adjacent tuberculous exudate. The intima of the vessels may eventually be affected similarly or these may be eroded by a fibrinoid-hyaline degeneration. Thus, the lumen of the vessel may be completely occluded. Ischaemic cerebral infarction, thus, results which is a common sequel of tuberculous arteritis, most often in the distribution of middle cerebral artery (reflecting the presence of tuberculous exudate within the Sylvian fissure) and the lateral striate arteries as they penetrate the base of the brain. Infrequently haemorrhagic infarcts have been described. The vascular lesions cause various types of neurodeficits, seizures and cognitive disturbances.

Border-Zone Encephalitis

TBM is appropriately characterised as a meningo-encephalitis because it affects not only meninges but also parenchyma. There are pathological changes in the brain immediately underlying the infected meninges. Frequently there is only a glial reaction; occasionally the changes may be of inflammatory nature with peri-vascular cuffs of small mononuclear cells, and later on gliosis. It is seen most frequently in the Sylvian fissure.

Hydrocephalus

It results from profound disturbances in the circulation of the CSF due to blockage of CSF pathway by the dense basal exudates. There is also interference in the absorption of the CSF by the arachnoid granulations. All these result in communicating hydrocephalus. Isotope cisternoventriculography with iodine-labelled human albumin has been used to confirm it. Sometimes, the obstruction may be at the level of aqueduct of Sylvius or foramen of Monroe leading to obstructive hydrocephalus.

Tuberculoma Formation

If a tubercle situated deep in the brain parenchyma or spinal cord enlarges at the expense of the parenchyma, a tuberculoma is formed. Its centre gets liquefied by the caseous necrosis. Initially solitary lesion or a cluster of microscopic foci are formed in the cortical or subcortical region. Lesions may coalesce later forming larger lesions, even tuberculous abscess.

Tuberculous Encephalopathy

This entity is apparently independent of other pathology. It consists of cerebral oedema occasionally with peri-vascular demyelination or haemorrhagic leucoencephalopathy. These changes occur deep in the white matter of the brain at a distance from vascular abnormalities or exudates. Some observers hypothesise that it is a purely allergic phenomenon, mediated by tissue hypersensitivity to either bacillary antigens or possibly to a myelin-related antigen of brain tissue itself.

Spinal Meningitis

Spinal meningitis is a common asymptomatic accompaniment of cranial meningitis. In most cases, there is extension of basal exudates downwards. However, tuberculous spinal arachnoiditis can present first time as spinal cord disorder and may move upwards often asymptomatically into the cranial cavity.

CLINICAL FEATURES

Tuberculous Meningitis (TBM)

The clinical picture of TBM is quite variable, with substantial differences among patients of different ages. The clinical manifestations depend upon a variety of factors related both to the organism and the host like pre-existing malnutrition, coexistence of HIV infection, BCG vaccination, etc.

Among children, majority of cases (75% to 85%) are below the age of 5 years. The onset of the disease may be acute, i.e. within 6 days, sub-acute or gradual, taking more than 3 weeks to develop. Among adults, the disease typically presents in a somewhat indolent fashion. The classical form of the disease evolves through a prodromal stage, a stage of meningeal irritation, leading to a stage of diffuse or focal cerebral involvement. Nausea, vomiting, anorexia, abdominal pain, constipation and behavioural changes are among most commonly reported symptoms. Headache is reported in less than 25% of children than in adults (50% to 75%) (**Table 2**). Some degree of fever is usual, but it may be of low grade and absent in 10% to 15% of children and 25% to 30% of adults. As the disease progresses, signs of meningeal irritation will develop, though it is less commonly seen in infants, instead fullness of fontanelle is seen. Seizures may present at any stage of the disease. Ten to twenty per cent of subjects may have seizures during the initial period, later it may be seen in up to 50% of cases. Psychobehavioural changes are frequently observed at onset in adults. Signs and symptoms of raised intracranial pressure like enlargement of head in children and papilloedema may be seen early in the disease.

Table 2: Clinical Presentation of Patients with Tuberculous Meningitis

Feature	Among Children	Among Adults
Headache	20% to 50%	50% to 60%
Nausea/vomiting	50% to 75%	8% to 40%
Apathy/behavioural changes	30% to 70%	30% to 70%
Seizures	10% to 20%	0% to 13%
Prior history of tuberculosis	55%	8% to 12%

Focal neurological signs, which are common in the later part of the disease, most frequently consists of unilateral or, less commonly, bilateral cranial nerve palsies. Most frequently affected is the sixth cranial nerve followed by III, IV, VII and less commonly II, VIII, X, XI and XIIth. Visual impairment may be there due to optochiasmatic

arachnoiditis, tuberculoma compressing the optic nerve, secondary optic atrophy from papilloedema or ethambutol toxicity. Fundoscopic examination may reveal papilloedema, disc pallor or choroid tubercles, which are seen in 10% of cases with TBM and it is a very useful clue to diagnosis. There may be isolated pupillary involvement without other features of III nerve palsy. Rarely, there may be internuclear ophthalmoplegia and horizontal gaze paresis due to intrinsic brainstem lesion. Other common findings include hemiparesis, monoparesis and aphasia due to ischaemic infarction in 10% to 45% of cases. Less frequently neurological signs include a variety of abnormal movements like chorea, hemiballismus, athetosis, myoclonus and cerebellar ataxia. Persistent movement disorder may persist even after recovery from meningitis, especially among children.

In untreated cases, there may be deterioration of the consciousness from drowsiness to deep coma and brainstem dysfunction. Rarely intra-cranial bleeding may complicate TBM. Intraventricular haemorrhage may result from rupture of tuberculous mycotic aneurysm and parenchymal haemorrhage from moyamoya phenomenon of tuberculous arteritis.

In order to assess severity of the disease and guide to prognosis, it is useful to stage patients clinically at the time of diagnosis, based on the British Medical Research Council classification.

Stage 1 (early disease)

Patient has meningeal signs only, consciousness is undisturbed and no focal neurological signs are present.

Stage 2 (medium severity)

Consciousness is disturbed but the patient is not comatose or delirious. Focal neurological signs and cranial nerves palsies are present. Raised intra-cranial pressure may occur secondary to hydrocephalus. In infants, fontanelle bulges and head enlarges, and in adults there is papilloedema.

Stage 3 (advanced disease)

Patient is deeply comatose with evidence of brainstem dysfunction, decerebrate or decorticate posturing, fixed dilated pupils, irregular pulse and respiration. Untreated patients progress the three stages and usually die.

Children may develop a rare but clinically distinct entity called tuberculous encephalopathy. The distinctive feature of which is a young child or infant with pulmonary TB who develop a diffuse cerebral disorder in which drowsiness comes early with convulsions, without focal neurodeficit.

In BCG-vaccinated children atypical localised form of meningeal tuberculosis has been reported. Others may have transient, recurrent and mild serous meningitis.

Tuberculoma

Approximately 1% of tuberculosis patients develop CNS tuberculoma. In one-third of cases tuberculoma may be multiple. Clinical presentation depends on site, size and pathological stages of the lesions. In children, tuberculoma is most commonly seen in the posterior fossa, in contrast to adults where these are mostly found in supratentorial compartment.

Clinical manifestations include that of slowly progressive space-occupying lesions with or without features of raised intra-cranial pressure or meningeal irritation. Patient may present first time with seizure. There may be involvement of cranial nerves like III, VI, VII or II. They can present like pituitary space occupying lesions with cranial nerve dysfunction, which may resolve completely with anti-tuberculosis therapy. There may be focal neurodeficit like hemiparesis, paraparesis or lateralised ataxia. Multiple tuberculoma or large solitary tuberculoma may present with features of encephalopathy. Constitutional systemic symptoms are present in less than one-third of cases.

Spinal Tuberculosis

This may be due to involvement of spinal meninges, of spinal cord secondary to vasculopathy or tuberculoma, or of the bony elements of the spine (caries) with secondary involvement of the cord (Pott's paraplegia).

Tuberculous spinal meningitis may be due to secondary spread of cranial meningitis or from spinal caries, or may be primary spinal meningitis presenting with single or multiple level ascending or transverse radiculomyelopathy. Symptoms include fever, spinal pain, radicular pain, paraesthesia, combined upper and lower motor features in lower limbs and bladder disturbances. Chronic spinal arachnioditis may be indistinguishable from spinal cord compression.

Vertebral involvement accounts for more than 50% of all skeletal tuberculosis. Thoracic and lumbar spines are most commonly involved due to paucity of movement. Multiplicity of vertebral body involvement (up to 50%) and posterior element lesions are frequently seen, which may lead to sudden paraplegia due to 'concertina' collapse of the involved vertebrae or vascular thrombosis. In about 70% of cases, paraplegia recovers completely if treated promptly.

DIAGNOSIS

Cerebrospinal Fluid Analysis

Typically the fluid is clear or slightly opalescent with raised opening pressure. A cobweb may develop when the CSF is allowed to stand for short time, though it is not a specific finding. A moderate lymphocytic pleocytosis up to 500 cells/mm^3 is characteristic of TBM. However, counts of more than 1000/mm^3 and predominantly polymorphonuclear leucocytes may be found in the early part of the illness. There is moderate elevation of CSF protein (100 to 500 mg/dL) and depression of glucose (<40mg/dL). Hypoglycorrhachia has been correlated with more advanced stage of clinical disease and a rise in CSF glucose after therapy indicates better prognosis.

In tuberculoma, the CSF may be normal or may show a lymphocytic pleocytosis with increased protein levels. In spinal meningitis, there may be spinal block with CSF xanthochromia, very high protein levels (>1 gm/dL) and lymphocytic pleocytosis.

Identification of tuberculous bacilli in the CSF confirms diagnosis though it is difficult. A variety of techniques have been proposed.

Direct smear

Detection rate is 15% to 20%. It may be increased by centrifuging large volume of CSF and preparing a thick smear of the deposit, and examination of cobweb.

Culture

Traditional culture in Lowenstein-Jensen media is a time consuming procedure. Newer radiometric (BACTEC 460 TB) and non-radiometric, semi-automated and fully automated liquid

systems have decreased the time to a positive result to 1 to 3 weeks with good rates of positivity (80% to 95%).

Polymerase chain reaction (PCR)

PCR technique held promise in the confirmation of diagnosis of TBM. It has a high specificity (98%) but low sensitivity (56%). Three regions of the *M. tuberculosis* genome are targeted: IS 6110 sequences, MBP 64 gene codes and 541 bp regions.

Real-time PCR combines rapid cycle DNA amplification with fluorimetry. In cultured samples it has 100% specificity and can detect as few as 10 organisms. Nested real-time PCR may further improve the sensitivity.

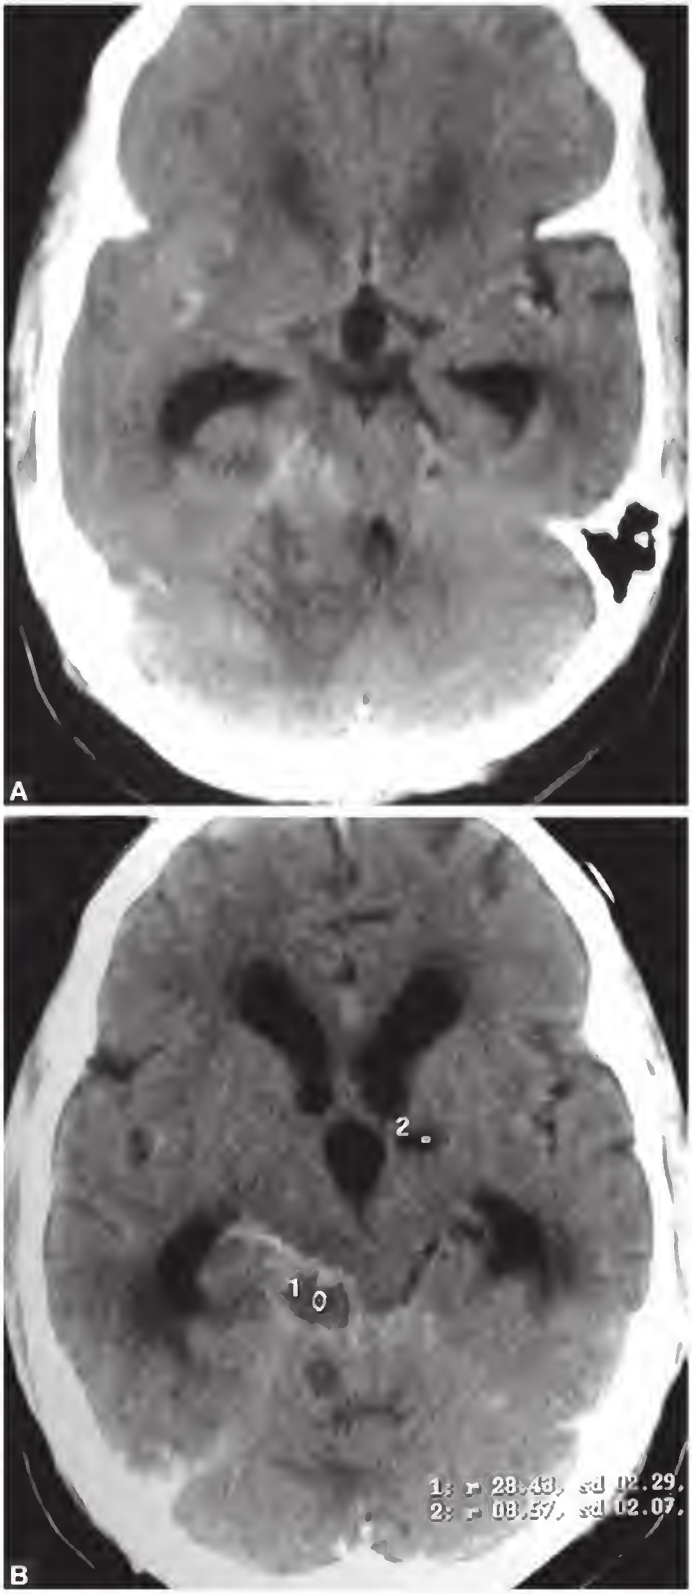
Indirect tests that are helpful in the diagnosis of TBM include adenosine deaminase level in CSF, radiolabelled bromide partition test, CSF tuberculostearic acid level, and mycobacterial antigen and antibody detection by ELISA (**Table 3**).

Table 3: Newer Diagnostic Tests for Tubercular Meningitis

Test	Sensitivity	Specificity	Time Required
Radiolabelled bromide partition test	90% to 94%	88% to 96%	48 hours
CSF ADA level	73% to 100%	71% to 99%	<24 hours
CSF tuberculostearic acid level	95%	99%	<24 hours
CSF mycobacterial antigen	79% to 94%	95% to 100%	<24 hours
CFS mycobacterial antibody	27% to 100%	94% to 100%	<24 hours
PCR	83% to 100%	80% to 100%	<24 hours

CSF = Cerebraspinal fluid; ADA = Adenocine deaminase activity; PCR = Palymearse chain reactian.

Radiology



Contrast-enhanced CT scan and MRI are invaluable in the diagnosis of neurotuberculosis but none of the radiological changes are pathognomonic. MRI is better than CT scan in detecting diffuse and focal meningeal granulomatous lesions, small tuberculoma and focal infarcts.

Tuberculous meningitis

Meningeal enhancement is frequently seen, most commonly in the basal subarachnoid cisterns, Sylvian fissures and around brainstem. There may be associated hydrocephalus or infarction. Hydrocephalus is the single-most common abnormality (50% to 80%), which can be of either communicating or obstructive type (**Figures 1A and B**).

Tuberculoma

The radiological features of tuberculoma on CT vary according to its stage. Mature lesions appear as a well-defined round or oval ring enhancing mass with occasionally a target sign. The immature tuberculoma are iso/hypodense on plain CT and show ring or nodular contrast enhancement. In many cases, solitary tuberculoma may be indistinguishable from abscess, tumour and cysticercus granuloma (**Figure 2**). On MRI, solid caseating granulomas are isointense on T1 and iso/hypointense on T2-weighted images. Occasionally, there may a central hyperintense area with hypointense rim on T2-weighted images. Non-caseating granulomas are usually hypointense in T1 and hyperintense in T2-weighted images, with homogeneous contrast enhancement. Conglomerated lesions are often seen in gadolinium-enhanced MRI.

Figures 1A and B: CECT brain showing basal enhancing exudates with obstructive hydrocephalus.

Magnetic resonant spectroscopy (MRS) can provide biochemical information from a tissue. MRS of a tuberculoma usually shows presence of lipid/lactate peak with increased choline:creatine ratio, but usually less than two.

Magnetisation transfer imaging with contrast is a more sensitive imaging modality in tissue characterisation and helpful in differentiating tuberculoma from cysticercus granuloma.

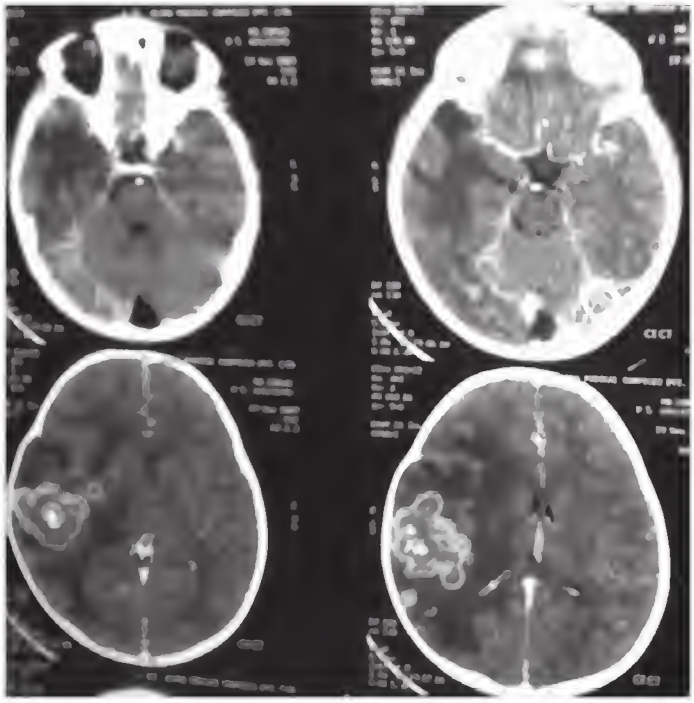


Figure 2: CECT brain showing tuberculoma as large mass like lesion with extensive perifocal oedema, mass effect and midline shift and also basal exudates.

Spinal disease

Non-invasive MRI has replaced conventional myelographic techniques in detecting spinal diseases. Abnormalities on MRI have included obliteration of the subarachnoid space, clumping of nerve roots, oedema of cord, central and ecentric cavitation of the cord, and extensive signal abnormalities within the substance of the cord. Intramedullary tuberculoma are hypointense in both T1- and T2-weighted images with marked gadolinium enhancement.

MANAGEMENT

It is very important to start treatment at the earliest to prevent neurological sequelae and mortality. Often treatment is started empirically, before confirming reports are available.

Chemotherapy

Available antituberculosis drugs are divided on the basis of efficacy and toxicity into first-line [isoniazid (H), rifampicin (R), ethambutol (E), pyrazinamide (Z) and streptomycin (S)] and second-line (para-aminosalicylic acid, ethanolamine, cycloserine, kanamycin, capreomycin and amikacin) agents. Newer second-line drugs like fluoroquinolones (ciprofloxacin or ofloxacin) and macrolides (azithromycin and clarythromycin) are used in multidrug resistant (MDR) cases or when first-line drugs are not tolerated.

Isoniazid and rifampicin are bactericidal and other first-line drugs are bacteriostatic. Isoniazid, pyrazinamide and ethambutol have good CSF penetration and others have poor CSF concentration (**Table 4**).

Treatment Regimens

World Health Organization (WHO) recommends use of 4 drugs (HRZE) for 2 months followed by 2 drugs (HR) for 6 to 7 months for the treatment of TBM. The same drug regimen is prescribed for tuberculoma and spinal disease.

Table 4: Recommended Dosage of First-Line Anti-Tuberculosis Drugs

Agent	Usual Daily Dose	Adult Daily Dose
Isoniazid	5 to 10 mg/kg	300 mg
Rifampicin	10 to 12 mg/kg	450 to 600 mg
Pyrazinamide	25 to 30 mg/kg	1 to 1.5 g
Ethambutol	15 to 25 mg	800 mg
Streptomycin	15 to 20 mg	0.75 to 1 g

In spite of WHO recommendations, universal consensus regarding duration of treatment has not developed. The current UK guidelines recommend 12 months of anti-tuberculosis treatment (ATT) in uncomplicated cases of TBM (including tuberculoma without meningitis) extending to 18 months if pyrazinamide is omitted. The American Thoracic Society's recent recommendation is a course of 2 months of HRZ, followed by 4 months of HR for adults and 10 months HR for children. In a recent study from South India by Venugopal and co-workers, it has been seen that directly observed treatment, short-course (DOTS) intermittent regimen is an effective treatment for neurotuberculosis.

A paradoxical worsening of clinical and laboratory parameters has been noted by many clinicians immediately after starting ATT, including enlargement of tuberculoma. Addition of corticosteroids may lessen this paradoxical response.

Multidrug-Resistant Neurotuberculosis

Drug resistance may be primary or secondary. Exact incidence of MDR of neurotuberculosis is not known due to difficulty in isolating mycobacteria from the CSF. In other forms of tuberculosis, prevalence of resistance to any drug is 13% to 25% and of MDR is about 13%. Most case reports of MDR TBM from India are among immunocompromised patients due to HIV infection. There is no standard protocol for the treatment. Every attempt should be made to isolate the organism and test for sensitivity. At least two agents to which the organism is sensitive are to be continued for a full 18 to 20 months.

Corticosteroids

Despite a substantial literature accumulated over the past 40 years, the place of corticosteroids in the treatment of TBM remains unclear. It is most beneficial when complications appear. These include raised intra-cranial pressure, cerebral oedema, stupor, focal neurological signs, spinal block, hydrocephalus and basal opto-chiasmatic arachnoiditis (**Table 5**).

Table 5: Corticosteroids in Neurotuberculosis

Indications	
Clinical	Stage 2 or 3 disease Raised intra-cranial pressure Focal neurodeficit suggesting vasculitis Tuberculous encephalopathy
Radiological	Cerebral or perilesional oedema Hydrocephalus Infarcts Opto-chiasmatic arachnoiditis
CSF	Rising CSF protein suggesting spinal block
Doses	Adults: Prednisolone—60 mg per day or 1 mg/kg per day, or Dexamethasone—8 to 16 mg per day Children: Dexamethasone—0.3 to 0.6 mg/kg per day
Duration	3 to 6 weeks, then slowly tapered over 2 to 4 weeks or longer depending upon the clinical response and experience of clinicians

Surgery

Surgical intervention in TBM is primarily directed at relief of hydrocephalus by ventriculo-peritoneal shunt. Progressive hydrocephalus refractory to medical treatment or deterioration of level of consciousness are indications for urgent CSF diversion. The use of temporary external ventricular drainage in conjunction with prophylactic antibacterial agents has been advocated as a safer and convenient alternative to indwelling shunt in TBM.

Surgical excision in tuberculoma is indicated when the anterior optic pathway is compressed with resultant visual impairment or for large tuberculoma with great rise of intra-cranial pressure not permitting for effective medical therapy. Surgery is also useful in tuberculous spondylitis to decompress the cord and to stabilise the spine.

PROGNOSIS

The most firmly established prognostic factor is clinical stage of disease at the start of treatment. There is two-fold increase in mortality when treatment is started at advanced stage of the disease as opposed to the early stage. Other poor prognostic factors include extremes of age and co-existence of miliary disease. The sequelae are common among children seen in 25% to 50% of cases, and include mental regression, behavioural changes, seizures, visual and auditory loss, other cranial nerve palsies, movement disorder, hemiparesis/paraparesis/quadriparesis and various endocrinopathies due to hypothalamic-pituitary damage.

PREVENTION

Large-scale studies demonstrated efficacy of BCG vaccination in preventing pulmonary tuberculosis varying from 0% to 80% and in preventing TBM is 52% to 84%.

The provision of adequate nutrition, housing, and basic healthcare are essential components of disease control programme.

20.13 Neurosyphilis

S Prabhakar, M Modi

Syphilis, a chronic systemic disease caused by *Treponema pallidum*, is usually considered to involve the central nervous system (CNS) late in the course of the disease. In fact, CNS syphilis represents a continuum encompassing early invasion (within the first few weeks or months of infection) to a prolonged period of asymptomatic involvement in the latent phase; and, only in a small per cent of cases, progressing to late neurological manifestations.

EPIDEMIOLOGY

Reports from South-West Asia and Africa estimated the prevalence of syphilis to range from 0.35% to 15%. Data on prevalence of syphilis in India are scanty and seroprevalence has been estimated to be 1.4% and 2.4% in Kerala and Aurangabad, respectively. In the last decade, there has been a 50-fold increase in syphilis in Eastern Europe and epidemics continue to occur with a 7 to 10 year cycle in the USA.

AETIOPATHOGENESIS

Treponema pallidum, a spirochete, is a thin delicate organism with 6 to 14 spirals and tapered ends. Humans are the only known natural host for *T. pallidum*. Virulent strains of *T. pallidum* are grown and maintained only in rabbits, as none of the pathogenic treponemes has been successfully cultured. Nearly all cases of syphilis are acquired by sexual contact with an infectious lesion. Less common modes of transmission include non-sexual personal contact, infection in-utero, and blood transfusion.

T. pallidum rapidly penetrates the intact mucous membranes or microscopic skin abrasions and enters the lymphatics and blood within few hours to produce systemic infection and metastatic foci long before the appearance of primary lesion. The incubation period (from inoculation to appearance of primary lesion) varies from an average of 3 weeks, up to 6 weeks. The primary lesion (chancre) usually persists for 4 to 6 weeks and then heals spontaneously. The generalised parenchymal, constitutional and mucocutaneous manifestations of secondary syphilis usually appear 6 to 8 weeks after the healing of primary lesions. In some patients, it may appear several months after the chancre has healed and some patients may enter the latent phase without secondary lesions. In the latent asymptomatic phase, the disease is apparent only by serology. In the pre-antibiotic era, about one-third of patients with untreated latent syphilis developed clinically apparent tertiary disease; today specific treatment and coincidental therapy for early and latent syphilis have eliminated tertiary syphilis, except for sporadic cases of neurosyphilis, infected with or without HIV.

Neurosyphilis spans all the stages of disseminated disease. CNS invasion occurs during the first few weeks or months of infection and cerebrospinal fluid (CSF) abnormalities are detected in as many as 40% of patients during the secondary stage. Syphilis characterises the most chronic form of meningitis and pathological changes are sequelae of the chronicity of the meningeal reaction. Meningeal, meningovascular and parenchymatous syndromes are perhaps best viewed as a continuum of disease, rather than as discrete disorders. All these disease processes are different clinical expressions of the same fundamental pathological events, especially meningeal invasion, obliterative endarteritis, and parenchymal invasion. Factors which transform the intermediate stage of asymptomatic syphilitic meningeal infection to the late form of parenchymal neurosyphilis are unknown.

CLASSIFICATION OF NEUROSYPHILIS

The classification of neurosyphilis is given in **Table 1**.

Table 1: Classification of Neurosyphilis

Asymptomatic neurosyphilis
Symptomatic neurosyphilis
Meningeal
Meningovascular
Parenchymal
General paresis
Tabes dorsalis

CLINICAL FEATURES

Asymptomatic Neurosyphilis

The diagnosis of asymptomatic neurosyphilis is made in patients who lack neurologic symptoms and signs, but have CSF abnormalities. The CSF abnormalities include mono-nuclear pleocytosis, increased protein concentration or a reactive Venereal Disease Research Laboratory (VDRL) slide test. In primary and secondary syphilis such abnormalities may be found in up to 40% of untreated patients and *T. pallidum* can be isolated in up to 30% of the patients. In patients with untreated asymptomatic neurosyphilis, the overall cumulative probability of progression to clinical neurosyphilis is about 20% in the first 10 years; the likelihood is highest among patients with the greatest degree of pleocytosis or protein elevation in the CSF.

Symptomatic Neurosyphilis

In the antibiotic era, symptomatic neurosyphilis may present not as one classic syndrome, but as mixed, subtle or incomplete forms of disease. The onset of symptoms usually comes one year after infection for meningeal syphilis, at 5 to 10 years after for meningovascular syphilis, after 20 years for general paresis and after 25 to 30 years for tabes dorsalis.

Meningeal Syphilis

This condition may be concurrent with or follow secondary syphilis. Patients often present with headache, nausea, vomiting, neck stiffness, cranial nerve involvement (usually 7th and 8th), seizures and changes in mental status. There may be involvement

of the brain or spinal cord. Rare complications of acute syphilitic meningitis include hydrocephalus, myelitis or lumbosacral radiculitis.

Meningovascular Syphilis

Meningovascular syphilis accounts for 3% to 17% of all cases of neurosyphilis. This reflects diffuse inflammation of pia and arachnoid, together with evidence of widespread arterial involvement. These patients usually present with prodromal symptoms consisting of headache, vertigo, insomnia and psychological disturbances, weeks to months before the onset of the ischaemic deficit. Most patients develop ischaemia in the middle cerebral artery territory and not uncommonly multiple bilateral infarctions. Two types of arteritis have been described in patients with meningovascular syphilis. 'Heubner arteritis' is the most common form and involves the large and medium sized arteries. It is characterised by inflammation of the intima, thinning of media and interstitial proliferation. 'Nissl arteritis' is characterised by endothelial and adventitial proliferation, involving small vessels preferentially. Computed tomography (CT) or magnetic resonance imaging (MRI) demonstrate multiple small infarctions in different vascular distributions involving both the white matter and the cortex and conventional angiography reveals segmental stenosis with occasional beaded appearance in the basal artery and focal stenosis and aneurysmal dilatations in more peripheral ones. The findings are diffuse, accounting for the multiple bilateral infarcts.

Parenchymal Neurosyphilis

General paresis

This encephalitic form reflects widespread parenchymal damage and typically presents as progressive dementia beginning 15 to 20 years after original infection. The disease manifestations can be remembered by the mnemonic *PARESIS* (**Table 2**).

Table 2: General *PARESIS* Mnemonic

P	:	Personality
A	:	Affect
R	:	Reflexes (hyperactive)
E	:	Eye (Argyll Robertson pupils)
S	:	Sensorium (illusions, delusions, hallucinations)
I	:	Intellect (decrease in recent memory, orientation, calculation, judgement, insight)
S	:	Speech

Tabes dorsalis

Tabes presents with symptoms and signs of demyelination of posterior columns, dorsal roots and dorsal root ganglia. Tabes is characterised by lightening pains, autonomic dysfunction and sensory ataxia. Affected patients have normal strength with hyporeflexia in the legs and a positive Romberg's sign. Pupils are abnormal in more than 90% of the cases. Other associated features include optic atrophy, ophthalmoplegia, ptosis, gastric or other visceral crisis (pharyngeal, laryngeal, genitourinary, intestinal, rectal), impotence, faecal incontinence and pain and temperature loss leading to trophic changes such as Charcot's joints and perforating foot ulcers. The small irregular Argyll Robertson pupil, a feature of both tabes dorsalis and general paresis, reacts to accommodation but not to light.

DIAGNOSIS

Cerebrospinal Fluid

The diagnosis of neurosyphilis is based on clinical evidence and is supported by CSF abnormalities, particularly CSF pleocytosis and reactive CSF VDRL tests. The CSF pleocytosis in neurosyphilis is lymphocytic and is generally mild. Mild elevations of CSF protein concentration ranging from 45 to 200 mg/dL are also common, with higher values in early neurosyphilis compared to late neurosyphilis. The CSF VDRL is considered to be the gold standard for diagnosis of neurosyphilis. The accepted sensitivity of CSF VDRL ranges from 30% to 70%, though it is considered to be very specific. False-positive results may be seen when CSF is visibly blood tinged. Thus, a reactive CSF VDRL establishes the diagnosis of neurosyphilis, but a non-reactive test does not exclude the diagnosis. In contrast to CSF VDRL test, CSF treponemal antibody tests, such as CSF fluorescent treponemal antibody absorption test, are more sensitive but less specific for the diagnosis of neurosyphilis. Thus, a non-reactive CSF treponemal antibody may exclude the diagnosis of neurosyphilis but a reactive test does not establish the diagnosis.

T. pallidum can be identified in the CSF by inoculation of CSF into rabbits. However, rabbit inoculation is too cumbersome and expensive to be used clinically. Polymerase chain reaction (PCR) or reverse transcriptase PCR can be used to detect *T. pallidum* in CSF. Detection of *T. pallidum* in CSF is more common in early syphilis compared to late syphilis.

Neuroimaging

Neuroimaging in patients with asymptomatic neurosyphilis usually shows no abnormalities. Imaging in syphilitic meningitis

Figure 1: Contrast enhanced T1-weighted MRI image showing enhancement of meninges in the region of right third nerve (CSF VDRL positive).

involving brain and spinal cord may show enhancement of meninges, cranial nerves or spinal roots (**Figures 1 and 2**). CT or MRI of brain may show one or more areas of infarction in meningovascular syphilis. Cerebral gummas usually enhance, as may the associated meninges. Angiography may show segmental arterial narrowing, focal narrowing and dilatations or 'beading' and occlusion. Syphilitic vasculitis more commonly affects the supraclinoid segment of the internal carotid artery.

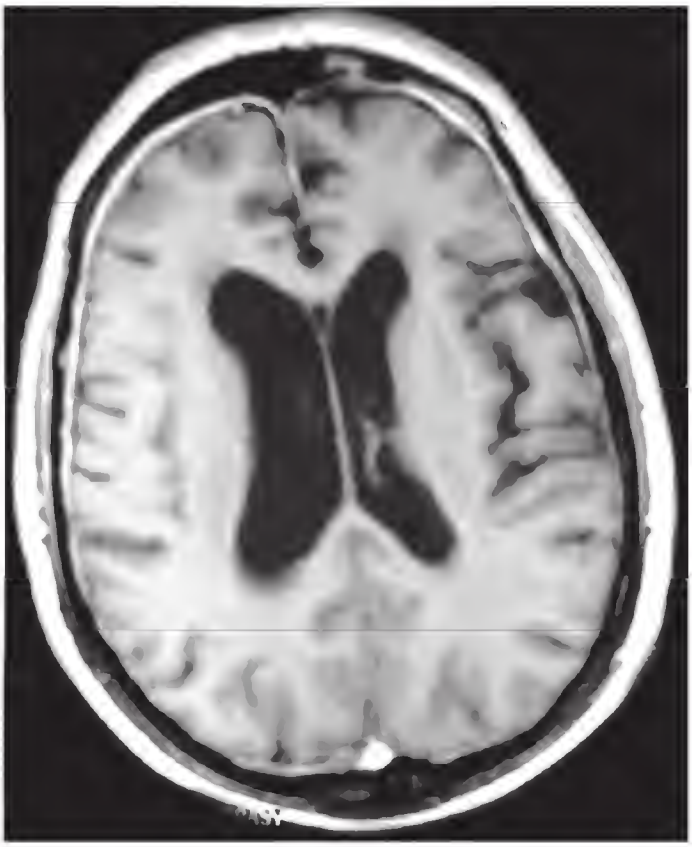

Figure 2: Contrast enhanced T1-weighted MRI image showing diffuse enhacement of pachymeninges and brain atrophy in a patient of general paresis.

TREATMENT

The Centre for Disease Control (CDC) recommend high dose intravenous penicillin G as first-line therapy and prevention for neurosyphilis and intramuscular procaine penicillin with oral probenecid as an alternative in adults, but not in children (**Table 3**).

The success of neurosyphilis therapy is judged by resolution or stabilisation of clinical abnormalities and by resolution of CSF abnormalities. CDC guidelines state that CSF WBC (white blood cell) counts should decline at 6 months and all CSF abnormalities should resolve by 2 years after the treatment. Careful follow-up after neurosyphilis therapy is mandatory for all patients. CSF should be re-examined 3 months after therapy. If CSF WBC countis normal and the CSF VDRL is non-reactive at 3 months, no further LP is required. For those with persistent CSF abnormalities at 3 months after therapy, CSF should be re-examined at 6 months after therapy and every 6 months thereafter until CSF WBC and CSF VDRL reactivity normalise. Failure of the CSF WBC count to decrease 6 months after therapy or failure of CSF VDRL to decline four-fold (or to non-reactive if initial titer is <1:2) 1 year after therapy is an indication for re-treatment. Serum VDRL or rapid plasma reagin test should be obtained at 3, 6 and 12 months after therapy and every 3 to 6 months thereafter until they are non-reactive.

Table 3: Treatment of Neurosyphilis

Recommended Regimen

Adults	:	Aqueous crystalline penicillin G, 18-24 MU IV per day given as 3 to 4 MU IV q 4h or as a continuous IV infusion for 10 to 14 days
Children	:	Aqueous crystalline penicillin G, 200,000-300,000U/kg/day IV, given as 50,000 U/kg IV q4-6h for 10 days

Alternative Regimen (adults only)

Procaine penicillin, 2.4 MU IM once daily plus, probenecid 500 mg p.o. q.i.d., both for 10 to 14 days

Experimental Regimen (adults only)

Ceftriaxone: 2 g IV once daily for 10 to 14 days

Alternative Drugs in Patients Allergic to Penicillin

Doxycycline	:	100 mg p.o. b.i.d for 2 weeks
Tetracycline	:	500 mg p.o. q.i.d for 2 weeks
Erythromycin	:	40 mg/kg/day (max 500 mg/dose) p.o. in divided doses for 2 weeks

NEUROSYPHILIS AND HIV

Syphilis is most common in individuals who are at risk of HIV infection or who are already infected with HIV. Patients who have both HIV infection and syphilis may be more likely to fail therapy for early syphilis and to develop early neurosyphilis. Neurosyphilis may be more difficult to diagnose in the setting of concomitant HIV infection. HIV infected patients may be more likely to fail therapy for neurosyphilis.

20.14 Acute Viral Infections of Central Nervous System

Nadir E Bharucha

ACUTE VIRAL INFECTIONS

Acute viral infections of the central nervous system (CNS) have a sudden onset and run a short course over days to weeks. They result in meningitis, encephalitis, myelitis, radiculitis or combinations of these. Certain features of viral infections are noteworthy. This includes tropism—viruses may infect specific cells and anatomical areas of the nervous system, e.g. anterior horn cells are affected in poliomyelitis, the dorsal root ganglion cells in varicella zoster infection and the neurons in rabies. Certain viruses (e.g. herpes simplex and varicella zoster) have the ability to remain latent in the nervous system and get reactivated months to years later. Most viruses replicate in extraneural tissues before invading the CNS and involvement of the nervous system is usually only an occasional complication of the systemic viral infection. The majority of viruses enter the nervous system via the haematogenous route, except herpes simplex and rabies viruses. Often the viral agent cannot be identified during the acute illness and the diagnosis can only be made retrospectively. Viruses may affect the CNS by means other than direct invasion; peri-venous encephalomyelitis usually follows a systemic viral infection or vaccinations and is an allergic reaction to viral antigen.

ACUTE VIRAL MENINGITIS

Viral meningitis is inflammation of the meninges due to a viral infection and in the majority of cases is a benign, self-limiting illness. Cerebrospinal fluid (CSF) examination shows an increase in lymphocytes and proteins with normal sugar.

'Aseptic meningitis' is a non-specific term indicating any form of meningitis where the CSF is bacteriologically sterile, accompanied by a lymphocytic pleocytosis and normal sugar content. Viral meningitis is a common but not the only cause of aseptic meningitis.

Aetiology

The most common viruses causing meningitis are the enteroviruses (poliovirus, coxsackie, ECHO, enterovirus [EV]-70), arboviruses, HIV and herpes simplex viruses (HSV 1 and 2). Others are the lymphocytic choriomeningitis virus (LCMV), Epstein-Barr virus (EBV), influenza, adenovirus and the mumps virus. Enteroviruses are the commonest cause of viral meningitis.

Clinical Features

All age groups are susceptible, but it is more common in those below 30 years of age. There is often a prodromal phase with fever, headache, myalgia and malaise. Many enteroviral infections give rise to a skin rash or gastrointestinal symptoms. Upper respiratory symptoms may accompany adenovirus and influenza infections. Measles and chickenpox usually present with their classical skin lesions before invading the CNS. Mumps meningitis may be accompanied by parotitis or pancreatitis.

With the onset of meningitis there is fever, headache, photophobia, nausea, vomiting and neck stiffness. The sensorium is usually clear and focal neurological signs are rare.

Investigations

Routine blood investigations are usually normal. CSF examination shows a clear fluid with mildly raised pressure, moderately increased proteins, normal sugar content and pleocytosis ranging from 50 to 500 cells/mm^3. The pleocytosis is mainly lymphocytic although very early in the disease there may be a predominance of neutrophils. High CSF cell counts in thousands is seen in LCMV and mumps and CSF glucose may be mildly reduced in LCMV, mumps, HSV-2, varicella-zoster virus (VZV). Culture of the virus from the CSF, blood, urine or stool is only rarely possible. CSF PCR is now being increasingly used to identify replicating viruses in the acute stage and is useful for diagnosing HSV, VZV, CMV and EB viruses. Demonstration of virus-specific IgM antibodies in serum also suggest acute infection and if such antibodies are found in the CSF, acute CNS infection may be presumed. However, seroconversion does not occur immediately and in most instances, the diagnosis is made retrospectively by measuring the viral antibody levels in the acute and convalescent phases. A four-fold increase in specific antibody titres in acute and convalescent serum or CSF is considered to be positive and even IgM antibodies may persist for months in the serum and CSF.

Differential Diagnosis

It is important to exclude other causes of aseptic meningitis. These include partially treated pyogenic meningitis, tuberculosis, fungal infections, syphilis and carcinomatous meningitis. Parameningeal foci of infection such as, brain abscess and subdural empyema can present with aseptic meningitis, though usually have focal signs. Subarachnoid haemorrhage is an important clinical consideration.

Treatment

Acyclovir may be used in HSV-1 and 2, EBV and VZV infection and HAART in HIV meningitis. But viral meningitis is usually a self-limiting illness and specific treatment with anti-viral drugs is usually not required. Symptomatic care, like relief of headache, bed rest, provision of adequate nutrition and maintenance of fluid and electrolyte balance is usually sufficient.

ACUTE VIRAL ENCEPHALITIS

In viral encephalitis there is inflammation of the brain parenchyma resulting in an acute febrile illness, with evidence of meningeal involvement and signs and symptoms of diffuse and/or focal neurological deficits. If the spinal cord is also involved, the term encephalomyelitis is used. Viral encephalitis is a far more serious illness than viral meningitis.

Aetiology

A large number of viruses can cause encephalitis, but the more common ones are shown in **Table 1**.

Table 1: Common Viruses Causing Acute Encephalitis

Arboviruses	Japanese, St. Louis, Western equine, California
Herpes virus	Varicella-Zoster virus, Epstein-Barr virus, Cytomegalovirus
Rhabdovirus	Rabies
Enteroviruses	Coxsackie, ECHO Virus
Influenza	Parainfluenza
Others	Mumps, measles, rubella, lymphocytic choriomeningitis

Pathogenesis and Pathology

Microscopic examination reveals perivascular and parenchymal infiltration with mononuclear cells, glial nodules and neuronophagia. Inclusion bodies may be seen in the cytoplasm or nucleus of brain cells. These, though characteristics, are not specific enough to identify the particular virus involved, except the Negri bodies of rabies. The CNS may be involved diffusely or there may be predominant involvement of localised areas.

Clinical Features

There is often a prodromal period, lasting for a few days, of mild fever, bodyache, headache and malaise. In addition, there may be specific signs and symptoms which could help identify the causative virus, e.g. skin rashes with coxsackie and echoviruses and herpangina with certain enteroviruses. Upper respiratory symptoms are common with influenza and respiratory viruses. Mumps may present with parotitis or pancreatitis. The characteristic skin lesions of chickenpox, measles and rubella are usually evident before the patient develops the rare complication of encephalitis.

After the prodromal phase there may be a short afebrile period before signs and symptoms of encephalitis commence. This biphasic pattern is commonly seen in arboviral encephalitis.

The onset of encephalitis is usually acute with fever, headache, photophobia, nausea, vomiting and signs of meningeal irritation. Diffuse CNS inflammation results in confusion, disorientation, agitation, stupor and sometimes coma. Convulsions are common. Focal neurological deficits may manifest as aphasia, hemiparesis, sensory deficits, visual field defects, ataxia, ocular palsies and other cranial nerve palsies. Spinal cord involvement may result in myelitis with varying degrees of paraparesis.

Hypothalamic involvement can give rise to diabetes insipidus and autonomic instability. Syndrome of inappropriate ADH secretion (SIADH) is also a common manifestation. Brainstem involvement can compromise the respiratory centre. In severe cases, cerebral oedema can raise the intra-cranial pressure and precipitate brain herniation.

Investigations

Examination of the blood is usually unremarkable except for the occasional finding of atypical lymphocytes in EBV infection, increased serum amylase in mumps, and hyponatraemia in SIADH. CSF examination reveals a lymphocytic pleocytosis with moderately raised protein and normal sugar content. Serological tests, using acute and convalescent serum, can help identify the causative virus if there is a four-fold increase in specific antibody titres. Viral culture from serum and CSF is sometimes possible. Nucleic acid amplification using the PCR is likely to become useful in the future.

CT or MRI scans of the brain may show non-specific diffuse or focal changes with cerebral oedema. The EEG usually shows a bilateral slowing with disappearance of the normal waveforms and occasional high-voltage spike-and-wave discharges. When these studies show focal changes in the frontotemporal areas of the brain, one should consider the possibility of HSV encephalitis.

Diagnosis

Other conditions that may mimic viral encephalitis should be ruled out (**Table 2**). These include non-infectious encephalopathies, septic encephalopathy occurring as a remote effect of systemic sepsis, post-infectious acute disseminated encephalomyelitis and infectious inflammatory encephalitis of non-viral aetiology. The epidemiological setting is important in making a diagnosis because certain types of encephalitis, especially those due to arboviruses, tend to cause epidemics, affecting a large number of people in a restricted geographical area. The prodromal symptoms and signs can also help in identifying the causative virus.

Table 2: Differential Diagnosis of Acute Viral Encephalitis

CNS Infections and Related Conditions	Other Primary CNS Disorders	Metabolic, Toxic and Other Systemic Diseases
Bacterial e.g. partially treated meningitis, parameningeal infections, brain abscess, tuberculosis, neurosyphilis	Structural brain lesions e.g. those caused by vascular disease, trauma or tumour	Acute sodium and carbohydrate imbalance, porphyria, phaeochromocytoma
Fungal e.g. *Cryptococcus, Candida*	Acute psychotic disorders	Salicylate, heavy metal, barbiturate intoxication
Protozoal e.g. cerebral malaria, toxoplasmosis	Seizures, e.g. postictal or complex partial	Sarcoidosis, collagen vascular disorders, neoplasm, infective endocarditis
Metazoal e.g. cysticercosis	Status epilepticus, neoplasm	
Acute post-infectious encephalomyelitis		Systemic infections, e.g. typhoid, septicaemia, Hypertensive encephalopathy

Treatment

Vital parameters should be closely monitored and supportive and symptomatic treatment should be initiated. Raised intra-cranial pressure may be decreased using mannitol in a dose of 0.5 gm/kg of 20% solution intravenously over 20 minutes every 4 to 6 hours. Steroids may also be used to decrease the cerebral oedema. Anticonvulsants are probably best given prophylactically and the drugs of choice are phenytoin and carbamazepine.

Antiviral therapy with acyclovir significantly improves prognosis in HSV encephalitis. It can also be of use in severe encephalitis due to VZV and EBV.

SPECIFIC ACUTE VIRAL INFECTIONS

Poliomyelitis

Poliomyelitis is caused by the poliovirus, an RNA virus belonging to the picornavirus (enterovirus) family. There are three serotypes, 1, 2 and 3. It can cause acute asymmetrical flaccid paralysis which may produce a permanent disability. Poliomyelitis-like syndromes can also be caused by coxsackie viruses A and B, enterovirus 70, and viruses usually associated with an encephalitic illness, such as the Japanese encephalitis and West Nile viruses. Prophylactic vaccination is the most effective means of preventing poliomyelitis.

Post-polio syndrome

Some patients, years after the acute attack of poliomyelitis, develop progressive weakness and atrophy in the paralysed limb and sometimes also unaffected parts of the body. The pathogenesis is not clear but may be due to a delayed dysfunction of surviving enlarged motor units coupled with ageing, overuse or disuse.

Japanese Encephalitis

This arboviral encephalitis, caused by a flavivirus, is one of the most common causes of epidemic encephalitis in India.

Epidemiology

Japanese encephalitis is endemic in China, Thailand, Korea and many other parts of South-East Asia. In India, sero-conversion was first detected in areas of Tamil Nadu in 1955. Following this, there have been frequent epidemics in different parts of the country, viz., Tamil Nadu, Karnataka, Andhra Pradesh, Puducherry, Goa, Maharashtra, Madhya Pradesh, Uttar Pradesh, Bihar, West Bengal, Assam and Manipur. Epidemics usually occur in the summer and monsoon months.

Clinical features

Children and young adults are mainly affected, except in populations with little resistance. The incubation period ranges from 5 to 15 days. A large number of subclinical cases occur and it is only the occasional patient (1:300 to 1:1000) who manifests signs and symptoms of encephalitis.

The onset is abrupt. About 90% of patients experience severe rigors initially. Other features of viral encephalitis then manifests. Seizures are common in children and focal neurologic deficits occur. Involuntary movements like chorea, myoclonus and tics are also seen. Hyperthermia may occur. A lower motor neuron type of muscle weakness and wasting has been noted rarely. The mortality rate ranges from 20% to 40% and may even be greater. In those who survive, there may be sequelae such as seizures, persistent paralysis, ataxia, mental retardation and, rarely, Parkinsonism.

Investigations

There may be peripheral leucocytosis. CSF examination shows lymphocytic pleocytosis, with elevated proteins and normal sugar. During the acute illness, a probable diagnosis can be made if there is a significant increase in specific antibody titre in serum or CSF to the particular virus, as compared to antibody titres to other flaviviruses. Recently, a specific and sensitive serologic test (using ELISA) has been developed which detects IgM antibody in the CSF during the acute phase of the illness. The diagnosis can be confirmed if there is a four-fold increase of antibody titres between acute and convalescent sera or CSF. Viral culture is usually not successful.

Treatment

No specific antiviral drugs are available and only supportive care such as reduction of cerebral oedema, control of seizures and circulatory and respiratory support can be given.

Prevention

There is an effective inactivated vaccine that should be given to high-risk groups, especially children, in the inter-epidemic period. Two doses of 1 mL each (0.5 mL for children less than 3 years) are given subcutaneously at an interval of 7 to 14 days. A booster dose of 1 mL is given after a few months (but before 1 year). Protective immunity develops one month after the second dose. Vaccination may be repeated after 3 years.

Other preventive measures include vector control methods, vaccination of animal reservoirs such as pigs and use of mosquito nets.

Rabies

Rabies is a fatal zoonosis that affects only the CNS. It is found worldwide except Antarctica, being spread by mammals to man, dogs being important vectors in Asia and Africa but more commonly by bats in developed countries. It was known to ancient Babylonians 4000 years ago. Its name derives from 'rabhas' (Sanskrit) to rage or 'rabere' (Latin) to rave. It affects 30,000 to 70,000 people per year throughout the world. The RNA rhabdovirus of the genus Lyssavirus is responsible. There are several serotypes. The organism is transmitted either by a bite or a scratch, by inhalation or organ transplant.

Clinically, there are 5 stages – an incubation period (average 20 to 60 days), a non-specific prodrome, the encephalitic phase (furious rabies), coma and death. Typically there is local pain or paraesthesia or fasciculation related to the entry of virus into the peripheral nervous system. Hydrophobia and aerophobia are due to brainstem involvement and there is abnormal autonomic activity. Dumb rabies or paralytic rabies is much less common and can masquerade as the Guillain-Barre syndrome. Diagnosis can be confirmed by identification of the virus in saliva or in the nerve endings around hair follicles in a full thickness nuchal skin sample or by the presence of antibodies in serum and CSF. There is no treatment apart from symptomatic care. The only survivors are those who have been immunised. Rabies can be prevented by pre-exposure prophylaxis and post exposure wound care and active and passive immunisation according to established guidelines.

Herpes Simplex Encephalitis

The HSV commonly cause infection but rarely produce encephalitis. Herpes simplex encephalitis is the commonest fatal cause of sporadic encephalitis. All age groups are affected but it is most common in children and young adults.

Pathogenesis and pathology

HSV-1 accounts for more than 95% of cases. It is a double-stranded DNA virus and is the causative agent of herpes labialis (cold sore). Encephalitis may be a manifestation of primary infection by the virus, in young people. In such cases, the virus first infects the face or mouth and then presumably enters the CNS via the olfactory bulb. But the virus also has the ability to remain latent in sensory ganglion cells (especially of the trigeminal nerve) and probably also in the CNS itself. It is postulated that the majority of cases of herpes simplex encephalitis occur as a consequence

of reactivation of the latent virus. The incidence of herpes simplex encephalitis is thought to be more in patients with AIDS and in other immunosuppressed patients.

There is predominant involvement of the medial temporal lobes, other parts of the limbic system and orbital surface of the frontal lobes. There is haemorrhagic necrosis in these areas with mononuclear cell infiltration and often intranuclear (Cowdry type A) inclusion bodies in neurons and glial cells.

Clinical features

The onset is usually abrupt, with fever and headache. Early in the course, there may be behavioural changes, confusion and hallucinations, suggesting an acute psychotic illness. But soon there is a progressive decline in the level of consciousness associated with myoclonic jerks and focal, complex partial or generalised seizures. Motor weakness is less commonly seen. Mortality is high. Among those who survive, many have residual dementia with prominent impairment of retentive memory. In young children HSV-1 encephalitis more often presents as diffuse encephalitis without the typical localisation seen in older children and adults.

Investigations

CT of the brain often shows areas of low absorption, oedema and contrast enhancement in the temporoparietal cortex. MRI is more sensitive than CT and shows hyperintensity and cerebral oedema in the frontotemporal, cingulate or insular regions on T2-weighted images. Cortical and meningeal contrast enhancement is also seen. If possible, MRI brain should be the first investigation.

CSF findings are similar to that seen in other forms of encephalitis. The CSF may also show a significant number of RBCs (>500 cells/mL) but this finding is common to other forms of encephalitis with haemorrhagic necrosis. CSF may be normal in 5% of patients with HSV encephalitis. EEG may show epileptiform high voltage periodic lateralising discharges. Serologic studies are usually unhelpful in the acute stage since a rise in specific antibody titre is delayed. Viral isolation from CSF and blood is usually unsuccessful. Probably the most sensitive and specific early non-invasive method for the diagnosis is the demonstration of HSV DNA in CSF using the PCR. The sensitivity of the test is about 95% in the first week (possibly less in the first 24 to 48 hours), but becomes less over the subsequent weeks.

Treatment

The drug of choice is acyclovir which is given as an intravenous infusion over 1 hour at a dose of 10 mg/kg every 8 hours for 14 days in PCR proven cases. The patient should be well hydrated to avoid the transient renal insufficiency that may result due to crystallisation of the compound in the renal parenchyma. Treatment should be prolonged to 21 days in immunosuppressed patients to reduce the possibility of relapse.

When acyclovir is given early in the disease, the mortality can be reduced from 70% in untreated patients to less than 30%, and surviving patients have markedly decreased residual symptoms.

Other Herpes Virus Infections

HSV-2

About 50% of infants delivered by the vaginal route to mothers suffering from a primary attack of genital herpes (caused by HSV-2) develop a meningoencephalitis that is often very severe. The incidence is much less if the mother is having a reactivation of genital herpes. HSV-2 also produces encephalitis in immunocompromised patients.

About 25% of patients with acute genital herpes develop transient symptoms and signs of viral meningitis. Moreover, the virus may invade the sacral spinal cord resulting in bladder and bowel disturbances and impotence. Transverse myelitis is a rare complication of HSV-2 infection. In some patients there may be recurrent attacks of aseptic meningitis. Indeed HSV is thought to be the commonest cause of Mollaret's meningitis. Acyclovir may be useful in selected cases such as those with recurrent aseptic meningitis.

Varicella-zoster virus

VZV causes varicella in children and herpes zoster in adults. The commonest neurological complication of varicella is a self-limiting cerebellar ataxia. Less common complications include meningoencephalitis, transverse myelitis and Reye's syndrome. VZV is a much commoner cause of encephalitis than HSV. The neurological syndromes associated with herpes zoster include cranial and peripheral nerve palsies, cerebral vasculitis and encephalomyelitis. Both HSV1 and VZV have been associated with Bell's palsy. Treatment is with acyclovir 10 mg/kg 8 hourly for 7 days together with prednisolone 60 to 80 mg/day for five days if there is cerebral vasculitis.

Epstein-Barr virus

Neurological complications are very rare. Encephalomyelitis, aseptic meningitis, and cranial and peripheral neuropathies can all occur. Diagnosis depends on recognition of the clinical syndrome of infectious mononucleosis and its laboratory correlates. Serum EBV, IgG and IgM antibodies are elevated and EBV DNA will be identified in CSF by PCR.

Cytomegalovirus

CMV often causes an encephalitis, mass lesions and myeloradiculitis in immunocompromised patients, including those with AIDS. Diagnosis is made by CSF PCR. If the foetus is infected by the virus in utero, congenital malformations and mental retardation occur. Treatment is by ganciclovir and should be continued in HIV as long as the CD4 count is depressed.

Human herpes virus 6, 7, 8

Human herpes virus types 6, 7 and 8 are being found increasingly in specific situations such as renal transplant. Human herpes virus 6 is thought to be associated with multiple sclerosis.

Chikungunya

Chikungunya, meaning which bends up, is a viral illness producing fever, rash and joint pains, carried by *Aedes aegypti*, like dengue and yellow fever. It recently reached epidemic proportions in central and southern India. It rarely produces neurological manifestations, but affects all levels of the neuraxis, meninges, brain, spinal cord and peripheral nervous system. Residual defects may be severe and there is no specific treatment.

Encephalitis Lethargica (von Economo's Disease)

This is a type of encephalitis which mainly affects the thalamus and midbrain. There was a pandemic around the time of World War I, but sporadic cases continue to be reported. Many of these

patients, months or years later, develop a slowly progressing Parkinsonism which is often associated with episodes of oculogyric crisis (tonic deviation of the eyes to one side, usually upwards, for minutes to hours). The symptoms of Parkinsonism can be relieved by levodopa.

SLOW VIRAL INFECTIONS OF THE CNS

These diseases are characterised by a long incubation period ranging from months to years. Once the disease manifests, it progresses slowly and insidiously over several months without fever and the other usual features of an infection. Because of these characteristics, slow viral infections behave more like degenerative and hereditary diseases. The reason for such an atypical course is not well understood. Slow viral infection may be classified as those caused by conventional viruses and those by non-conventional agents (prions).

SLOW VIRAL INFECTIONS CAUSED BY CONVENTIONAL VIRUSES

Subacute Sclerosing Panencephalitis (SSPE)

SSPE, formerly called inclusion body encephalitis, is a subacute form of encephalitis caused by the measles virus. The disease mainly affects young children between 5 and 15 years of age, but rarely young adults may also be involved. Most patients have had measles at an unusually young age, usually before the age of 2 years. The incidence of SSPE has greatly decreased after the introduction of measles vaccination.

Pathogenesis

It is postulated that measles virus, lacking M protein in its membrane, is able to remain dormant in brain cells and this subsequently results in death of neurons.

Clinical features

The onset of the disease is insidious and usually manifests as behavioural disturbances and poor performance in school. The child then becomes clumsy and begins to have involuntary movements, especially myoclonic jerks. Visual disturbances are common. There is no fever. Symptoms and signs of pyramidal and extrapyramidal system lesion are seen and dementia then supervenes. Death is almost invariable within 1 to 2 years.

Investigation

High antibody titres to the measles virus are present in the blood and CSF, but characteristically, there are no antibodies against the M protein of the measles virus. The CSF is acellular with mild increase in proteins and shows a marked increase in oligoclonal gamma globulin. The EEG shows a 'burst suppression' pattern with periodic bursts (every 5 to 85) of high voltage sharp slow waves followed by a period of suppression with attenuated waveforms. In the later stages, the CT and MRI may show cortical atrophy and multifocal changes in the white matter as a result of demyelination.

Treatment

The disease is almost always fatal, but antiviral drugs like inosiplex and intrathecal interferon have been reported to prolong survival. Clonazepam can be used to control the myoclonus.

Rarely, subacute measles encephalitis, unlike SSPE occurs shortly after measles in children with defective cell-mediated immunity. Also rare is progressive rubella panencephalitis, which occurs several years after congenital rubella and is similar to SSPE, but rubella antibodies, not measles antibodies, is found in serum and CSF.

Progressive Multifocal Leucoencephalopathy (PML)

PML is a rare disease caused by a papovavirus, named after the initial patient, JC virus. It usually occurs in patients with haematologic malignancies, AIDS, other immunosuppressed states or chronic debilitating diseases, in whom there is defective cell-mediated immunity, and now with a variety of drugs (natalizumab).

Clinical features

The disease usually presents with visual field defects especially hemianopia and impairment of higher functions with dementia and personality changes. As the disease progresses, motor and sensory deficits occur. Fever and seizures are not common. Death usually occurs within 6 months.

Investigations

MRI is useful in detecting the demyelinating lesions in the white matter. These lesions are typically T2 hyperintense, minimally enhancing and located periventricularly in the centrum semiovale, parieto-occipital region and cerebellum. CSF is usually normal. Serological tests are unhelpful because nearly 90% of the adult population is seropositive for the JC virus, but PCR can be used with high specificity to identify JC virus in the CSF.

Treatment

PML is almost always fatal but if the immunosuppressed state can be reversed, e.g. by treating HIV, the disease process may be arrested. Cytosine arabinoside has been tried but its usefulness is unproven. Plasmapheresis has been tried for natalizumab-induced PML.

PRIMARY HIV INVOLVEMENT OF THE CNS

HIV can directly involve the nervous system, resulting in many neurological syndromes (**Table 3**).

Table 3: Manifestations of Primary HIV Involvement of the Nervous System

CNS Syndromes	Neuropathies	Myopathies
Aseptic meningitis AIDS dementia complex Vacuolar myelopathy Vasculitis	Inflammatory demyelinating polyneuropathy (acute and chronic) Distal symmetric sensori-motor polyneuropathy Mononeuritis multiplex Progressive radiculopathy	Polymyositis Nemaline rod myopathy

Meningitis

Many patients, at or soon after sero-conversion, develop signs and symptoms of meningitis. This is usually benign and self-limited.

AIDS Dementia Complex (ADC)

ADC is a form of subacute encephalopathy and manifests insidiously with impairment of memory, poor concentration, behavioural changes and difficulty in writing. Tremor, ataxia, defective ocular movements, paresis, hyperreflexia, and bowel and bladder disturbances then supervene.

There is a moderate increase in CSF proteins and IgG and there may be mild lymphocytic pleocytosis. Antibodies to the virus are present in high titres in the serum and CSF, especially in the latter. The virus may be cultured from the CSF. CT shows mild cerebral atrophy and multifocal white matter changes are detected by MRI in a large number of patients. The EEG shows a generalised slowing or may be diffusely disorganised.

Histopathology shows multinucleated giant cells throughout the cortex and white matter with reactive gliosis. The giant cells contain HIV particles and viral antigens. The endothelial and glial cells may also contain viral antigens but the neurons are rarely infected. Neuronal injury probably is a consequence of cytokines and neurotoxins released by infected immune and glial cells.

In addition to symptomatic care, early treatment with HAART may slow the progress of the disease and produce cognitive improvement.

Differential diagnosis

As shown in **Table 4** patients with AIDS are prone to opportunistic infections and neoplasms that also cause CNS manifestations. These should be excluded because many of them can be treated effectively. Sometimes, stereotactic brain biopsy may be required to arrive at a definite diagnosis.

Table 4: Opportunistic Infections and Neoplasms Affecting the Nervous System in Patients with AIDS

Opportunistic Infections		Neoplasms
Viral	**Non-viral**	
Cytomegalovirus	*Cryptococcus*	Primary CNS lymphoma
JC Virus	*Toxoplasma*	Metastatic systemic lymphoma
HSV-1, 2	*Mycobacteria*	Metastatic Kaposi's sarcoma
Varicella-zoster virus	*T. pallidum*	
	Aspergillus	
	Nocardia	
	Mucormycosis	

AIDS = Acquired immunodeficiency syndrome; HSV = Herpes simplex virus; CNS = Central nervous system.

Vacuolar Myelopathy

Ten to thirty per cent of patients with AIDS develop a vacuolar myelopathy, characterised by a progressive spastic-ataxic paraparesis with urinary incontinence. Most also have evidence of AIDS dementia. Pathologically there is vacuolar degeneration of the white matter of the lateral and posterior columns, especially affecting the thoracic spinal cord. It resembles B12 deficiency, there may be coexisting B12 deficiency, but B12 deficiency is not responsible. There is oedema of the myelin sheath of nerve fibres and the HIV virus can be isolated from the spinal cord of those affected. There is no effective treatment for vacuolar myelopathy, unlike HIV encephalopathy.

Neuropathies

Seropositive individuals may also develop acute inflammatory demyelinating polyneuropathy (AIDP, GBS) which is similar to that seen in seronegative patients. But, unlike these patients, the CSF shows a monocytic pleocytosis, in addition to a raised protein level and normal sugar. Chronic inflammatory demyelinating polyneuropathy (CIDP) runs a more chronic course. As in seronegative patients, plasmapheresis and high dose immunoglobulin therapy are likely to be useful in the management. Both AIDP and CIDP are rare forms of neuropathy in HIV-infected patients. They occur only when the CD4 count is over 400/mm^3.

The most common form of neuropathy in HIV-infected patients is a painful, distal, symmetric sensory neuropathy. It occurs when CD4 count is low, usually less than 200/mm^3. Patients initially complain of paraesthesiae and pain in the feet. Examination shows impaired pain and temperature sensation with loss of ankle jerks. Symptomatic relief of pain can be achieved with analgesics, tricyclic anti-depressants and duloxetine, and anti-convulsants, such as carbamazepine, gabapentin and pregabalin.

TROPICAL SPASTIC PARAPARESIS (TSP)

TSP is a chronic neurological disease characterised by a slowly progressive spastic paraparesis and variable sensory abnormalities. It is strongly associated with the HTLV-1 virus although environmental toxins and nutritional factors may occasionally play a role. The disease is prevalent in Japan (where it is also called HAM or HTLV-1-associated-myelopathy), Seychelles, the Caribbean Islands, parts of South America and Western Africa.

Clinical Features

The disease mainly affects those in the third and fourth decades of life with a greater prevalence among women. Patients present with a gradually progressive spastic paraparesis with hyperreflexia and positive Babinski sign. Sensory symptoms like paraesthesias are common in the distal lower limbs, and sensory deficits particularly of position and vibration sense are frequent. Bladder symptoms supervene and constipation is common. Spasticity and weakness may also be present in the upper limbs but are much less than in the lower limbs. Pathologically, there is degeneration of the lateral columns, especially the corticospinal tracts. To a lesser extent, degenerative changes may also be seen in the posterior columns and the spino-cerebellar and spino-thalamic tracts.

Investigations

The CSF may show a mild pleocytosis but proteins are usually raised. High titres of antibodies to the virus can usually be detected in the serum and CSF and the virus can also occasionally be cultured from lymphocytes in the CSF and blood. MRI may show evidence of demyelination in the spinal cord.

Treatment

Patients often show a favourable response to oral or parenteral steroids. Zidovudine may retard progression of the disease by limiting viral replication.

20.15 Slow Virus Infections and Prion Diseases

SK Shankar

The term 'prion' was coined by Stanley Prusiner in 1982 to describe the atypical infectious proteinaceous agent causing transmissible spongiform encephalopathies, a group of infectious neurodegenerative diseases with long incubation periods and invariably fatal outcomes affecting a broad spectrum of host species. In humans, prion disease results from infectious modes of transmission: new variant Creutzfeldt-Jakob disease (vCJD) following consumption of infected beef; iatrogenic CJD following blood transfusion or cadaveric tissue grafting; inherited modes following non-conservative germ line mutation of the prion protein (PRNP) gene open reading frame - familial CJD, Gerstmann-Straussler-Scheinker disease (GSS), fatal familial insomnia (FFI), or by mechanisms not well understood-sporadic CJD (sCJD). The clinical symptoms associated with each of the forms vary dramatically. The disease associated prion-protein (PrPsc) is a partially protease resistant, misfolded β pleated , insoluble, disease specific isoform of the host encoded native cellular prion protein (PrPc), accumulating in neural and reticuloendothelial tissues.

CREUTZFELDT-JAKOB DISEASE

The global incidence of CJD varies from 0.3 cases per million to 1.1 cases per million population. sCJD accounts for 80% to 85% of cases, occurring world wide and affects people in the middle and old age. Inherited (familial) form of CJD (fCJD) accounts for about 10% to 15% of cases. The CJD Registry at National Institute of Mental Health and Neurological Sciences (NIMHANS), Bangaluru has recorded 124 cases over 45 years (1968–2009), with an approximate incidence of 0.124 cases per million population. Majority of the patients presented between the age of 55 years and 65 years and another peak at a younger age (35 to 45 years), with male preponderance. The disease in India appears to be manifesting a decade earlier compared to the West. Among the cases recorded in the Registry, 10 of the 25 cases where the history was available were vegetarians, confirming that CJD can occur in vegetarians and represents the sporadic form occurring due to genetic mutation. In India, there have been no authentic cases of iatrogenic CJD (iCJD) following blood transfusion or corneal transplantation.

Replication of the prion protein occurs in lymphoid tissues like spleen and lymph nodes, well before neuroinvasion. Prions are lymphotropic in sheep scrapie and vCJD, but less so in sCJD and bovine spongiform encephalopathy. PrPc, encoded on chromosome 20 in humans is absolutely essential for transportation of PrPsc to the central nervous system (CNS). Haemopoietic cells transport prions from the site of entry to the lympho-reticular system, where they replicate. Recent studies have documented deposits of PrPsc in nerves and muscle of humans, and a human case of CJD with myositis and deposition of PrPsc in muscle and brain has been reported.

The dynamic prion pathogenesis probably has distinct phases of infection like peripheral replication, transmigration from the periphery to CNS and neurodegeneration. The infective PrPsc initiates a thermodynamically controlled cascade causing conformational change of native PrPc into the insoluble, fibrillary form. The PrPc and PrPsc are not neurotoxic and the precise cause of neuro-degeneration is not clear. In cases of fCJD, two important codon mutations at 178 and 200 have been identified. Polymorphism at PrP codon 129 is critical to determine the clinical phenotypes; valine at codon 129 results in classical CJD while methionine substitution at the same site presents as FFI.

Infectious Form of CJD

Iatrogenic CJD has been reported following corneal transplantation, accidental use of contaminated neurosurgical instruments and electroencephalography (EEG) electrodes, dura mater grafts and parenteral administration of pituitary growth hormone derived from contaminated cadaveric sources. The clinical features differentiating iCJD from sCJD are an early age of onset (10 to 40 years), long incubation period of 4 to 30 years, prominent cerebellar symptoms, and terminal dementia.

OTHER FORMS OF HUMAN TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

Gerstmann-Straussler-Scheinker Disease (GSS)

It is a rare autosomal recessive disorder (not a single case reported from India), with diverse clinical symptoms like ataxia, spastic paraparesis, extrapyramidal signs and dementia. Immunopathologic hallmarks are a variable degree of spongiform change in the brain, multicentric PrP immuno-reactive plaques in the cerebellar molecular layer, neurofibrillary tangles in cerebral cortical neurons, and β amyloid plaques resembling Alzheimer's disease.

Fatal Familial Insomnia

This phenotype of CJD shares similar mutation at codon 178 with fCJD, in addition to methionine at codon 129. The age of onset of FFI varies from 25 to 61 years and the duration of illness 7 to 33 months. Sleep disturbance is an early feature followed by automatism, endocrine and motor system involvement. On EEG, classical periodic complexes are rare. Pathologically, severe neuronal loss and astrogliosis in ventral and dorsomedial thalamus, minimal neocortical spongiosis and absence of PrP plaques are the features.

Kuru

Identification of Kuru heralded the study of spongiform encephalopathies and their association with prion disease. It is a neuro-degenerative disorder confined to the Fore tribe of Papua New Guinea in the South Pacific and has disappeared with discontinuation of ritualistic cannibalism. The disease was more common among females, manifesting with progressive cerebellar degeneration, ataxia, tremor and terminal dementia. Histopathologically, mild spongy change, severe Purkinje and

granule cell loss, presence of periodic-acid-schiff positive, PrP immuno-reactive amyloid plaques with radiating spikes in the granule cell layer of cerebellum were characteristically found.

NEW VARIANT OF CJD

With the recognition of bovine spongiform encephalopathy (BSE) in cattle following changes in the practice of commercial production of cattle feed, a distinct and fatal form of CJD has been recognised, manifesting at a young age (16 to 48 years, mean 28 years). The clinical presentation is dominated by psychiatric symptoms like personality changes, depression, sensory parasthesias and dysesthesias affecting face, hands, legs and feet followed rapidly by cerebellar ataxia, myoclonus, chorea, pyramidal and extrapyramidal signs and terminal akinetic mutism. Duration of clinical illness is longer (9 to 30 months, average 14 months). EEG does not show the characteristic triphasic waves. The characteristic magnetic resonance imaging (MRI) feature is hypointensity on T1W images in posterior thalamus (pulvinar sign). Molecular genetic analysis of cases of vCJD revealed methionine homozygosity at codon 129 of the PrP gene. Not a single case of vCJD has been reported from India.

ANIMAL PRION DISEASES

Scrapie in sheep, BSE in cattle, chronic wasting disease in mule, elk and deer and feline spongiform encephalopathy are the animal forms of this disease; lower medulla oblongata being the classical site of involvement in addition to other areas. Not a single case of BSE has been reported from India, though rare occurrence of scrapie has been recorded from Northern India.

Clinical Features

Majority of the cases of CJD reported are of the sporadic variety. Rapidly progressive dementia is the commonest manifestation (100%) associated with myoclonus (91%), and motor disturbances (extrapyramidal, cerebellar, pyramidal and anterior horn cell symptoms). The clinical features suggesting CJD are often preceded by a prodromal period with non-specific clinical signs like fatigue, sleep and memory disturbances, behavioural changes, vertigo and ataxia. Visual complaints are reported in 54% and psychiatric features in 25% of the cases. Masters and Richardson, reviewing the clinical spectrum of human prion diseases, subclassified CJD into: Heidenhain variant with visual symptoms and significant occipital cortical pathology, striatal variant resembling Huntington disease, thalamic variant including FFI, cerebellar variant resembling Kuru, clinical forms with oculomotor disturbances resembling progressive supranuclear palsy and panencephalitic form with white matter demyelination (reported from Japan). Recently, cases are being reported presenting with non-convulsive status epilepticus, deafness and dysesthesia of the arm. Because of expanding clinical forms, an occasional case may escape clinical recognition. The clinical syndrome of vCJD has not changed from the initial description. The duration of illness of CJD reported from India varied from 3 months to 3 years, majority dying within 6 months and presenting a decade earlier than patients reported from the West. Occasional cases of probable familial CJD are noted in India.

Diagnosis

The ability to diagnose the disease early is vital for therapeutic intervention in animals destined for human consumption and humans participating in tissue and blood donation programmes. There is a demand for diagnosing prion disease in the asymptomatic stage. EEG, cerebrospinal fluid (CSF) analysis and MRI examination form the trio for premortem diagnosis of CJD in the symptomatic stage. The diagnostic EEG feature is pseudo-periodic sharp triphasic waves with a sensitivity of 64% and specificity of 84% using standardised set of criteria to define positive and negative tracings. Diagnostic sensitivity of EEG is found to correlate with PrP genotype in the patients.

CSF usually shows mild elevation of protein without pleocytosis. Detection of 14-3-3 protein is the single most useful laboratory test for the diagnosis of sCJD, correlating with the clinical settings. Estimation of neuronal specific enolase (NSE), S-100b and tau protein have yielded good results, though slightly inferior to 14-4-3. The sensitivity tends to increase as the illness progresses, being negative in the early stages. Sensitivity is higher for classical than for atypical cases of CJD and is also influenced by molecular genotype of the disease.

Demonstration of bilaterally symmetric hyper intensities in the basal ganglia on T2W images in association with rapidly progressive dementia are fairly diagnostic of CJD. Diffusion-weighted imaging (DWI) and fluid attenuation inversion recovery (FLAIR) imaging are superior in detecting cortical abnormalities with or without striatal hyper intensities. MRI abnormalities are found at an early stage of illness, especially DWI. In contrast to the lower sensitivity of EEG and CSF analysis in the diagnosis of vCJD, hyperintensity of posterior thalamus (pulvinar sign) is exceptionally useful with its diagnostic accuracy further enhanced with the use of FLAIR imaging. Pulvinar sign is very rarely reported in cases of sCJD and iCJD.

DIAGNOSIS ON BRAIN BIOPSY AND AUTOPSY (Figures 1 to 5)

Demonstration of spongiform encephalopathy, neuronal loss, gliosis and PrPsc protein in various morphological forms, especially around the spongy vacuoles and in plaques by immunohistochemistry is the gold standard for diagnosis of CJD and other prion diseases. The degree and extent of the cardinal pathological features vary depending on the duration of illness.

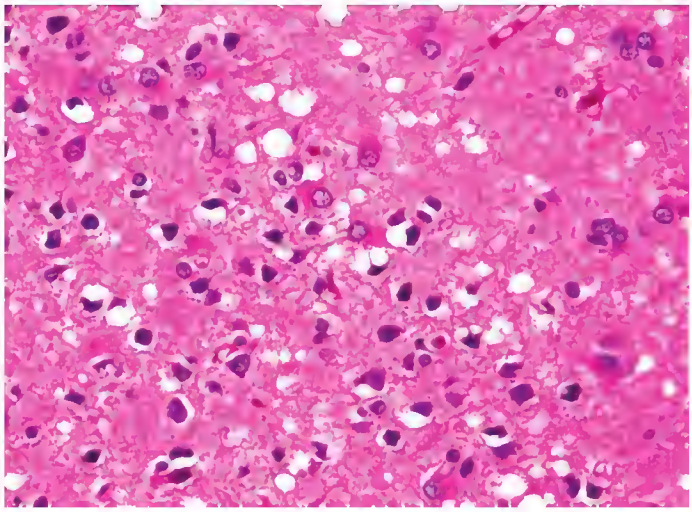

Figure 1: The cerebral cortex showing multiple vacuoles in the neuropile abutting the neurons and reactive astrocytosis (Haematoxylin and Eosin x 100).

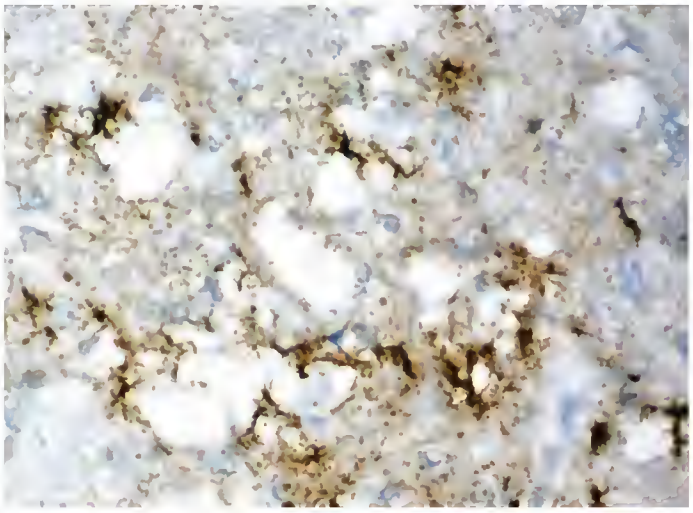

Figure 2: Immunostaining with KG-9 antibody prion protein labelling the edge of the vacuoles and the septae establishing diagnosis (Immunoperoxidase x 300).

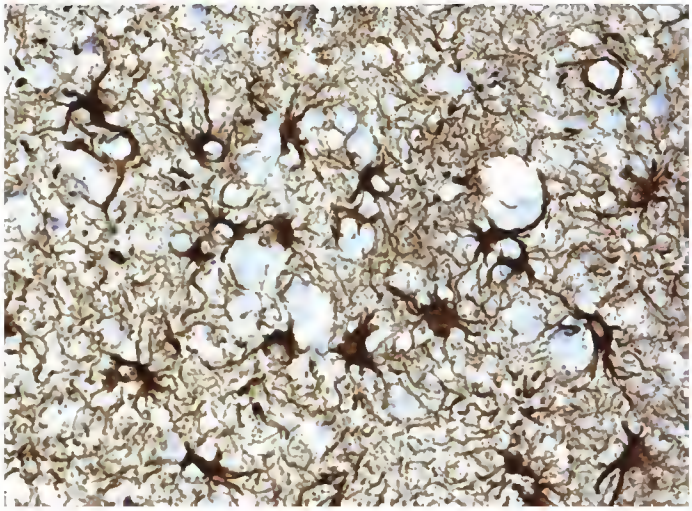

Figure 3: GFAP immunolabelling of reactive astrocytes, some of the processes encircling the vacuoles (Immunoperoxidase x 300).

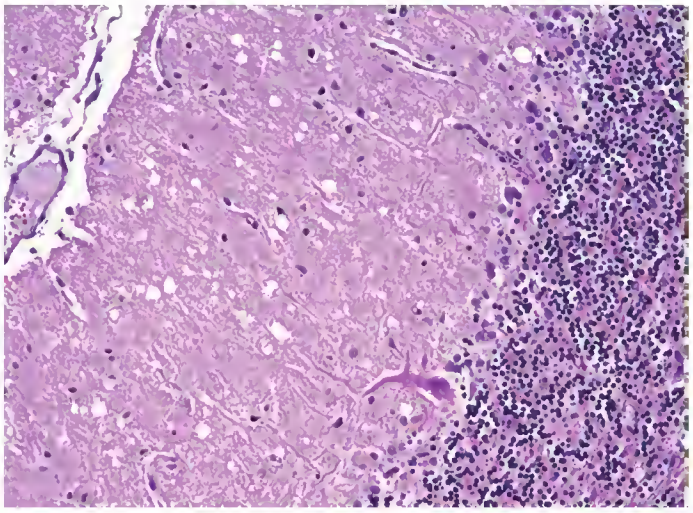

Figure 4: Cerebellum in a case of CJD showing neuropil vacuoles in the molecular layer (Haematoxylin and Eosin x 60).

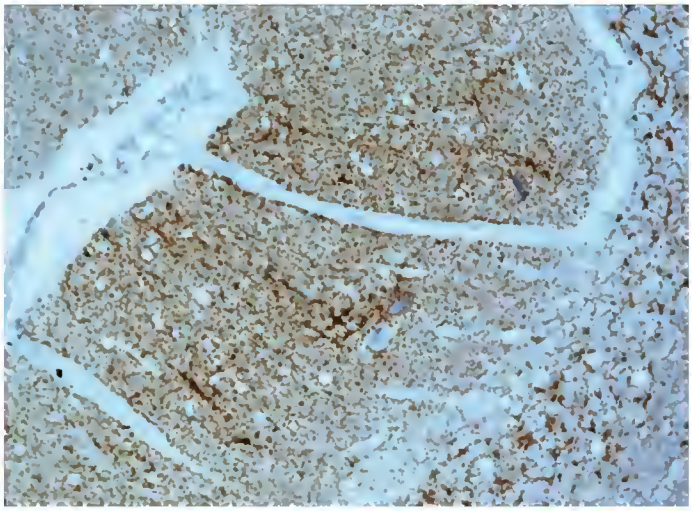

Figure 5: Immunostaining with KG-9 antibody to PrPsc labelled the neuropile of cerebellar molecular layer. In some places linear labelling is seen reflecting deposition of PrPsc along the dendrites (Immunoperoxidase x 60).

Western-blot analysis utilising a small bit of fresh brain tissue is a sensitive method to detect PrP, even before the evolution of characteristic pathological features. Facilities for western-blot and molecular genetic analysis of CJD cases are not available in India, while immunohistochemistry on formalin-fixed paraffin-embedded brain tissue is carried out at NIMHANS, Bengaluru. National Prion Disease Pathology Surveillance Centre at Case Western Reserve University, Cleveland, Ohio, USA (http://www.cjdsurviellance.com) assists in diagnosis. Biopsy of extraneural sites like tonsils and vermiform appendix (sites rich in lymphoreticular tissues) are of diagnostic use only in cases of vCJD and not other forms.

TREATMENT

Till date no treatment is available. Compounds that work *in vitro* have no significant beneficial effects when administered at the onset of symptoms in animals or after clinical manifestation in humans. Until we have a precise understanding of the physico-chemical nature of the infective agent, the molecular and biochemical mechanisms leading to neurodegeneration or the physiological function of PrPc, the search for therapeutic interventions will continue.

20.16 Fungal and Parasitic Diseases of Nervous System

Ashok Panagariya, Bhawna Sharma

CENTRAL NERVOUS SYSTEMS FUNGAL INFECTIONS

Fungal infections of the central nervous systems (CNS) were considered rare but are increasingly recognised in recent times. The internist is intimidated when confronted with the challenge of managing patients with CNS fungal infections. A high index of suspicion is vital for an early diagnosis and timely appropriate management may prove life saving. Fungal infections although traditionally thought to be of relevance in the immunocompromised subjects not uncommonly, may also be encountered in the immunocompetent populations. Myriad clinical presentations of the CNS fungal infections often mimicking other common diseases may pose diagnostic dilemmas.

Pathogenic fungi include yeasts, filamentous fungi and dimorphic fungi. Yeasts are unicellular organisms and include the relatively common *Cryptococcus* and *Candida*.The filamentous fungi (moulds) are characterised by branching hyphae, which are either septate or aseptate and include the more common *Aspergillus* and the *Zygomycetes* (including Rhizopus, Rhizomucor and Mucor). Dimorphic ('endemic') fungi are filamentous at 25°C and yeasts in the host tissue which include Blastomyces, Histoplasma, Coccidioides and Paracoccidioides. *Cryptococcus, Aspergillus, Zygomycetes (Mucor),* and *Candida* species are universally distributed. *Cryptococcus* and *Mucor* account for the common CNS mycosis.

Most fungi are of low virulence and are non-pathogenic. Pathogenic fungi invade the brain usually in the setting of predisposing risk factors (**Table 1**). Pathogenic fungi enter the host usually through inhalation and initiate a self limiting asymptomatic or mild pulmonary infection. If the fungemia overcomes the host's immune defence system in a predisposed individual, it may cross the blood-brain barrier and enter the CNS. Local extension into brain due to a contiguous infection of paranasal sinuses, ear and orbit is another important portal of entry. The other routes of fungal invasion include indwelling arterial lines or venous catheters that can be infected by *Candida* leading to fungaemia. Less common routes of infection are skin (*Sporothrix*), oral and gastrointestinal tract *(Candida)* and nasal sinuses (*Aspergillus* and *Zygomycetes*). Finally, direct inoculation of fungus into skull fracture wounds or during neurosurgical procedures also predisposes to CNS fungal infections. CNS mycosis may present with a number of clinical syndromes (**Table 2**).

DIAGNOSIS OF CNS FUNGAL INFECTIONS

Cerebrospinal fluid (CSF) sampling is indicated in all patients with suspected CNS mycosis. CSF reveals lymphocytic pleocytosis (*Cryptococcus, Candida*), neutrophilic predominance (*Aspergillus, Blastomycosis*) or eosinophilia (Coccidioides). CSF examination usually shows low glucose and high protein. CSF culture for fungal meningitis is far less sensitive compared to bacterial meningitis. Larger volume of CSF and centrifuged sediment analysis increase the diagnostic yield of fungal staining and culture. Most fungal examinations are time consuming. CSF antigen testing is available for *Cryptococcus* and *Histoplasma*, with high sensitivity and specificity rates (90%).

Table 1: Predisposing Risk Factors for Central Nervous System Fungal Infections

Prolonged antibiotic use
Diabetes mellitus
Cancer chemotherapy
Human immunodeficiency virus
Malignancy
Intravenous drug abuse
Neurtropaenia
Hereditary immune deficiency disorders
Indwelling catheters
Surgery
Trauma

Table 2: Clinical Syndromes of Central Nervous System Fungal Infections

Meningitis/encephalitis
Meningovascular syndromes
Focal infection/mass lesions
Infarction or haemorrhage

The spectrum of radiographic characteristics ranges from no abnormality on MRI and CT to meningeal enhancement, abscesses, intraventricular or intraparenchymal granulomas, gelatinous pseudocysts and/or hydrocephalus. If non-invasive methods fail brain biopsy may help in establishing the definitive diagnosis.

Fungaemia is seen with a few species, including *Candida*, *Histoplasma* and *Cryptococcus*, however yield from blood culture is usually poor and time consuming.

Only common CNS fungal infections relevant in the Indian context are being described here.

CRYPTOCOCCOSIS

Cryptococcus neoformans, an encapsulated yeast-like fungus is the most common CNS mycosis. It is found in mammal and bird faeces, particularly in pigeon droppings. CNS infection can be meningeal or less commonly parenchymal. Disseminated disease occurs commonly in immunocompromised while cryptococcomas (granulomas) occur in imm unocompetent hosts. Cryptococcal meningitis is thought to be a reactivation of the dormant lesion in the lung similar to Ghon's focus of pulmonary tuberculosis.

Headache is the most common symptom. Other symptoms more typically seen in bacterial meningitis like neck stiffness

or photophobia are distinctly uncommon. Basal meningitis may cause obstructive hydrocephalus (**Figure 1**). Focal lesions like cryptococcomas or infarction present with focal neurological deficits or seizures. The commonest parenchymal sites are the mid-brain and the basal ganglia. Infarctions in basal ganglia, internal capsule and thalamus may rarely occur.

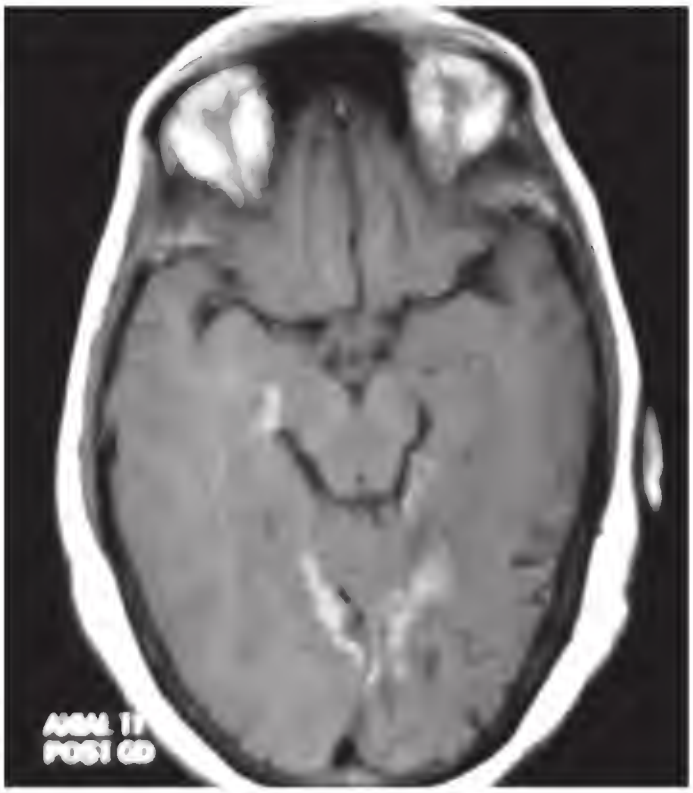

Figure 1: Axial T1W contrast image showing enhancement of basal cisterns and tentorium in a patient of cryptococcal meningitis.

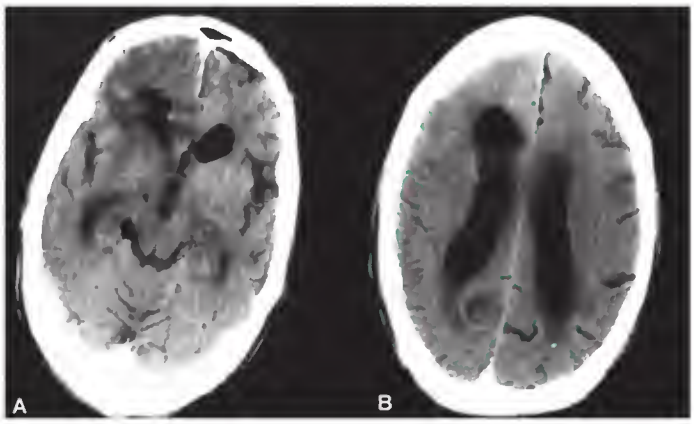
CSF in cryptococcal meningitis shows a lymphocytic pleocytosis with exceptionally high protein levels. CSF may, however, be normal in exclusively parenchymal disease. CSF India ink preparation shows the polysaccharide capsule of the cryptococcus as a clear 'halo' surrounding the organism. CSF staining and culture may yield positive results if adequate samples are obtained. Cryptococcal latex antigen detection test relies on agglutination tested at differing titres of CSF and has a sensitivity of 90%. Imaging may reveal meningeal enhancement, abscesses, cryptococcomas, gelatinous pseudocysts and hydrocephalus.



Treatment comprises of combination chemotherapy with conventional amphotericin B and flucytosine for 2 to 4 weeks and then switching to fluconazole for 8 weeks. Lifelong flucanazole therapy is indicated in patients with AIDS.

ZYGOMYCOSIS

These filamentous fungi (*Mucor* and *Rhizopus)* grow profusely on decaying vegetables, fruits, animal excreta and bread rich in carbohydrates. Unlike most other mycoses in which cerebral involvement is secondary to a primary focus in the lung (aerosol entry), this mycosis occurs most commonly from an infection of the facial skin, nasal and paranasal sinus mucosa or nasopharynx and leads to vascular invasion and thrombosis. The basifrontal area is involved by direct venous invasion through the orbital plate and cavernous sinus. A black regional discharge, such as from the nose, indicates necrosis of the underlying tissue and should suggest the diagnosis of mucormycosis.

ASPERGILLOSIS

Aspergillus is a ubiquitous fungus in soil, water, decaying vegetation and organic debris. *Aspergillus fumigatus, A. terreus,* and *A. flavus* cause CNS infection. Spread to CNS occurs haematogenously or by direct inoculation into the CNS during surgical procedures or from contiguous structures. CNS aspergillosis can present as solitary or multiple lesions, meningitis and less commonly mycotic aneurysm, dural abscess, myelitis and invasion of carotid or vertebral arteries. Patients usually present with fever, altered mental status, focal neurological deficits and less often signs of meningeal irritation. Imaging reveals several patterns: solid enhancing lesions (aspergilloma) or ring-like enhancing lesions, infarction/haemorrhage, mycotic aneurysms and rarely pneumocephalus (**Figures 2A and B**).

Figures 2A and B: Axial CT head plain images showing ventricular pneumocephalus in a diabetic patient with aspergillosis.

TREATMENT OF CNS FUNGAL INFECTIONS

Amphotericin B is an effective agent for most CNS mycoses. Amphotericin B is a polyene antibiotic that binds to ergosterols in the fungal cell wall and disrupts the cell wall integrity leading to increased permeabilty, K^+ leakage and cell death. Depending on its concentration, it can be fungistatic or fungicidal. It is used in a dose of 0.3 to 1.5 mg/kg body weight per day intravenously daily as a 1 to 4 hour infusion. It has poor penetration of blood-brain barrier, reducing its ability to achieve effective fungicidal levels in the brain. Side effects include renal toxicity, hypokalaemia, hypomagnesaemia, normocytic normochromic anaemia and 'flu-like' allergic reaction during or after intravenous infusion. Lipid-based amphotericin B compounds although costlier have lesser adverse effects. Most CNS fungal infections require long treatment periods of 4 to 10 weeks often guided by CSF culture reports.

Oral flucytosine, a cytosine analogue, commonly used as an adjunct to amphotericin B in case of invasive infections with *Cryptococcus*, *Candida* and *Aspergillus,* is usually well tolerated but may rarely cause bone marrow suppression, especially with concomitant use of amphotericin B.

Azoles (ketoconazole, fluconazole, itraconazole, voriconazole) although broad-spectrum are weak antifungals. They have good bioavailability on oral administration and are usually well tolerated.

Hydrocephalus may require an external ventricular drainage or shunt surgery. Surgical interventions comprise of exenteration of the infected facial, nasal and intra-cranial tissues in cases of mucormycosis and aspergillosis and drainage of cerebral abscesses.

Fungal infections are difficult to eradicate and have a high relapse rate, especially in immunocompromised states despite best antifungal regimens. The cure rate for cryptococcal meningitis is about 75% and 25% for aspergillosis and zygomycosis. The past few years have seen major advances in the development of newer antifungal agents including a novel class of drugs, the echinocandins and improved azole molecules with better efficacy.

CNS PARASITIC INFECTIONS

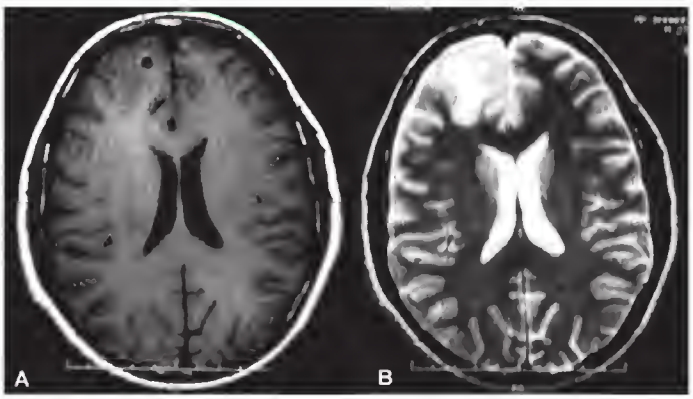
Parasitic diseases of the CNS are not only common in the developing countries but their incidence is also rising in the developed world due to increased international travel and increase in the number of immunocompromised hosts.

Parasites involving the CNS fall into two major categories – protozoa and helminths. Protozoa are unicellular microbes, e.g. plasmodium, toxoplasma, acanthemoeba while helminths are multicellular, macroscopic organisms, e.g. *Taenia*, *Echinococcus*. Cerebral malaria and cysticercosis are by far the most common CNS parasitic infections.

Parasitic infections do elicit immune responses in the body but immunity against parasites is weaker as compared to other pathogens. This is due to complex structure and antigenic diversity of the parasites. Also intra-cellular parasites lodging in body cavities or vesicular cysts escape humoral immunity.

NEUROCYSTICERCOSIS (NCC)

NCC is the most common parasitic disease of the nervous system and is the main cause of acquired epilepsy in developing countries. In India 40% of adult onset focal seizures are due to NCC. It is absent in Israel and Muslim countries, where pig rearing is unacceptable for religious reasons.



Taenia solium has a two-host biological cycle, with man as the definitive host carrying the intestinal tapeworm and pig as the intermediate host harbouring the larvae or cysticerci. Humans, like pigs, can become intermediate hosts if fresh vegetables, uncooked food or water contaminated with human faeces is ingested or by direct ingestion of poorly cooked pork infected with cysticercus. Cysts evaginate in the small intestine, enter the bloodstream and reach the tissues, especially CNS, where they reside as cysticerci.

Parenchymal cysts evolve through following four stages—vesicular, colloidal, granulonodular and calcified. Vesicular stage harbours the live larva with scolex and translucent liquid around without any evidence of host reaction. As the cyst degenerates it passes through transitional stages of colloidal and granulonodular stages which have perilesional oedema. Finally, when the cyst dies, it can disappear or become an inactive calcified nodule. Uncommonly cysticerci may present with diffuse encephalitic form, leptomeningitis or may be located in the subarachnoid space or ventricular system (multilobulated racemose forms).

It affects people of all ages and both sexes. The clinical manifestations depend on the number and topography of lesions and the viability of the parasite. Following syndromes have been described with cysticercosis: subclinical, parenchymal, subarachnoid, intraventricular, spinal, and ocular.

Many individuals with NCC remain entirely asymptomatic. Most patients with parenchymal cysticercosis present with focal seizures and less commonly with focal neurological deficits like motor or sensory deficits, ataxia, involuntary movements, brainstem dysfunction and neuropsychiatric changes. Headache and increased intra-cranial pressure is more common with extraparenchymal disease. Hydrocephalus may occur with intraventricular cysts or arachnoiditis. Spinal NCC is relatively rare. Ocular cysticercosis is associated with variable degrees of uveitis, endophthalmitis, and impaired vision. Cysticerci may lodge in skeletal muscle and present as pseudohypertropic myopathy.

Neuroimaging forms the cornerstone of diagnosis. When the larva is viable, the CT shows circumscribed, rounded, hypodense lesion of 4 to 20 mm size without perilesional oedema or contrast enhancement. On MRI, the vesicular larva appears CSF isointense on all sequences. Both MRI and CT may show a high intensity, 2 to 4 mm mural nodule pathognomonic of cysticercus. Colloidal and granulonodular stages are degenerating stages and, therefore, have irregular perilesional oedema and ring enhancement in the former and solid enhancement in the latter (**Figures 3A and B**). Calcified cyst is seen as punctuate hyperdensity on CT and hypointensity on both T1 and T2 MRI without any oedema or enhancement. Other causes of inflammatory granuloma like tuberculoma must be differentiated (**Table 3**).

Figures 3A and B: Axial T1W and T2W images showing a single small round cystic lesion in right frontal lobe with perilesional oedema in Neurocysticercosis.

Table 3: Neurocysticercosis versus Tuberculoma

	Neurocysticercosis	Tuberculoma
Size of the lesion	Usually <20 mm	Often >20 mm
Margin of lesion	Thin smooth wall	Thick irregular wall
Perilesional oedema	Mild to moderate	Moderate to marked
Focal neurological deficit	Usually none	Often present, persistent

Subcutaneous calcified nodule may be visible on X-ray corroborative with NCC. Serological tests have a limited value due to poor sensitivity and specificity. Recent advances include the upcoming serological assays for identification and sequencing of specific antigens of cysticercus but such tests

need further validation. A brain biopsy may be required when other modalities fail to reveal the cause.

In patients with a single ring-enhancing lesion presenting with seizures, treatment with an anticonvulsant drug alone is advocated, as most of these cysts resolve spontaneously. Seizure management requires appropriate anti-epileptic drugs. A number of controversies surround the appropriate treatment of NCC. Asymptomatic viable NCC or calcified NCC do not require specific anti-parasitic treatment. There is considerable controversy whether the colloidal or granulonodular stages require anti-parasitic drugs as the cyst is already dying. Potential harms with anti-parasitic treatment comprise of neurological worsening in case of multiple parenchymal NCC or subarachnoid cyst rupture leading to arachnoiditis. A recent Cochrane review shows minimal benefit of anti-parasitic treatment in terms of somewhat quick resolution of cyst but no better seizure control. Cysticidal treatment should be avoided in ocular, brainstem and spinal NCC. Options for cysticidal treatment comprise of albendazole or praziquantel. Albendazole is preferred because it has better penetration into subarachnoid cysts and does not pharmacologically interfere with corticosteroids and anticonvulsants. The dose of albendazole is 15 mg/kg body weight per day divided in 3 oral doses for 7 to 28 days along with dexamethasone. Praziquantel in 3 oral doses of 25 mg/kg body weight at 2-hour intervals, followed 5 hours later by dexamethasone 10 mg intramuscularly has also shown good therapeutic results.

TOXOPLASMOSIS

CNS toxoplasmosis is an AIDS-defining condition that occurs in *T. gondii*-seropositive patients due to reactivation. In an immunocompromised host *T. gondii* reactivation leads to variable clinical features – headache, acute confusional state, focal neurological deficits, focal seizures, personality change or, movement disorders according to the site of involvement. Details are available in chapter Toxoplasmosis of section Infectious Disease.

ECHINOCOCCOSIS (HYDATID DISEASE)

Echinococcosis is a zoonotic parasitic disease. Patients present with headache, vomiting, papilloedema, focal/generalised seizures, hemiparesis, dysarthria, and cranial nerve palsies. Hydatid disease rarely may affect spinal cord. Imaging reveals large rounded cystic lesions which are CSF isointense without perilesional oedema or contrast enhancement (**Figure 4**). Serological tests and hydatid cyst at other sites may further aid the diagnosis.

Surgical resection of the cyst is the treatment of choice. The size of the cyst can be shrunken by pre-treatment with albendazole. Details are available in section Infectious Diseases of chapter Tapeworm and Hydatid Diseases.

AMOEBIC MENINGOENCEPHALITIS

Free-living amoebae rarely invade the CNS, but intra-cranial amoebic infections are fatal. Three amoebic parasites are known to invade CNS (*Naegleria fowleri*, *Acanthamoeba* and *Entamoeba*) and cause primary amoebic meningitis (PAM) or granular amoebic meningoencephalitis (GAM). It is suspected when there is a history of water exposure (swimming/diving in

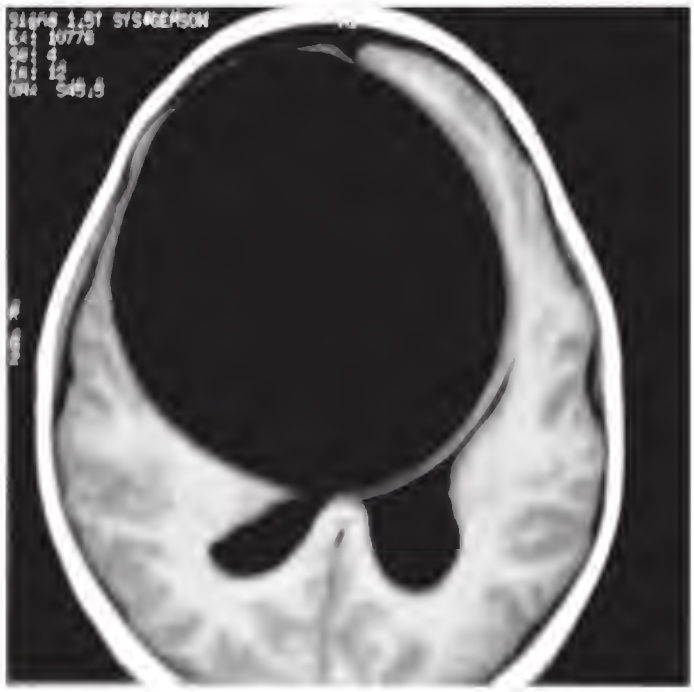


Figure 4: Axial T1 W image showing a large round CSF isointense cystic lesion without perilesional oedema in a patient with CNS hydatid disease.

warm fresh water ponds contaminated by free-living amoebae). Trophozoites penetrate the nasal mucosa and ascend along the olfactory nerves to invade the brain. It causes acute purulent meningitis, necrotising haemorrhagic encephalitis, brain oedema and necrotic vascular invasion.

A patient of PAM is typically a previously normal child presenting with a clinical picture compatible with acute pyogenic meningitis (high-grade fever, headache, stiff neck, seizure, altered mental status). The disease rapidly progresses to coma and death due to raised intra-cranial pressure and cerebral herniation. GAM affects all ages with a male predilection in immunocompromised hosts. Clinical picture resembles that of brain abscess or chronic meningitis.

CSF examination typically reveals polymorphonuclear and rarely eosinophilic pleocytosis with increased protein and low glucose levels. Motile trophozoites may be seen on CSF wet mount preparation. Imaging is usually normal in PAM and reveals multiple enhancing lesions in GAM. Outlook remains poor with a mortality rate greater than 80%. Many drugs, including amphotericin B, rifampin, tetracycline and trimethoprim have been tried in anecdotal cases with variable results.

CEREBRAL MALARIA

Cerebral malaria is caused by *Plasmodium falciparum* and rarely by *P. vivax*. *Cerebral malaria* is a neurological emergency that requires urgent intervention. It is a diffuse severe bihemispheric dysfunction with paucity of localising signs caused by the parasitic sequestration within the vasculature of the brain.

The pathogenesis of cerebral malaria is not completely understood. Sequestration of parasitised RBCs caused by cytoadherence of RBCs to the endothelial cells of the capillary and post-capillary venules is traditionally believed to play a key pathogenetic role. The parasitised RBCs adhere to microvascular endothelial cells leading to brain ischaemia. Also such cyto-

adhesion causes cytokine (e.g. TNF alpha and interleukins) production and complement activation leading to an increase in blood brain barrier permeability causing perivascular haemorrhages and diffuse cerebral oedema.

Incubation period is usually 10 to 18 days. The case definition of cerebral malaria by World Health Organization (WHO) requires (1) impairment of consciousness, (2) presence of asexual forms of *P. falciparum* in peripheral blood film or bone marrow smear, and (3) exclusion of other causes of encephalopathies. Impaired consciousness should at least last for 30 minutes. The fever may be classically intermittent, irregular or continuous. Patients typically have a diffuse encephalopathy with bilateral pyramidal signs, decrebrate and decorticate posturing occuring in severe cases. Generalised seizures occur in approximately half the patients. Focal deficits and nuchal rigidity is reported in some cases while papilloedema is rare.

The key to the diagnosis is a high index of suspicion in patients with febrile encephalopathy in malaria-endemic areas. Demonstration of *P. falciparum* on thick and thin smear examination of the peripheral blood after staining with Giemsa or Field stain establishes the diagnosis. Cerebral malaria occurs when more than 10% of the peripheral RBCs are parasitised. At least 3 smears prepared at intervals of 6 to 8 hours should be declared negative before excluding the diagnosis of malaria. Recently, rapid antibody-based serologic tests and PCR test for the detection of plasmodium DNA have been introduced.

Brain imaging is usually normal in cerebral malaria but may show diffuse cerebral oedema, white matter abnormalities and cortical or subcortical infarcts in the watershed zones. CSF in cerebral malaria often shows a mild degree of lymphocytic pleocytosis (10 to 50 cells/μL), mild increase in protein and normal glucose.

In a malaria-endemic zone, treatment should be started in a suspected case without waiting for laboratory confirmation of the diagnosis. Management includes specific anti-malarial chemotherapy and supportive therapy for multiorgan dysfunction. In patients with a very high parasitic burden, an exchange transfusion has been recommended.

Due to widespread resistance of *P. falciparum* to chloroquine, the drug of choice is intravenous quinine sulphate or parenteral artemisinin derivatives. Intravenous quinine is administered by slow infusion in a loading dose of 20 mg/kg body weight in 5% dextrose over 4 hours, followed by a maintenance dose of 10 mg/kg body weight infusion every 8 hours. For treatment details, refer to chapter on Malaria in the section Infectious Diseases.

The mortality from cerebral malaria varies from 20% to 33%; in children the case fatality rate can be up to 40%. Recovery is usually complete in early treated cases. Approximately 5% of cases, mostly children, are left with residual neurological dysfunction. Recombinant human erythropoietin has shown beneficial effect in experimental cerebral malaria and will soon enter into large clinical trials.

20.17 Raised Intra-Cranial Pressure and Hydrocephalus

Daljit Singh

Normal intra-cranial pressure (ICP) is the pressure of the brain contents within a closed intra-cranial cavity, i.e. skull. In adults, it varies from 5 mm Hg to 15 mm Hg. It is a dynamic pressure influenced by several factors including blood pressure, respiration and position of the person. Nevertheless, it provides a very important parameter in deciding the treatment of several neurological disorders.

In simple words, ICP is a reflection of the volume of brain, blood and cerebrospinal fluid (CSF) in the skull. Any change in any content would lead to displacement of blood or CSF from the skull into internal jugular vein or spinal canal, respectively. This enables the autoregulation to maintain constant ICP (Monro Kelly doctrine) as well as cerebral blood flow. In other words; the changes in the volume can maintain the constant ICP up to a point beyond which any change in the volume will result in rise of ICP (**Figure 1**).

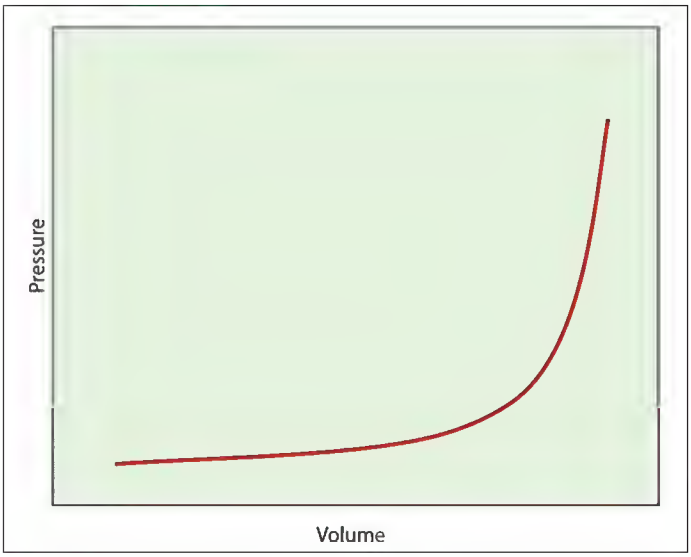

Figure 1: Pressure volume curve depicting a constant intra-cranial pressure initially followed by a rapid rise.

The change of volume or pressure within the cranial cavity is dependent upon the size of skull, age of patient, status of fontanels, condition of sutures and condition of brain. Old age can accommodate a large amount of displacement due to atrophy whereas children can do the same with the help of suture diastases or open fontanelles. Adults are most susceptible to changes in ICP.

There can be features of raised ICP in several diseases of brain as well as systemic disorders. Several drugs and chemicals are also known to produce raised ICP, e.g. lead, mercury, tetracylines, etc. Anaemia polycythaemia and hypoxia due to any cause can result in changes in ICP.

Normal capacity of the adult skull is around 1400 cc. CSF is constantly secreted at 500 to 700 cc (per 24 hours). At a given time, the brain has around 75 cc of blood and 75 cc of CSF of which 35 cc remains in the ventricles. CSF is produced at the rate of 0.35 cc per minute. Intra-cranial circulation of blood is about 750 to 1000 litres per day. Cerebral perfusion pressure (mean arterial pressure—ICP) is maintained constant by autoregulation. Failure to maintain a constant blood flow or cerebral perfusion pressure results in failure of auotoregulation.

Lundberg described three wave patterns in ICP; A waves are pathological with a level of 50 to 100 mm Hg; B waves are rhythmic variations related to respiration and are of shorter duration; and C waves are Traube-Hering-Mayer waves with a frequency of 6 waves per minute. These are of little clinical significance.

An understanding of the basics of ICP plays an important role in the management of hydrocephalus. In hydrocephalus, ICP can be raised due to ventricular enlargement as well as due to other associated conditions, e.g. oedema, infarction, impaired cerebral blood flow, impaired autoregulation, etc. Therefore, while treating hydrocephalus, the clinical impact of each one of these contributory factors should be kept in mind.

HYDROCEPHALUS

Hydrocephalus is a clinical syndrome of raised ICP with ventriculomegaly. It should be differentiated from ventriculomegaly without raised ICP, which is a condition of large ventricles and is usually asymptomatic. However, both these terminologies are wrongly interchanged by most clinicians. It is important to understand that hydrocephalus requires treatment whereas only ventriculomegaly does not.

Pathogenesis

The reported incidence of hydrocephalus ranges from 0.2 to 3.5 per 1,000 births.

CSF is produced in the lateral ventricles by the choroid plexus. The production is an active process regulated by an osmotic gradient as well as by the enzyme carbonic anhydrase. After production, CSF flows from the lateral to the third ventricle via the Foramen of Monroe. There are two foramina, one on each side. From the third ventricle, CSF flows to the fourth ventricle via the aqueduct of Sylvius, which is usually 8 to 12 mm in length. The fourth ventricle is a small chamber which holds some amount of CSF and has four openings for the CSF to egress from it. The paired laterally placed foramina of Luschka, a single median foramen of Magendie and a central hiatus which opens into the central canal of spinal cord.

The CSF, after flowing out of the fourth ventricle, ascends up to the brain surface, bathes the brain parenchyma and is absorbed with the help of arachnoid Pacchonian granulations along the mid line by the superior sagittal sinus. This entire concept is known as *bulk flow of CSF.*

It is important to understand that besides this, CSF is also absorbed by capillaries in the subarachnoid space and 2nd, 7th, 9th and 10th cranial nerves.

The flow of CSF inside as well as outside the ventricles is regulated by the cardiac cycle. The flow is out of the ventricle in systole and towards the ventricle in diastole. This *pulsatile flow of CSF* has added a newer understanding in the pathogenesis of hydrocephalus (**Figure 2**).

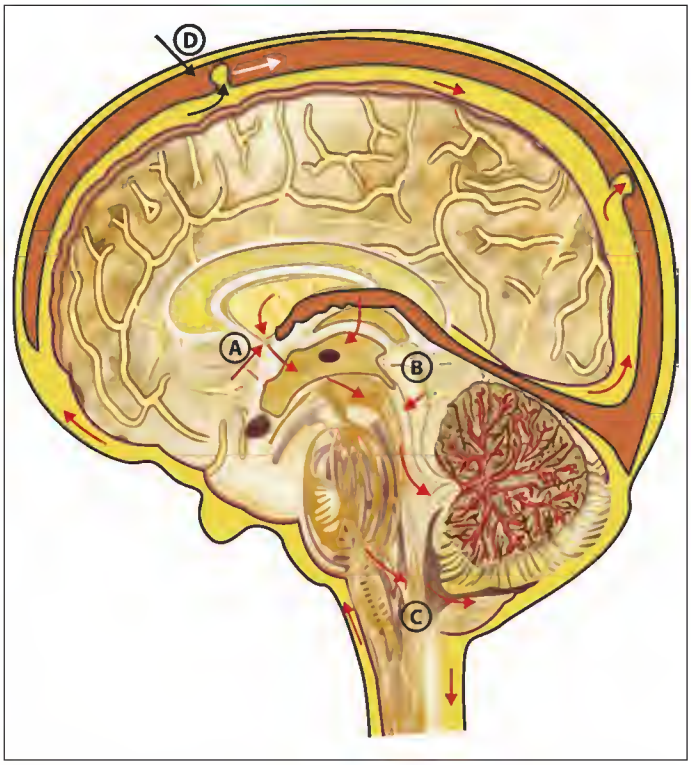

Figure 2: The cerebrospinal fluid flow in the brain and types of hydrocephalus. Sites A to C, non-communicating and site D, communicating hydrocephalus.

Classification

Hydrocephalus is classified in several ways, however, none is accurate. For simplicity, it is divided *functionally* into *communicating (Non-obstructive)* and *non-communicating (Obstructive)*. It can be further classified as *acute and chronic*. There are special categories of hydrocephalus, namely normal pressure hydrocephalus (NPH), otic hydrocephalus, hydrocephalus ex vacuo, double compartment hydrocephalus, latent hydrocephalus of adults, benign external hydrocephalus, and arrested hydrocephalus.

Dandy described the functional divisions of hydrocephalus, i.e. communicating and non-communicating which are still used by many. Whereas obstructed hydrocephalus refers to obstruction to the flow at any level from the lateral to the fourth ventricle outlet, communicating hydrocephalus results due to poor absorption at the level of the subarachoid space.

Clinical Findings

The presentation of hydrocephalus is variable. It depends upon the age of the patient and ability to withstand the change in the volume of CSF and pulsatility of the blood vessels.

Acute hydrocephalus will present with headache, vomiting, nausea, respiratory difficulties (cheyne-stokes) and papilloedema. Besides children may present with wide and tense fontanelles, irritability, lack of interest, and rejection of food. Neurogenic pulmonary oedema can be an associated fatal condition due to refractory raised ICP. Decerebration and decortication can occur if hydrocephalus remains untreated. Altered sensorium or loss of consciousness may be terminal in such cases.

Chronic hydrocephalus presents with an enlarged head, Macewen's sign (crackpot sign), impaired gaze of eyes, upward gaze paresis (sunset sign), Perinaud's syndrome, sutural diastasis, visible scalp veins, and impaired mentation. Many a time the only presentation can be a generalised seizure, which is ischaemic in origin.

Bradycardia, hypertension, arrhythmia and asystole can be associated findings. False localising signs, e.g. unilateral or bilateral 6th nerve palsy are not uncommon.

A classical triad of urinary incontinence, gait ataxia and memory impairment is seen in normal pressure hydrocephalus, however, the classical presentation is seen in ony 50%.

Radiologically, such patients may show beaten silver appearance of skull, ballooning of third ventricle into sella or empty sella syndrome. However, such appearances are rarely seen these days.

Diagnostic Criteria

Computed tomography (CT)/Magnetic resonance imaging (MRI)

The CT or MRI provide adequate information about aetiology and type of hydrocephalus. Cine Mode MRI can show the flow of CSF via the aqueduct and is helpful in establishing aqueductal stenosis.

Early hydrocephalus can be picked up by the presence of enlarged temporal horns of more than 2 mm. Temporal horns are normally not visible or may be slit-like. Absence or invisibility of the Sylvian and inter hemispheric fissures adds to the features of raised ICP. Similarly, absence of CSF in subarachoid spaces (sulci of brain) suggests obstructive hydrocephalus.

The ratio of frontal horn diameter (FD) and inner diameter of brain at that level (ID) of more than 50% is suggestive of hydrocephalus. Similarly the ratio of FD maximal bi-parietal diameter (BPD) of more than 30% (Evans ratio) is suggestive of hydrocephalus (**Figure 3**).

Presence of periventricular lucencies suggest transudation of fluid from the ventricle and is mostly seen in obstructive hydrocephalus.

There can be unilateral dilatation of a ventricle in obstructed foramen of Monroe, triventriculomegaly in aqueductal obstruction or quadri-ventriculomegaly (pan-ventriculomegaly) in outlet obstructions. Enlargement of all ventricles with excessive CSF in subarachoid spaces suggests communicating hydrocephalus or ex-vacuo dilatation.

Intra-operative ultrasonography can pickup congenital hydrocephalus in most of the cases.

Aetiology

Hydrocephalus is commonly associated with congenital diseases, e.g. neural tube defects (meningomyelocoele) Chiari malformation, Dandy-walker syndrome, primary or secondary aqueducatal stenosis, neonatal infections and post

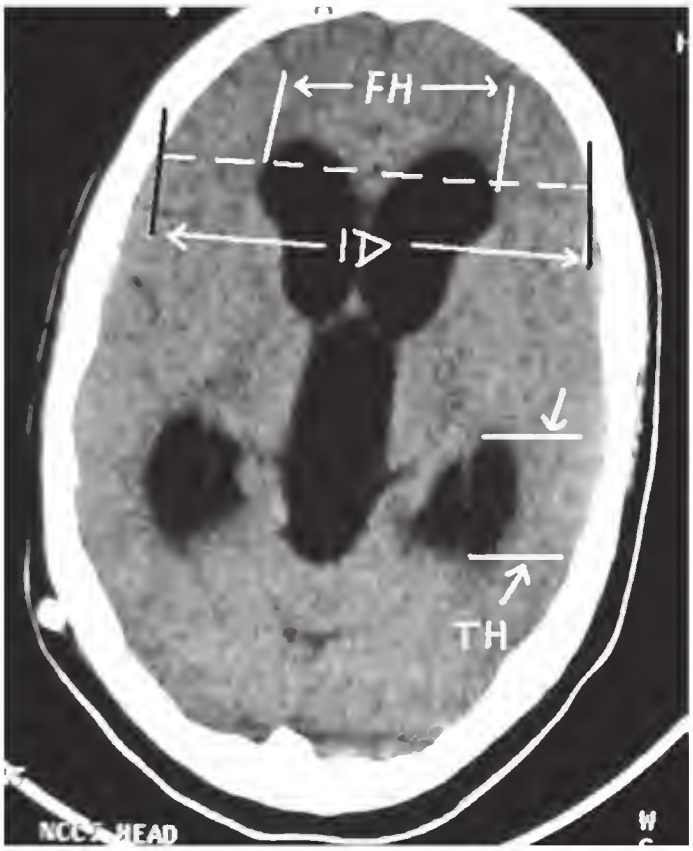

Figure 3: CT diagnostic criteria for hydrocephalus.

TH = Temporal horns; FH = Frontal horns; ID = Inter hemispheric diameter at frontal horns.

haemorrhagic. Secondary hydrocephalus can occur in tuberculosis or brain tumours at various locations in relation to CSF pathways. Posterior fossa tumours, e.g. medulloblastoma, ependymoma are common causes of hydrocephalus in children. Spinal tumours, Craniopharangioma and colloid cyst are some of the other conditions associated with genesis of hydrocephalus. Choroid plexus papilloma and early tubercular meningitis can result in excessive CSF production, resulting in hydrocephalus (**Figure 1**).

Treatment

There is a lot of debate and controversy regarding the optimal treatment of hydrocephalus. Similarly, there are controversies regarding optimal time of surgical intervention.

Medical Treatment

Acetazolamide, a carbonic anhydrase inhibitor can be used in a dose of 25 mg/kg per day in three divided doses and increased up to 100 mg/kg per day with a strict watch on electrolytes, and arterial blood gases. Acetazolamide may act for non-communicating hydrocephalus, tubercular meningitis, and as a temporary adjunt before surgical intervention.

The other diuretics, e.g. frusemide 0.5 mg/kg and mannitol 0.25 to 0.5 gm/kg 6 hourly act as additional agents to lower ICP. It has no role to play in decreasing the size of ventricles. Steroids (dexamethasone) 0.25 to 1gm/kg per day can be recommended for a short time in post infective hydrocephalus just to resolve the exudates in the prepontine and subarachnoid spaces. Controlled ventilation, without producing hypocarbia, can reduce ICP as well.

Surgical Interventions

Lumbar drainage

Tapping of CSF from the spinal subarachoid space can help in relieving ICP, particularly in communicating hydrocephalus. An lumbo-peritoneal shunt can be inserted in selected cases of hydrocephalus. Post tapping headache and tonsillar herniation can be sequelae of such procedures.

Ventriculo-peritoneal shunt (VP shunt)

The most accepted surgical procedure in the treatment of hydrocephalus is VP shunt. The CSF from the ventricles is drained via a silicon tube into the abdomen. A subcutaneous tunnel carries the shunt from the ventricle to the abdomen. At time ventriculoatrial shunt can be used to achieve the same target. As ventriculoatrial shunt may lead to hydrocephalus and endocarditis, hence, it has been abandoned by most neuro-surgeons.

VP shunt may require repeated revisions due to block, infection, or disconnection and can be associated with intestinal perforation, and cyst formations in the abdomen. Over drainage of shunt can lead to slit ventricle syndrome, subdural effusion and haematoma. One commonly used shunt in India is the Chhabra shunt. Flow regulated shunts (Medtronics) allow the controlled flow of CSF and are considered superior to other types of shunts.

The success rate of Chhabra shunt is 70% to 90%. It should be remembered that post-tubercular hydrocephalus can have associated vascilitis, cerebritis and brain oedema. All these associations can be a deterent of good recovery after a VP shunt.

Endoscopic third ventriculostomy (ETV)

ETV is an excellent procedure for hydrocephalus where internal shunting is done within ventricular system. An ostomy is made inside the third ventricle which drains CSF into the prepontine cistern bypassing the aqueductal obstruction. The procedure is simple and has no associated complications of shunt. The success rate varies from 60% to 100% depending upon the initial cause of hydrocephalus. ETV can be performed successfully in all types of hydrocephalus including post-tubercular and NPH.

Other endoscopic procedures include monroplasty, aqueductoplasty, stenting, and septostomy. Each of these procedures has its own indications. Choroid plexus fulguration (burning) can be done whenever there is excessive CSF production.

20.18 Dementia

PS Mathuranath

INTRODUCTION

Some of the most complex functions performed by the brain are cognition and behavioural functions. The cognitive functions, which are commonly known as intellectual and cortical functions, would include many domains, such as memory, language, orientation, attention, praxis, executive functions (such as planning, logic, judgement, insight, abstract thinking, etc.), and calculation. Dementia is a term that is used to refer to a collection of symptoms, some of which are listed in **Table 1**, resulting from the derangement of cognition and/or behavioural brain functions due to diseases. By a broad definition, an acquired impairment in more than one of these functions, that progresses over time, resulting in a decline in the occupational and functional abilities of the subject, and is not related to or occurring exclusively during delirium. It is important to emphasise that, by definition, impairment in cognitive functions present since birth is not dementia.

Table 1: Symptoms that could Occur in Dementia

Cognitive Symptoms	Behavioural and Psychological Symptoms
Amnesia	Behavioural symptoms
Episodic amnesia	Agitation
Language impairment (Aphasia)	Irritability
Non-fluent aphasia	Anxiety
Fluent aphasia	Apathy/Indifference
Visuospatial disorientation	Disinhibition
Disorientation to time	Aberrant motor behaviour
Disorientation to place	Appetite and eating changes (food faddisms)
Apraxia	
Impaired calculation	Stereotypes
Impaired attention	Psychotic symptoms
Impaired executive functions	Delusions
Impaired judgement	Hallucinations
Impaired planning	Depression
Impaired insight	Euphoria/elation
Perseveration	Illusions

EPIDEMIOLOGY, CLASSIFICATION AND CLINICAL FEATURES

Dementia is largely a disease affecting the elderly. Its prevalence in those over 60 years of age ranges between 5% and 20% in the developed nations. Both prevalence and incidence of dementia nearly doubles every 5 years in the population above 65 years, reaching a prevalence of nearly 35% in those above 85 years. A simple classification of dementia based on the aetiology is shown in **Table 2**.

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is the commonest type of dementia. It usually occurs after the age of 65 years, and is, therefore, considered senile dementia. Increasing age, presence of the epsilon 4 allele of

Table 2: Classification of Causes of Dementia

Primary Degenerative Disorders

† Potentially reversible or preventable (partial list).

apolipoprotein E (Apo E ε4) on chromosome 19, female gender and Down's syndrome are well-established risk factors for AD. Although not convincingly established, low education, head injury in the past, homocysteinaemia, and a family history of dementia are also believed to increase risk for AD while use of nonsteroidal anti-inflammatory drugs (NSAIDs) and statins are believed to reduce the risk for AD. Neuronal loss and deposits of intraneuronal amyloid plaques and intercellular neurofibrillary tangles characterise the histopathology. The amyloid plaques consist of aggregates of Aβ42, which is the toxic degradation product of the amyloid precursor protein. The neurofibrillary tangles consist of aggregates of hyperphosphorylated tau proteins. Typically, AD presents with loss of memory for recently acquired information (episodic memory). Confabulation for the lost information is not uncommon. This is usually followed by disorientation to time and then place. As the disease progresses, other domains like language and praxis get involved. Remote memory acquired years before, often remains preserved till late stages. Variance in the clinical presentation can occur very rarely. These include an occipital variant presenting with visual symptoms, a temporal variant presenting with language impairment, and a frontal variant presenting with behavioural symptoms. Impairment of episodic memory, however, remains the central feature in all forms of AD. In early stages, there is very mild dependence for activities of daily living. In the moderate stages, patients become more and more dependent for activities of daily living and self-care with advancing loss of cognitive domains. In severe stages, they are almost completely dependent for all activities of daily living. The average duration from presentation to death could vary from 8 to 14 years.

FRONTOTEMPORAL LOBAR DEGENERATION

Unlike AD, frontotemporal lobar degeneration (FTLD) is a syndrome consisting of heterogeneous group of diseases. It is the commonest pre-senile dementia syndrome, and affects individuals 60 years of age or less, sometimes as young as 35 to 40 years of age. It represents a form of a focal lobar degeneration of the brain whose presentation is determined by the region of the brain maximally affected. Thus, broadly two variants of FTLD are recognised—the behavioural variant called the frontal variant of frontotemporal dementia (fvFTD), and the aphasic variant called the primary progressive aphasia (PPA). PPA could further be of two types, progressive non-fluent aphasia (PNFA) and progressive fluent aphasia or semantic dementia (SD) (**Table 2**). fvFTD is the commonest type of FTLD, that is characterised by loss of insight, dysexecutive syndrome and behaviour and personality changes that are either dominated by apathy or by disinhibition. PNFA and SD initially present with non-fluent or fluent aphasia, respectively and over time may progress to involve other frontal functions. No specific risk factors have been identified for FTLD so far. Mutations on the tau gene on chromosome 17 are seen in some of the familial forms of fvFTD, while mutations in progranulin gene on the same chromosome has also been shown to cause fvFTD. Pathology in these cases is often non-specific and variable and could include Pick bodies, ballooned neurons, and focal microvacuolation. The course is progressive and survival is shorter than that in AD.

OTHER DEGENERATIVE DEMENTIAS

These are degenerative diseases where dementia is a co-morbidity accompanying involvement of other systems in the nervous system usually manifesting with subcortical features like motor problems (Parkinsonism, ataxia, etc.) (**Table 2**).

Lewy body dementias (LBD) are senile dementias characterised pathologically by the presence of cortical and sub-cortical Lewy bodies which clinically manifests as progressive cognitive decline accompanied by symmetrical Parkinsonism. LBD is further classified into two subtypes—dementia with Lewy bodies (DLB) and Parkinson's disease with dementia (PDD). DLB is clinically characterised by progressive memory loss, with bilateral appendicular akinetic-rigid parkinsonism occurring within one year before or after. Other characteristic features include visual hallucinations, and significant fluctuations of symptoms. Pathology shows loads of cortical Lewy body. PDD is characterised by onset of dementia in a patient with Parkinson's disease. The most consistent risk factors for PDD in patient's with Parkinson's disease include higher age, more severe parkinsonism (particularly rigidity), presence of postural instability and gait disturbance and presence of some mild cognitive disturbance at the time of onset of Parkinson's disease.

Corticobasal ganglionic degeneration (CBD) is a pre-senile dementia where asymmetrical Parkinsonism is usually accompanied by progressive cognitive deficit, alien limb phenomenon, apraxia, and often acalculia. Dementia is also a feature of progressive supranuclear palsy (PSP), which is characterised by bilateral parkinsonism with axial rigidity, frequent falls, eye-movement abnormalities, particularly vertical (up and down) gaze palsy, and pseudobulbar palsy. Huntington's disease (HD), which is linked to chromosome 4, is characterised by behavioural and personality changes which occurs along with chorea. Dementia is an accompaniment in some of the spinocerebellar ataxias (SCA).

VASCULAR DEMENTIA

Vascular dementia (VaD) is also a syndrome where the dementia is a result largely of clinically overt or covert cerebrovascular insults to the brain. Thus, it could result from many mechanisms (**Table 2**). The area of the brain insulted, dictates the clinical presentation and manifestations. Presence of cerebrovascular risk factors (like hypertension, diabetes, hypercholesterolaemia, history of strokes, or myocardial infarctions, etc.) in history and subcortical features (motor deficits, urinary incontinence, release reflexes, etc.) on examination are common in vascular dementia. Neuroimaging as well as histopathology show evidence for lacunar, infarcts or leucoareotic changes.

OTHER CAUSES OF DEMENTIAS

Many other diseases could also result in dementia. They are listed in **Table 2**. The dementia in many of these conditions is either partially or fully reversible with timely and appropriate intervention. Thus, early diagnosis is the key to the management of dementia in such conditions. Some of the common and typical conditions are briefly described below.

Infections and Toxins

AIDS-dementia complex (ADC) is probably the most significant one in this category. It occurs in the late stages of AIDS and probably represents the end stage of the disease. Extensive neuronal infiltration by the HIV is thought to be the cause for it and response to antiretroviral agents is limited. Before the advent of ADC, neurosyphilis was perhaps the most significant

infectious cause for dementia. Dementia is seen in both, meningovascular syphilis and in general paresis of insane. While the former presents with sensorial and cognitive changes, the latter usually presents with behavioural changes. Its importance lies in early diagnosis of the condition as both the conditions are eminently treatable and dementia can be reversed. Chronic meningitis, especially tubercular, could rarely present with dementia. Creutzfeldt-Jakob disease (CJD), a prion disease, is a less common cause of dementia in the elderly that is rapidly progressive and results in mortality in 12 to 18 months. Neurocysticercosis, a parasitic infection and subacute sclerosing panencephalitis, a late sequel of childhood measles infection, are causes of dementia seen in the younger age groups. Yet another common situation that could masquerade as dementia, especially in the elderly, is the multitude of medication-related effects due to drugs that they may be taking for comorbid conditions. In particular these are CNS depressants like benzodiazepines, conventional antipsychotics, and anticholinergics.

Metabolic and Nutritional Diseases

Vitamin B12 deficiency is associated with progressive psychosis and subtle cognitive and often behavioural impairment, especially in the malnourished population. Although the cause-effect relationship with dementia is ill-established, treatment of the condition has been shown to reverse some of the symptoms. Pellagra presents with dementia and dermatitis and is mostly seen in the malnourished and the alcoholics. It is an eminently treatable condition. Hypothyroidism and many of the endocrine, liver and renal diseases can have dementia as one of the manifestations. Appropriate treatment often helps in reversing the dementia. Wilson's disease is yet another potentially reversible cause of dementia in the younger age group.

Structural Diseases

Normal pressure hydrocephalus (NPH) is a typical example. NPH presents in the elderly with urinary incontinence, gait apraxia and dementia and responds to ventriculo-peritoneal shunting. Subdural haematomas following subtle falls and midline brain tumours such as, paramedian meningiomas can occur in the elderly and manifest as dementia. They are effectively treated surgically if diagnosed early.

EMERGING CONCEPTS IN DEMENTIA

Mild cognitive impairment (MCI) is thought to be the condition preceding overt manifestation of dementia. Amnestic variety of MCI, the most investigated form of MCI, is characterised by the presence of memory symptoms, objective memory impairment on testing, and relative preservation of other cognitive domains, activities of daily living, and occupational abilities. Most subjects with amnestic MCI have been shown over time to progress to AD. Vascular cognitive impairment (VCI) is a condition similar to MCI, but with associated vascular risk factors. Thus, VCI could be expected to progress to VaD. The importance of being able to define and diagnose such conditions is that they can help in early diagnosis of dementia and, therefore, provide an opportunity for effective intervention. It must be emphasised, however, that our understanding of these conditions is still preliminary.

APPROACH TO DIAGNOSIS

Figure 1 illustrates an algorithmic approach to dementia. Delirium and depression are the commonest conditions that could be mistaken for dementia. Delirium is characterised by sensorial, motor and autonomic hyper- and/or hypo-activity, which distinguish it from dementia. Depression, which could precede or be comorbid with dementia, is a more difficult condition to differentiate from dementia. Fluctuation over a period of time, a global impairment across many cognitive domains, and frequent 'do not know' answers on neuropsychological tests helps to differentiate depression from dementia. The next step will be to review the comorbid conditions and the medications that the patients may already be taking. The final step is to establish progression of the symptoms over time and impairment of activities of daily living. Once dementia is diagnosed, risk factors should be identified, and the type of dementia characterised following the steps shown in the algorithm.

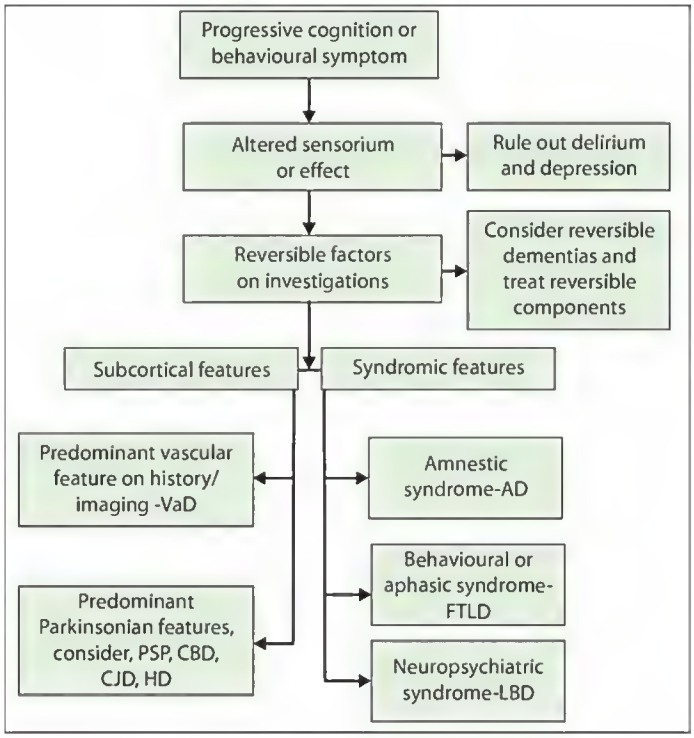

Figure 1: Algorithm for approach to diagnosis of dementia.

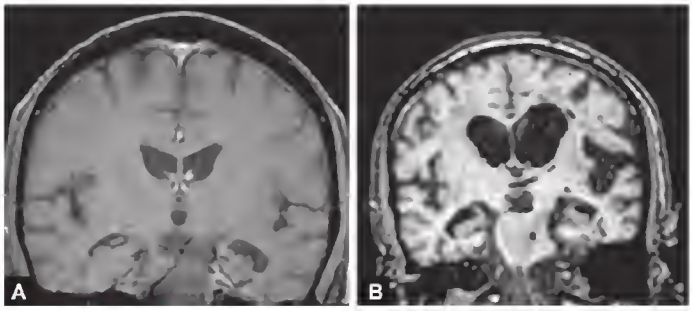
INVESTIGATIONS

The purpose of investigations in dementia is three-folds to confirm diagnosis, type, impairment, and severity; to look for partially or completely reversible aetiologies and comorbidities; and to gather information for appropriate treatment and rehabilitation and to follow-up. In addition to the standard tests, many other investigations could also be done aimed at specific aetiological causes that may be suggested by the history and clinical examination. A brief discussion on the major recommended investigations is provided below.



Blood Investigations

Haemogram and peripheral smear to look for anaemia, vitamin B12 deficiency, markers of acute/chronic infections and malignancies; renal and liver function tests to rule out acquired metabolic causes of dementia; thyroid functions and serum

calcium and phosphorus levels for endocrinal causes of dementia, serum VDRL, and serum vitamin B12 assay complement the evaluation of all patients with dementia.

Neuroimaging

A plain and contrast-enhanced CT scan of the head is sufficient in most cases to visualise tumours, CNS infections and major infarcts. MRI of the brain is finding an increasing role in the classification of degenerative and vascular causes of dementia (**Figures 2A and B**). It is also useful in the diagnosis of infectious causes of dementias.

Figures 2A and B: (A) Coronal MRI sections of Alzheimer's disease showing hippocampal atrophy and (B) primary progressive aphasia showing asymmetrical temporal neocortical atrophy resulting in widened Sylvian fissure on that side.

Electroencephalography (EEG)

Although not mandatory, EEG is a useful investigation in atypical or rapidly progressive forms of dementias like CJD.

Cerebrospinal Fluid Examination (CSF)

Like EEG, CSF examination through a lumbar puncture is presently not mandatory but useful in detecting covert, but reversible causes of dementia such as chronic neuroinfections. However, with increasing research for CSF biomarkers, such as CSF-tau and CSF-amyloid β protein in degenerative dementia like AD; it may become a mandatory investigation in future for the diagnosis and classification of dementias.

Neuropsychological Tests

A battery of neuropsychological tests for memory, orientation, language, visuospatial skill, etc. help in quantifying the impairment through standardised methods and minimise the subjective element involved in the clinical diagnosis of dementia. They also help in typing and staging the disease, planning the rehabilitation and following up the progress. Like any other investigation, it requires technical expertise of trained psychologists in administration of tests and interpretation of results. Mini-mental status examination is a useful bedside screening test for dementia.

MANAGEMENT

There are four basic principles in the management of dementias: treat all reversible causes and potentially treatable comorbidities; disease modifying pharmacological treatment; symptomatic pharmacological treatment; and non-pharmacological management and family counselling.

Removing potentially offending drugs, such as, anticholinergics and CNS depressants in the existing prescription, promptly treating infections, metabolic and electrolyte derangement and nutritional deficiencies and addressing comorbidities, such as depression, constitute the most important steps in the treatment. Disease modifying pharmacotherapy with appropriate agents in cases of reversible dementias (e.g. antituberculosis therapy in chronic tubercular meningitis presenting with progressive cognitive decline) is imperative. Disease modifying treatment for degenerative dementias are still under research and may become available in the near future.

In degenerative dementias, currently the essence of treatment is judicious use of symptomatic pharmacological treatment. They are broadly of two types—cognitive symptom-modifying agents that have been shown to slow down the disease progression and agents useful for the behavioural and psychological symptoms of dementia (BPSD). There are many agents useful in treating the cognitive symptoms and currently atypical antipsychotics are the ones usually recommended in the treatment of BPSD. Some of these agents are listed in **Table 3**.

The non-pharmacological measures include environment modification and counselling. Personal and extra-personal environment modifications are important since majority of dementia patients are older individuals. Personal environment modifications include minimising sensory deprivation (treat earwax and cataract, provide hearing aids), practical advise on avoiding falls and fractures, exercising caution in prescribing drugs (as dementia patients may be highly sensitive to many CNS active drugs when used in standard doses), treating constipation, maintaining personal hygiene (including oral and dental), ensuring adequate undisturbed sleep at night, etc. Extra-personal environmental modifications include clean-levelled flooring, well-lit rooms and toilets, grab-rails in toilets, rooms and stairways, regularising meal and sleep timings, etc. Many other forms of therapy, such as reality therapy, cognition therapy, reminiscence therapy, music therapy, behaviour-modification therapy, etc. may also have a role to play.

Family counselling for dealing with dementia patients and their maladaptive and aggressive behaviour is an important aspect of the management. Since caring for a patient with dementia is a stressful activity and the carers are more likely to be untrained family members than professionally trained carers, attending to the needs and minimising the stress of the caregiver constitutes an important activity in facilitating the management of the patient. Counselling should also include advice to the patient and family on the need for organising financial (e.g. operating joint bank accounts) and legal (e.g. making a will or power of attorney) issues since the patients with dementia could progressively lose the ability to manage their own affairs or make competent judgment.

There are two broad models of care in dementia. Home-based care model is useful in mild or moderate dementia. This can be supported by clinic care (visit to the doctors), respite care at home (when professional carers relieve the carer in the family for some time by taking over the care responsibilities) and day-care centre (when respite care is provided during a part of the day by a professionally run centre where the patient can be sent). The other is the community-based care model, which is

Table 3: Some Pharmacological Agents Useful in the Management of Dementia

Agents	Action/Type	Current Recommendations
Useful for cognitive symptoms		
Donepezil hydrochloride	Acetylcholinesterase inhibitor	Useful in all stages of dementia. Started at 5 mg/day and increase to 10 mg/day after 4–6 weeks
Rivastigmine	Acetylcholinesterase and butyryl-cholinesterase inhibitor	Useful in early and moderate stages. Started at 1.5 mg and increased every 3–6 weeks by 1.5 mg up to a maximum of 12 mg/day
Memantine	NMDA receptor antagonist	Useful in moderate and advanced stages Usually used as an add-on therapy. Started at 5 mg/day and increased by 5 mg every 3–6 weeks to 10 mg twice per day
Galantamine	Nicotinic receptor agonist	Useful in moderate and advanced stages. Usually used as an add-on agent. Initiated at 8 mg/day and increased every 4 weeks up to 24 mg/day
Useful in BPSD		
Quetiapine	Strong 5-HT_2 and D_2 blocker	Useful in delusions, hallucinations, aggression etc. Initiated at 25 mg/day and gradually increased by 25 mg up to a maximum dose of 400 mg
Olanzapine	Moderate D_2, 5-HT_2 and Muscarinic M1 blocker	Useful in delusions, hallucinations, aggression, etc. Initiated at 2.5 mg/day and can be increased up to 10 mg/day
Risperidone	5-HT_2 and D_2 receptor blocker	Useful in delusions, hallucinations, aggression etc. Initiated at 0.5 mg/day and can be increased up to 2 mg/day
Clozapine	Moderate D_2, 5-HT_2 and strong muscarinic M_1 blocker	Useful in delusions, hallucinations, aggression, etc. Should be used only in recalcitrant case. Initiated at 6.25 mg/day and increased by 6.25 mg once a week up to a maximum of 50 to 100 mg/ day
Escitalopram	Short-acting SSRI	Useful in depression, stereotype, etc. Initiated at 2.5 mg/day and increased up to 10 mg /day
Clonazepam	Short-acting benzodiazepine	Useful in anxiety, insomnia, aggression etc. Initiated at 0.25 mg/day and increased up to 2 mg/day.

useful for patients with advanced dementia, who are difficult to manage without constant medical or para-medical supervision. Thus, this involves institutionalisation of the patients at professionally run institutions that have adequate medical support.

THE INDIAN SCENARIO IN DEMENTIA

Increasing population and life-expectancy in India is resulting in an increase in the individuals at risk for dementia. Urbanisation, migration of the youth, and fragmentation of joint families in India is increasing the cognitive stress and decreasing the support to the growing number of people at risk for dementia and, thereby, perhaps increasing its incidence. Population-based studies from different parts of the country have shown that the prevalence of dementia (and AD) in those ≥60 years of age ranges from 0.8% (and 0.1%) in rural North India to 3.5% (and 1.31%) in urban South India. An increasing prevalence with advancing age has also been demonstrated by Indian studies. The only incidence data available so far is from rural north India, which is reported to be 4.7 per thousand person years. Data from most population-based studies suggest that AD is the commonest cause of dementia in India. Published hospital-based audits suggest, however, that patients with vascular dementia seem to be seen in the tertiary care hospitals more often than any other form of dementia. The prevalence of AD has been shown to be higher in women (1.8%) as against that of men (0.7%) in most studies. Prevalence rates were not very different in the illiterates and the literates in Indian studies, thus not supporting low education as a potential risk factor. Although the frequency of ApoE ε4 allele was lower in the Indian population, the risk of AD conferred by it in Indians (odds ratio 3.4) has been found to be comparable to that in the Western population.

Studies from Western India have suggested that there is low awareness of this condition in the population and in health professionals. Unpublished data from some of the tertiary care hospitals with specialised dementia care suggest that there is perhaps a higher frequency of psychosis in Indian patients when compared to western patients with AD. They have also shown that unlike in the west, the majority of the carers of dementia patients in India are family members, usually the spouse or the daughter-in-law. Furthermore, there is also evidence that the burden of care perceived by the carers of dementia patients in India is relatively lower than those of the patients in many western nations. While home-care model is popular and perhaps more widely practiced in India, availability of institutions providing day-care respite or community-care models are almost non-existing, thereby putting families with advanced dementia patients under severe duress. Availability of professional respite care providers is also scanty.

20.19 Extrapyramidal Disorders

BS Singhal

Extrapyramidal disorders relate to dysfunction of the basal ganglia. They result in disturbance of movement and posture without significant paralysis. The term 'movement disorders' is often used synonymously with extrapyramidal or basal ganglia diseases.

Movement disorders can be broadly divided into akinetic rigid syndromes (Parkinsonism) in which there is paucity of movement (akinesia or bradykinesia) often accompanied by an increase in muscle tone (rigidity) and hyperkinesias or dyskinesias which are associated with excessive abnormal involuntary movements (**Table 1**).

Table 1: Classification of Extrapyramidal Disorders

Akinetic rigid syndromes	
Idiopathic Parkinson's disease	
Secondary Parkinsonism (definable cause)	
Drugs	Phenothiazines, haloperidol, pimozide, metoclopramide, reserpine, lithium
Toxins	Manganese; 1-methyl, 4-phenyl tetra-hydropyridine (MPTP); carbon disulphide
Hypoxia	Carbon monoxide, cyanide
Viral	Encephalitis lethargica, Japanese B encephalitis, Creutzfeldt-Jakob disease, subacute sclerosing panencephalitis
Vascular	Atherosclerosis
Metabolic	Wilson's disease, hypoparathyroidism, GM1 gangliosidosis
Head injury	Punch-drunk syndrome
Brain tumour	
Parkinson-plus syndromes	
Progressive supranuclear palsy	
Multiple system atrophy (olivopontocerebellar atrophy, Shy-Drager syndrome, striatonigral degeneration)	
Corticobasal degeneration	
Diffuse Lewy body disease	
Familial basal ganglia calcification	
Huntington's disorder (juvenile variant)	

IDIOPATHIC PARKINSON'S DISEASE (PARALYSIS AGITANS)

This is the most common akinetic rigid syndrome. Parkinson's disease (PD) affects 1% of adults over the age of 60 years, with increasing frequency in older age groups. It affects both sexes equally.

Clinical Features

The symptoms start insidiously and tend to be unilateral or asymmetrical at the onset. The initial manifestations may be tremor, slowness, stiffness or clumsiness of an arm or, less commonly, of a leg.

Tremor, rigidity, akinesia and postural disturbances are the major clinical abnormalities. The tremor has a frequency of 4 to 6 Hz, is present mainly at rest (resting tremor) and is suppressed on voluntary movement. Distal muscles are affected more than the proximal, and the rhythmic tremor at the wrists and fingers has been termed 'pill-rolling' tremor. It disappears during sleep and is aggravated by emotional excitement or fatigue. This tremor may also be seen in the legs or lower jaw. Some patients also have fast action tremor at 8 to 12 Hz, mainly on sustained posture or action.

Akinesia and rigidity result in significant impairment of movement. There is lack (akinesia) or paucity (bradykinesia) of movement. Rigidity is present over the entire range of movement (lead-pipe rigidity). The face is expressionless ('mask-like'). Glabellar tap is often positive. There is a generalised slowing of motor activity. Motor acts like dressing, feeding and walking show a marked slowing. All recreational and work tasks, household chores and self-care functions become impaired. Handwriting becomes smaller (micrographia) and eventually may become illegible. Rapid, repetitive and alternating movements, such as finger-tapping, opening and closing of the fist, pronation-supination of the forearm and foot-tapping are performed slowly and clumsily. The combination of tremor and rigidity gives rise to 'cog-wheeling,' which is best appreciated on passive slow rotatory movement of the wrist.

The voice becomes soft (hypophonic), monotonous and stuttering, and the speech is more rapid than normal. In advanced cases, the speech is barely more than a mutter. Increased salivation and seborrhoea (greasy skin on face and forehead) are commonly seen but early and prominent bulbar symptoms suggest Parkinson-plus syndrome.

Postural instability and gait difficulty are a major problem in PD. The head usually tilts forwards and the body becomes stooped, often with pronounced kyphosis. The arms become flexed at the elbow and wrists. Flexion also occurs in the joints of the legs (**Figure 1**). A tonic extension of the great toe (striatal toe) has often been misinterpreted as an extensor plantar response. Rising from a sitting position may take several attempts, with frequent fall back into the chair. To assess postural instability, the physician performs the pull test. There is retropulsion.

The gait is slow and shuffling. With asymmetric involvement of lower limbs, there could be a noticeable limp. The associated arm swing is reduced. Patients may have a tendency to advance rapidly with short steps (festinating gait) as though they are chasing their centre of gravity. Sometimes, the feet may appear to be glued to the floor, the so-called freezing phenomenon. When combined with postural instability, freezing may result in forward falls. This is a late feature and its early occurrence suggests a diagnosis other than true Parkinson's disease. The salient clinical features are summarised in **Table 2**.

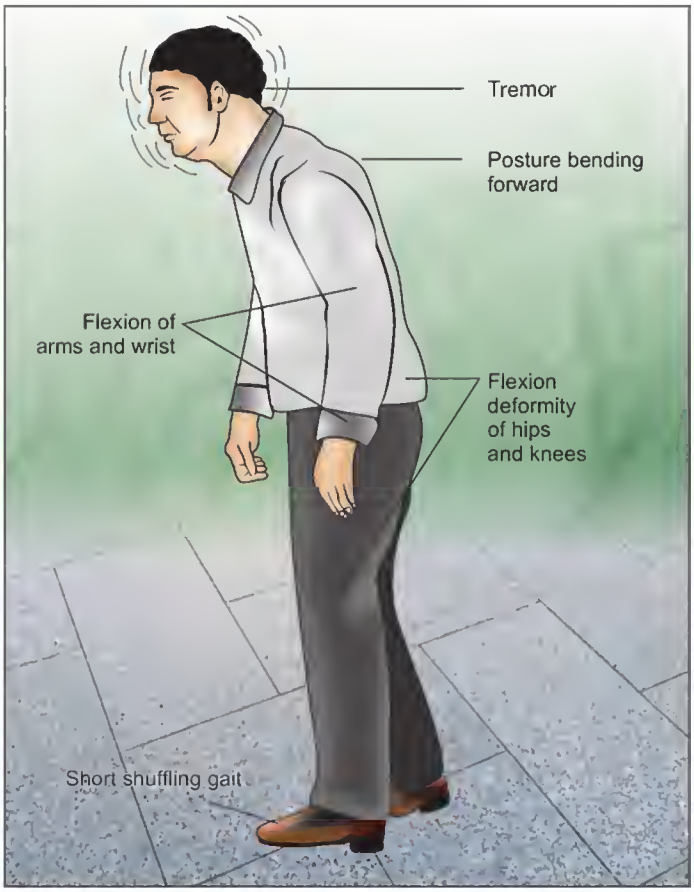

Figure 1: Typical posture of Parkinsonism.

Table 2: Parkinsonism - Clinical Features

Mask face
Slurred, indistinct speech
Festinant gait, stooped posture
Tremors—resting or postural
Rigidity—lead pipe or cog wheel

Non-motor symptoms

Although PD is recognised mainly by its motor manifestations, Non-motor symptoms (NMS) are also frequently encountered and can significantly impact the quality of life of PD patients.

NMS include autonomic and sensory disturbances, depression, anxiety, cognitive impairment and sleep disturbances.

Autonomic and sensory disturbance

Autonomic dysfunction, such as constipation, frequency of micturition and nocturia, and mild to moderate degree of orthostatic hypotension may occur. Anti-parkinsonian medications aggravate orthostatic hypotension. If autonomic features are very prominent and early, one must consider the possibility of Shy-Drager syndrome.

Subjective sensory dysfunction such as undefined muscle pain, abdominal discomfort, dysaesthesia in feet and painful neck movements, may be present.

Mood and cognitive disturbances

Depression and anxiety are frequently seen in Parkinson's disease and they often coexist. They significantly affect the quality of life in Parkinson's disease patients and must be appropriately treated.

Cognitive disturbances suggestive of frontal lobe dysfunction are common. Frank dementia is uncommon, and its presence in the early stages suggests conditions like Alzheimer's disease and multi-infarct dementia.

Sleep disturbances are common in PD. Fragmented sleep and REM sleep behaviour disorder (RBD) may precede or follow the onset of PD. Sleep disturbances lead to excessive daytime sleepiness and poor daytime functioning.

Pathology

The most consistent pathological finding is degeneration of the nigrostriatal tract. The degenerating neurons contain Lewy bodies. Though seen in other conditions, Lewy body is a highly sensitive marker for PD. Besides the nigrostriatal tracts, PD also affects other parts of the brain like the olfactory centre, lower brainstem, thalamus and cerebral cortex.

Neurotransmitters

Depletion of the dopaminergic neurons of the substantia nigra results in reduction of striatal dopamine, which is thought to be the main biochemical abnormality in PD. Normally equilibrium exists between acetylcholine and dopamine. With dopamine deficiency, there is acetylcholine hyperactivity; this may be a mechanism for parkinsonian symptoms. Norepinephrine, serotonin, somatostatin, substance P, and the enkephalins are also found to be depleted in varying degrees. Freezing has been attributed to degeneration of the noradrenergic pathways from the locus caeruleus. Depression may be related to reduced production of serotonin in the raphe nuclei. Degeneration of cholinergic neurons in the nucleus basalis of Meynert may be responsible for the dementia.

Aetiology

The cause of PD is not known. Environmental factors have been implicated. MPTP, a toxic product of heroin, was found to cause an acute clinical syndrome which was identical to PD, possibly even with formation of Lewy bodies. Chronic exposure to an MPTP-like toxin in the environment has been suggested. In Guam, Parkinsonism - ALS - dementia complex has been linked to the intake of cycad plant. Genetic factors may play an important though poorly understood role.

Disturbances in oxidative phosphorylation are seen, particularly a reduction in the activity of complex I of the mitochondrial electron transport chain. Free ion levels which may lead to formation of toxic free radicals are also increased. With normal aging, the population of viable nigral neurons gradually diminishes. Ageing may thus play a contributory role.

Genetics of PD

Although PD usually occurs sporadically, families with autosomal dominant and autosomal recessive PD have been identified, especially among patients with an early onset of disease.

The first gene mutation linked to PD was the gene for the protein alpha synuclein (SNCA) labelled PARK I. Since then, many other genes linked to PD have been identified. Mutation of the leucine rich repeat kinase 2 (LRRK2) gene is common in autosomal dominant PD. Mutation of the Parkin gene is

commonly associated with early onset autosomal recessive Parkinsonism (PARK2). These patients have a higher proportion of dystonia, hyperreflexia and severe treatment-related motor complications.

Investigations

Conventional laboratory studies do not help in the diagnosis of PD. Computed tomography (CT) and magnetic resonance scans are normal or show only variable degrees of atrophy.

Imaging

Positron emission tomography (PET) scans using fluoro-deoxyglucose (FDG) or dopamine transporter (DAT) and single photon emission computed tomography (SPECT) scans have been used to study dopaminergic terminals and help to differentiate PD from other Parkinson's plus syndromes.

Treatment

Pharmacotherapy is the mainstay of management. However, at every stage of the disease, the role of exercise and physiotherapy should be emphasised. The stiffness and slowness of movement require graded exercises-walking, fixed-bicycle or fixed-wheel exercises and deep breathing. **Table 3** lists the commonly available drugs used in the treatment of Parkinson's disease.

Table 3: Currently Available Drugs for Treatment of Parkinson's Disease

Drugs	Average Daily Dose Range	Side Effects
Levodopa preparations		
Carbidopa/levodopa [10/100;25/100;25/250]	300 to 1000 mg (of levodopa)	Anorexia, nausea, vomiting, agitation, confusion, psychosis, postural hypotension, arrhythmias, dyskinesias
Benserazide/levodopa [25/100; 12.5/50]	600 to 800 mg (of levodopa)	
Controlled-release carbidopa/levodopa [50/200]	200 to 800 mg (of levodopa)	Gastrointestinal and cardiac side effects are less with addition of decarboxylase inhibitors (carbidopa, benserazide)
Amantidine	100 to 200 mg	Anorexia, confusion, psychosis, pedal oedema, livedo reticularis
Anticholinergics		
Trihexylphenidyl	4 to 8 mg	Dry mouth, blurred vision, sphincter disturbances, psychosis, palpitations, nausea, vomiting
Procyclidine	7.5 to 15 mg	
Benztropine	1.0 to 1.5 mg	
Dopamine agonists		
Bromocriptine	5 to 10 mg	Nausea, vomiting, postural hypotension, psychosis, confusion
Ropinirole	3 to 12 mg	Hallucinations, cognitive decline
Pramipexole	1.5 to 4.5 mg	Somnolence, does not have ergot like side effect of bromocriptine
Apomorphine (subcutaneous injection)	1 to 6 mg	Nausea, vomiting, confusion, psychosis
COMT inhibitors		
Entacapone	400 to 800 mg	Diarrhoea, may aggravate dyskinesias, discoloured urine
Tolcapone	200 to 400 mg	Diarrhoea, dyskinesias, hepatotoxicity
MAO-B inhibitor		
Selegiline	5 to 10 mg	Hallucinations, confusion, postural hypotension
Rasagiline	0.5 to 1 mg	Somnolence, giddiness, orthostatic hypotension

Treatment of early PD

Levodopa combined with decarboxylase inhibitor (carbidopa or benserazide) is the most effective anti-parkinsonian drug. Most motor symptoms respond well to levodopa. However, the long-term side-effect of levodopa include motor fluctuation (shortened duration of benefit of each dose) and dyskinesias (involuntary movement). Hence, in the early stage of the disease, it is better to delay the use of levodopa and initiate treatment with other drugs like selegiline or amantidine or the newer dopamine receptor agonists (pramipexole or ropinirole). This is even more applicable when the onset of PD occurs at a younger age. The use of anticholinergic drug like trihexyphenidyl should be restricted only to young-onset PD patients with significant tremors. In PD patients over the age of 70 years, treatment should be started with levodopa. The golden rule for all anti-parkinsonian drugs is 'start low and go slow'.

On-off phenomenon

With prolonged use of L-dopa, as the disease progresses, one faces the problem of severe dyskinesia and on-off phenomenon, where the patient switches from a mobile state with aggravated dyskinesia to a helpless akinetic state.

Apomorphine is a dopamine agonist which has a rapid onset of action (5 to 10 minutes) and can 'revive' a patient from the akinetic spell. It is given subcutaneously.

New anti-Parkinson's drugs

Newer anti-Parkinson's drugs are available for patients in whom conventional drugs either are ineffective or have adverse side effects.

Dopamine receptor agonists

Besides the commonly used bromocriptine, the new dopamine agonists include ropinirole and pramipexole. Both of them are non-ergot compounds, hence the ergot related side effects of bromocriptine do not occur. Both of them have been found to be effective either as monotherapy in early onset Parkinson's disease (prior to starting levodopa) or as adjunctive therapy to levodopa in advanced Parkinson's disease. The incidence of somnolence in pramipexole treated patients is reported to be higher than patients on other drugs.

Catechol-O-methyl transferase (COMT) inhibitors

Tolcapone and entacapone are the COMT inhibitors used in Parkinson's disease. By inhibiting the COMT enzymes, which metabolise levodopa in the gut and liver, they increase the levels of levodopa in the brain and prolong the efficacy time of a levodopa dose. Entacapone is the COMT drug commonly used as reports of hepatotoxicity with tolcapone have restricted its use in clinical practice.

Rasagiline

This is new MAO-B inhibitor. It has been shown in clinical trials to be effective in early onset PD as well as in the later stages of disease.

Treatment of specific symptoms

Action tremor: The following drugs can be used: propranolol, primidone, and benzodiazepines, particularly diazepam, in the same way as for essential tremors.

Orthostatic hypotension: The following measures are employed—review of the drug regime, salt and fluid repletion, elevation of the head end of the bed; this promotes sodium retention and reduces nocturnal diuresis, elastic stockings, use of drugs like indomethacin, clonidine and propranolol, and if severe, one may have to use mineralocorticoid (fludrocortisone) starting at 0.1 mg daily. Sudden change of posture and prolonged standing should be avoided.

Depression: The treatment is usually initiated with a serotonin-reuptake blocker - fluoxetine 20 mg once daily or sertraline 50 mg once daily increasing to 100 mg twice daily. Tricyclic anti-depressants like amitriptyline may also be used.

Psychosis: Bromocriptine, amantidine, anticholinergics, selegeline and levodopa may all cause psychosis. Visual hallucinations are common.

Antiparkinsonian drugs are slowly discontinued, beginning with selegeline followed by anticholinergics and then dopamine agonists. The dose of L-dopa could also be reduced if required. Antipsychotic medication may have to be given. Phenothiazines and butyrophenones are not used as they increase the parkinsonian state. Newer atypical drugs used to treat hallucinations and psychosis in PD include clozapine, risperidone, olanzapine and quetiapine.

Clozapine is a new antipsychotic with the least extrapyramidal side effects. It is started as 12.5 mg at bedtime and slowly increased. Important side effects are agranulocytosis and sedation.

Sialorrhoea: Centrally acting anticholinergics like trihexiphenidyl can reduce saliva production and ameliorate other aspects of PD. If the central side-effects of these drugs prove intolerable, a peripherally acting anticholinergic agent like propantheline (15 to 30 mg 6 hourly) is helpful.

Constipation: It occurs in 80% of patients with PD. It is exacerbated by anticholinergics. These should be withdrawn if possible. A high-fibre diet is recommended. Bulk-forming agents like dietary fibre and stool-softening agents like dioctyl sulphsuccinate may be given. Cisapride has been found to speed colonic transit and ameliorate constipation.

Freezing: There are no suitable medicines to treat this symptom. Low-obstacle visual cues and rhythmic routines may minimise freezing episodes.

Advanced Parkinson's disease

Advanced PD is characterised by two types of motor fluctuations: (1) wearing off, in which the duration of benefit of each levodopa dose becomes progressively shorter, and (2) dyskinesias, characterised by abnormal involuntary movements of the face, trunk and limbs during the 'on' phase. Besides careful adjustment of PD drug dosages, two procedures may be of benefit in advanced PD.

1. Surgery – Deep brain stimulation (DBS).
2. Continuous enteral infusion of levodopa (Duodopa).

Surgery in Parkinson's disease

Stereotactic surgical procedures are nowadays being increasingly used for advanced Parkinson's disease with severe on and off phenomena and disabling dyskinesias in which medical therapy has failed to provide relief.

The procedures currently employed are ablative procedures like thalamotomy and pallidotomy and also DBS. Subthalamic nucleus stimulation (STN stimulation), globus pallidus stimulation (GPI stimulation) and ventral intermediate (VIM) thalamic nucleus stimulation are all different types of DBS procedures.

The above procedures require neurosurgeons with expertise in stereotactic techniques. Thalamotomy directed to the VIM nucleus is indicated for asymmetric, severe medically intractable tremor. Unilateral pallidotomy is indicated for advanced Parkinson's disease with motor fluctuations and drug induced dyskinesias along with significant bradykinesia and rigidity. Bilateral pallidotomy may have unacceptable side effects.

DBS of VIM thalamic nucleus is an alternative to thalamotomy for severe contralateral tremor in Parkinson's disease and essential tremors.

DBS of subthalamic nucleus is very effective. It is the surgical procedure of choice in many centres. It has been found effective in reducing almost all motor manifestations of PD with a high safety profile. DBS procedures are expensive.

Human foetal mesencephalic cell transplants have been tried in idiopathic Parkinson's disease who are poorly controlled with medicine and have motor fluctuations. Clinical trials have failed to establishes efficacy of this procedure and are currently not recommended in PD.

Continuous Enteral Infusion of Levodopa

In patients with advanced PD in whom DBS is not possible or is refused, the option of duodopa can be given to them. This is levodopa in a gel form which is infused continuously by a pump at a constant rate directly into the small intestine through a jejunostomy tube. Continuous enteral infusion has proved beneficial in reducing motor complications of advanced PD.

ATHEROSCLEROTIC PARKINSONISM

In patients with multi-infarct state, especially lacunar infarcts, some features of Parkinsonism may be present. Gait disturbance and freezing can be a prominent feature.

POSTENCEPHALITIC PARKINSONISM

Between 1916 and 1927, there was a worldwide epidemic of encephalitis lethargica. One-third of the patients were left with chronic neurological deficits, the most common being Parkinsonism. Parkinsonism was seen at any time from the acute stage of encephalitis to over 20 years later. Besides parkinsonian features, oculogyric crises were a common and unique phenomenon of the disease. Various forms of dystonia, chorea, myoclonus, pyramidal signs, behavioural changes and sleep-cycle alterations were also present. Sporadic cases of postencephalitic Parkinsonism continue to occur even today.

Other viral encephalitis like Japanese B encephalitis may be associated with Parkinsonism.

PARKINSONISM-PLUS SYNDROME

Atypical features, such as absence of tremor, early gait and postural abnormality, additional neurologic deficits and poor response to L-dopa suggest that the patient may not have idiopathic PD. The additional neurologic abnormalities are supranuclear ophthalmoparesis (progressive supranuclear palsy), dysautonomia (Shy-Drager syndrome), ataxia (olivopontocerebellar atrophy), laryngeal stridor (striatonigral degeneration) and dementia (diffuse Lewy body disease).

PROGRESSIVE SUPRANUCLEAR PALSY (PSP) (STEELE-RICHARDSON SYNDROME)

The patients present with frequent falls, axial and nuchal rigidity, and pseudobulbar symptoms like dysarthria and dysphagia. Tremor is usually absent. The pathognomonic feature is vertical supranuclear gaze palsy. The patients have fixed stare and poor convergence. In later stages horizontal gaze is also affected.

MULTIPLE SYSTEM ATROPHY (MSA)

MSA encompasses three entities, viz. Shy-Drager syndrome, striatonigral degeneration (SND) and olivopontocerebellar atrophy (OPCA). In the Shy-Drager syndrome autonomic disturbances in the form of orthostatic hypotension, sphincter disturbance and impotence predominate. In SND, besides the parkinsonian features the patients have laryngeal stridor and pyramidal features. Rest tremor is usually absent and findings are usually symmetrical. Cerebellar signs are most prominent in the OPCA variety of MSA.

PARKINSONISM-DEMENTIA-AMYOTROPHIC LATERAL SCLEROSIS COMPLEX

The disease complex was largely prevalent among the Chamorro population of Guam Islands. Besides parkinsonian features and progressive dementia, the majority of patients also have motor neuron disease. The aetiological hypotheses include a toxic agent from the cycad plant and disturbance in minerals like calcium and magnesium.

HYPERKINETIC MOVEMENT DISORDERS

Dystonia

Dystonia tumor and myoclonus is explained in details in chapter 20, Section 20.

NEUROLEPTIC MALIGNANT SYNDROME (NMS)

NMS is a life-threatening complication of neuroleptic therapy. Its incidence has been estimated at 0.5% to 1.0% of those taking neuroleptics. It can affect all ages and both sexes, but is most frequent in young men. Almost all the neuroleptic drugs can cause the syndrome, but it is more common with more potent dopamine antagonists and long-acting preparations. Most cases occur within two weeks of initiating therapy or of increasing the dose.

Clinically, NMS is characterised by extreme rigidity, fever, autonomic disturbance and a depressed or fluctuating level of consciousness. It develops over a period of 1 to 3 days. Occasionally, tremor, dystonia or other dyskinesias are prominent. The diagnosis is supported by finding an elevated serum creatine kinase level.

In the management of NMS, emphasis is placed on prevention. Factors which increase the likelihood of NMS include initiation of neuroleptic therapy at high doses, rapid increases in dosage, coexisting dehydration, organic brain disease and the concurrent use of other drugs like lithium and tricyclic anti-depressants. The neuroleptic drugs should be withdrawn as soon as the diagnosis is suspected. NMS is a neurological emergency requiring intensive care. Measures include maintenance of fluid and electrolyte balance and reduction of temperature - if needed by body cooling. Respiratory support and dialysis for rhabdomyolysis may be required. Bromocriptine is given orally in doses ranging from 7.5 to 60 mg/day. The oral dose of dantrolene sodium varies from 50 to 200 mg/day; the initial intravenous dose is 2 to 3 mg/kg/day. The drug is continued for 12 to 48 hours after the fever is controlled. Hepatotoxicity can occur with dantrolene. Without specific treatment, death may occur in about 25% of the cases.

TARDIVE DYSKINESIA (TD)

Refers to the development of a movement disorder after chronic exposure to dopamine-receptor antagonists. TD affects about 10% to 20% of patients exposed to neuroleptics for more than a year. Patients most at risk are women over the age of 50 years. It is characterised by stereotyped orolingual and masticatory movements taking the form of lip smacking and lip pursing, tongue protrusion, and licking and chewing movements. The muscles of the upper face are usually spared; the trunk and limb musculature may also be affected. The pathophysiology of TD is thought to be denervation super-sensitivity of striatal dopamine receptors or affection of GABA pathways.

Tardive dyskinesias are irreversible in about 40% of cases. Even those who improve do so several months after the neuroleptic drugs are stopped; elderly patients are the least likely to improve. Early detection to prevent the development of more severe manifestatio ns is important. Neuroleptic drugs may be used on a long-term basis only if absolutely necessary. Once TD is present, the causative drug should be withdrawn if possible. If TD is disabling, pre-synaptic dopamine blockers like reserpine and tetrabenazine may be used with some success. Occasional patients may benefit from a trial of baclofen or clonazepam.

20.20 Hyperkinetic Movement Disorders

Mohit Bhatt

INTRODUCTION

Hyperkinetic movement disorders refer to diseases characterised by excessive involuntary body movements that may span from subtle and barely noticeable to severely disabling. Based on the phenomenology hyperkinetic movement disorders can be classified as dystonia, chorea, myoclonus, tremor and tics. Inheritance plays an important aetiological role in hyperkinetic motor disorder but there are important treatable secondary causes that need attention. Identifying the type of hyperkinetic movement disorder, distribution pattern and associated neurological signs and medical condition helps in arriving at an accurate diagnosis.

DYSTONIA

Definition

Dystonia is defined as an involuntary movement that produces muscle spasms leading to twisting movements or abnormal sustained posture of the affected body part or region. Slow writhing movements in the affected part often described as athetosis are dystonic in nature. Dystonia may result in irregular alternating or tremulous movements. Dystonic tremor is jerky, with a variable amplitude and can be task or position specific. Dystonia is a manifestation of co-contraction of agonist and antagonist muscles. One of the interesting aspect of dystonia is its fluctuating nature. Certain posture or positions of body part can alleviate dystonia. Touching a body part (sensory trick, gesteantagoniste) can reduce dystonic spasm. It is best to ask the patient about sensory tricks as they can be variable and at times quite unusual. Dystonia can go into natural remission lasting minutes to days and even years and then recur.

It is important to classify dystonia as it helps to elucidate the possible diagnosis, plan investigation and prognosticate. Dystonia can be classified on the basis of following:

1. ***By distribution of body parts***
   (a) *Focal dystonia:* involvement of one body part, e.g. hand or neck; (b) *segmental dystonia:* involvement of two contiguous body parts, e.g. neck and arm; (c) *generalised dystonia:* involvement of two or more contiguous body parts and trunk.
2. ***By age***
   This helps prognosticate patients. Onset of symptoms before 25 years of age often indicates that the disease will spread or generalise and most likely be disabling. While adult onset dystonia or onset after 25 years of age indicates that the disorder is likely to remain anatomically restricted, e.g. Writer's cramp.
3. ***By aetiology***
   Clinically this is the most useful classification for dystonia and includes: primary dystonias, dystonias plus syndrome, secondary dystonias, *heredodegenerative dystonias* and paroxysmal dystonias.

When approaching a patient with dystonia, one has to decide if the dystonia is primary (inherited) wherein dystonia is the only clinical manifestation or secondary to structural brain lesion or a degenerative process. The most obvious clue to secondary dystonia is the presence of other neurological symptoms and signs, e.g. seizures, cognitive decline, pyramidal signs. Further, 'Red flags' for secondary dystonia include abnormal birth history and delayed developmental milestones, progressive neurological course, bulbar involvement and exposure to drugs. Patients with primary dystonia have normal scans and metabolic profiles, while secondary dystonias are associated with abnormal imaging and/or biochemical abnormalities, e.g. abnormal copper metabolism and magnetic resonance imaging (MRI) in Wilson's disease.

Primary dystonias are inherited and occur at a specific age group. If either of this rule is broken one must suspect presence of a secondary dystonia.

Primary Adult Onset (45 years and above) Dystonia

These are focal dystonias involving the cranio-cervical region and best treated with botulinum toxin injection. Classic examples of this are: (a) dystonic torticollis: turning of head to one side, (b) blepharospasm: involuntary spasms of eye closure, and (c) oromandibular dystonia: involvement of mouth, jaw and tongue.

Primary Adult Onset (25 to 45 years) Limb Dystonia

Patients have dystonia of usually the upper limb. Dystonia is observed during a particular task, especially repetitive tasks, e.g writing, money counters dystonia, typist's dystonia and musician's dystonia. The disability tends to increase for a few years and then plateau. Rest alleviates symptoms briefly. This form of dystonia is resistant to treatment but a small percentage of patients do experience partial relief with local botulium toxin injection.

Primary Young Onset (<25 years) Dystonia

This is often known as Torsion dystonia or Oppenheim's dystonia. It affects children in their teens with onset usually in the lower limb. Over 2 years or so the movements become generalised, though cranial and bulbar regions are rarely affected. Sixty per cent of patients have mutations in the DYT_1 gene on chromosome 9q. GAG deletion in DYT1 gene which codes for protein TORSIN –A expressed in the dopaminegic areas of the brain is responsible for symptoms in this condition. This mutation is expressed in all ethnic groups but highly prevalent in Ashkenazi-Jewish population because of founder effect. Inheritance is autosomal dominant with a gene penetration of only 30%. Therefore, not all carriers will express the disease and beyond 26 years of age it is unlikely that a carrier of DYT 1 gene may ever suffer from the disease. Expressions can vary from severe generalised dystonia to just focal limb dystonia.

Dystonia-Plus Syndromes

There are two types of syndromes: (a) dopa responsive dystonia (DRD), and (b) myoclonus dystonia syndrome.

Dopa responsive dystonia (DRD, Segava Syndrome) is a rare autosomal dominant disorder that can be effectively treated with L-Dopa in small doses. If not recognised it can lead to severe disability. The dose of L-Dopa required to ameliorate symptoms is usually quite small (levodopa 200 to 400 mg/day) and usually does not need to be escalated over time. Patients present in the young age with leg dystonia, spasticity and Parkinsonism. Fluctuations are common and females are more affected (ratio 4:1). Clinical manifestations can be quite variable and diagnosis is difficult. As a rule it is recommended that all patients with young onset (<25 years) dystonia be given a trial with L-Dopa.

Heredodegenerative Dystonias

Degenerative diseases associated with dystonia are presented in **Table 1** based on the neurological signs accompanying the dystonia.

Table 1: Degenerative Diseases Associated with Dystonia

Dystonia with Parkinsonism
- Parkinson's disease
- Multiple system atrophy
- Progressive supranuclear palsy (PSP)

Dystonia with eye movement disorder
- Niemann-Pick type C
- Ataxia telangiectasia
- Spinocereballar ataxia

Dystonia with bulbar involvement
- Neuronal brain iron accumulation (NBIA) (including PKAN and neuroferritinopathy)
- Neuro-acanthocytosis
- Wilson's disease

Dystonia with ataxia
- Spinocerebellar ataxia
- Wilson's disease
- Huntington's disease

Dystonia with peripheral neuropathy
- Metachromatic leucodystrophy
- Spinocerebullar ataxia
- Neuro-acanthocytosis

Treatment of Dystonia

1. Medical
   (a) Trihexyphenidyl, benzodiazepines and tetrabenazine
   (b) Botulium Toxin: For focal dystonias
2. Surgical: Deep brain stimulation of globus pallidusinternus
3. In all patients with young onset primary dystonias, a trial with L-Dopa for 3 months is essential, before classifying the dystonia as L-dopa non-responsive. Usually a dose of 300 to 600 mg/day of levodopa is required.

CHOREA

Chorea is defined as brief quasipurposeless involuntary movements that flit and flow from one body part to another. Patients with chorea often appear restless and fidgety. Chorea is often generalised but can remain focal, e.g. face or one side of the body (hemi-chorea). In clinical practice the terms chorea and choreoathetosis are often used interchangeably. However, athetoid movements are slow, distal and more accurately defined as dystonia. Therefore, the terms like athetosis or choreoathetosis are best avoided. A clinician should be able to differentiate chorea from dystonia at bedside.

Severe proximal chorea resulting in wild flinging movement of limbs is known as ballism. Hemiballism refers to ballism restricted to one side of the body. Vascular injury involving the subthalamic nucleus is the commonest cause for hemiballism. Diseases characterised by chorea are listed in **Table 2**.

Table 2: Diseases Characterised by Chorea

Inherited/ Degenerative	Huntington's disease Wilson's disease Neuroacanthocytosis Benign hereditary chorea
Autoimmune (post-infection)	Systemic lupus erythematosus Antiphospholipid syndrome Hashimoto's chorea Sydenham's chorea
Infections	HIV Encephalopathy Creutzfeld-Jakob disease (CJD)
Drugs	Dopamine receptor blockers Levodopa Oral contraceptives Anticonvulsants
Structural Lesions	Basal ganglia (caudate) lesions
Metabolic	Hyperthyroidism Hyperglycaemia Sodium disturbances Calcium, manganese and iron deposition disorders

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant degenerative disease characterised by behavioural disturbance, dementia and chorea, described by Huntington in 1872. It has a prevalence of 4 to 8 per 100,000 world over. HD is rare in the first two decades of life and when present it manifests with Parkinsonism and rigidity (Westphal variant). In later age group initial symptoms are variable and include features of dementia, psychiatric problems or chorea. Presence of a strong autosomal dominant pattern of inheritance helps clinch the disgnosis. Lack of inhibition leading to inappropriate behaviour, disorganisation, lack of executive function, apathy, depression and paranoia present in variable combination. Chorea may be subtle at the onset but steadily progresses making the diagnosis obvious.

Eye movement abnormality often assists in the diagnosis and includes: (a) slow hypometric saccades, (b) impersistence of gaze, (c) difficulty in initiating saccades. Patients blink or use head thrust to look from one point to another.

Bizarre gait is another common feature of HD. With advanced disease chorea gives way to Parkinsonism and dystonia. Genetic testing clinches the diagnosis.

Genetics of HD

This is a triplet-repeat disorder. A mutation in the Huntington's gene on chromosome 4 leads to enlargement of the polyglutamine portion to be added to the Huntington's protein. The protein aggregation leads to cell death. The number of repeats in this gene determines when the disease will manifest. Higher the number of CAG repeats younger is the age of manifestation of HD.

Treatment for behavioural problems

1. Selective serotonin reuptake inhibitors for depression
2. Benzodiazepines for anxiety and insomnia
3. Psychological therapy

Treatment for movement disorder

1. Tetrabenazine
2. Amantadine and valproate
3. Dopamine blocking agents

Sydenham's Chorea

Thomas Sydenham was an English Physician of great repute who described this condition in children. This is now known as Syndenham's chorea and is an immune-mediated disorder that follows streptococcal infection (rheumatic fever). Patient develops chorea weeks or months (<6) after streptococcal infection. It is more common in young girls. Associated dystonia may dominate the movement disorder in some children. Behavioural disturbance is often associated with the movement disorder. Antibodies against streptococcal antigen bind to basal ganglion leading to clinical manifestation. Usually, complete remission occurs within few weeks or months of onset of chorea and only seldom are drugs are required for a long period to suppress chorea. Tetrabenazine, valproic acid and occasionally with dopamine antagonists are used in such cases.

Relapses of chorea are seen in 20% of cases while a small number develop chronic persistence of chorea. Patients with refractory chorea may benefit from immunoglobulin or plasma exchange. As in rheumatic carditis penicillin prophylaxis well into adult life is required to prevent another bout of streptococcal infection and recurrence of the disease.

MYOCLONUS

Myoclonus is a brief electric shock like jerk. Physiological myoclonus is experienced by all as hiccups or jerks while falling asleep (hypnic jerk). Myoclonus results from brief activation of a group of muscles. This activation can be from the cortex, subcortical structures like brainstem; spinal cord or nerve, root and plexii. Analogus to the phenomenon of 'positive myoclonus', a brief cessation of muscle activation produces loss of muscle tone produces negative myoclonus as seen in liver flaps (asterix).

Clinically it may be possible to localise the origin of myoclonus. Cortical origin manifests as small amptitude distal limb jerk and is often focal. It may be stimulus sensitive, i.e gently tapping the affected body part triggers the myoclonic jerk. While subcortical myoclonus is large amptitude and generalised.

Various causes of myoclonus are presented in **Table 3**.

Electrophysiology and Myoclonic Jerks

Myoclonic jerks are caused by brief (<50 ms) bursts of muscle activity. It is not possible to generate voluntary contraction for such brief periods. This gives a myclonic recording on EMG evidence of organicity. Further, voluntary motor activity is preceded by a slow wave called Bereitschaft potential (BP) on electroencephalogram (EEG). Consistent presence of a Bereitschaft potential prior to myoclonic jerk helps to diagnose a psychogenic myoclonus.

Table 3: Causes of Myoclonus

Primary myoclonus	Hypnic jerks, hiccups
	Benign infantile myoclonus with feeding/sleep
	Essential myoclonus
Myoclonus with epilepsy	West's syndrome
Lennox-Gastaut syndrome	—
Epilepsia partialis continua	—
Progressive myoclonic	Lafora body disease
Epilepsy and ataxia	Unverricht-Lundborg disease
	Neuronal ceroidlipofuscinosis
Sialidosis	Myoclonus epilepsy with ragged red fibres (MERRF)
Symptomatic myoclonus	Liver failure
With encephalopathy	Renal failure
	Drug intoxication (alcohol, lithium)
	Post hypoxia (Lance-Adams syndrome)
Without encephalopathy	—
Plus dementia	Alzheimer's disease
Creutzfeldt-Jakob disease	—
Plus Parkinsonism	Cortico-basal degeneration
	Multiple system atrophy
Other	Whipple's disease
	Coeliac disease
Paraneoplastic	—

Symptomatic Myoclonus

1. Generalised myoclonus with encephalopathy may be a manifestation of metabolic disease. Acute hepatic encephalopathy may manifest with generalised or focal myoclonus (flaps). Once the metabolic condition improves the myclonic jerks abate.
2. Post-hypoxic myoclonus (Lance-Adams syndrome): This is a result of hypoxic brain damage due to cardiac or respiratory arrest. It is characterised by generalised multifocal non-progressive, stimulus sensitive cortical myoclonus, often accompanied with ataxia and encephalopathy. Presence of severe myclonus in such a setting is a poor prognostic sign. It is resistant to most medical treatments.
3. Subacute sclerosing pan encephalitis (SSPE): Reactivation of measles virus can cause progressive encephalopathy, periodic slow myoclonic jerks, abnormal EEG. Myoclonic jerks are periodic and are time locked to periodic slow complexes on EEG in a 1:1 ratio. Successful vaccination against measles has reduced this disease. It is always fatal, therefore, the need to vaccinate all children against this virus infection. Anecdotal reports suggest benefit of isoprinosine and interferon alpha.

Spinal Segmental Myoclonus

Spinal cord lesions like demylenation, tumours or traumatic injury produce segmental myoclonus. It can be stimulus sensitive and imaging studies localise abnormal region often helps. Jerking of the affected segment is continuous and often will continue even in sleep.

Treatment

Drugs that are used for myoclonic jerks include clonazipam, primidone, piracetam, levetiracetam and sodium valproate.

Often combination of the above drugs is required to control the myoclonic jerks.

TREMOR

Definition

Tremor is defined as rhythmic sinusoidal oscillation of a body part, usually due to alternating activation of agonist and antagonist muscles. Tremor seen when body part is at rest is called rest tremor, while tremor triggered by movement is called a kinetic tremor. Postural tremor seen in certain postures i.e. out stretching of hands and action tremor, seen during movement are types of kinetic tremors. Therefore, to study tremor in a patient first look for tremor when limbs are at rest then ask the patient to stretch out their limbs and lastly make them do alternating action like finger-nose-finger movements. Most tremors manifest in the arms but some tremors are localised to jaw, chin, or legs or generalised. Disorders associated with tremors are presented in **Table 4**.

Table 4: Disorders Associated with Tremors

Rest Tremors	
	Parkinson's disease (typically 3 to 5 Hz)
	Drug Induced
Postural Tremors	
	Essential tremor
	Hyperthyroidism
	Task specific tremor
	Neuropathic tremor—IgM paraproteinemia
Kinetic Tremors	
	Cerebellar disease
	Holme's tremor
	Wilson's disease

Focal Tremor Syndromes

1. Orthostatic tremor is characterised by fine high frequency (16 Hz) leg triggered on standing, resulting in sense of imbalance and unsteady feeling. Walking alleivates the symptoms. It is usually seen after 50 years of age, and drugs like clonazepam helps.
2. Head tremor is also known as titubation. Direction of head nods may be either of Yes – Yes or No – No pattern. Common causes for head nodding is Parkinson's disease, as part of Essential tremor or dystonia and rarely seen with 3rd ventricular tumours (Bobble Head Doll syndrome).
3. Jaw tremor is seen with Parkinson's disease and as an adverse effect of dopamine blocking drugs.
4. Palatal tremor is usually caused by lesions in the brainstem (Gullian-Mollaret triangle).

Disorders Mimicking a Tremor

1. Chin tremor or geniospasm is an inherited (autosomal dominant) disorder. The movements respond well to botulium toxin injections.
2. Oculomasticatory myorhythmia: These are characterised by rhythmic contraction of facial and ocular muscles is and are diagnostic of Whipple's disease.

TICS

As the name suggests tics are brief involuntarty stereotypic movements or vocalisations. An important characteristic of tics is patient's ability to suppress them for short periods. Patients feel a sense of subjective discomfort during suppression of tics. The discomfort is released by flurry of tics. Tics are common and 15% of population will have tics at some time. In a smaller proportion it is the beginning of chronic tic disorder.

Simple motor tic: Eye blinking, eyebrow raising, winking, forehead raising, pouting, nose wrinkling, shoulder raising.

Complex motor tic: Head shaking, touching self, touching others, kicking, jumping, hopping, copropraxia, echopraxia.

Simple vocal tic: Grunting, sniffing, coughing, humming, whistling.

Complex vocal tic: Saying words or parts of words, coprolalia, echolalia, pallilalia.

Clinical Features Associated with Tic Disorders

Copropraxia: production of obscene gestures

Echopraxia: coping the movements of others

Coprolalia: saying obscene words

Echolalia: coping the words of others

Pallilalia: repetition of the same phrase, word, or syllable (e.g. 'My name is Mohit…t…t…t…t')

The most important tic disorder is Tourette's syndrome named after the French Neurologist Gilles de la Tourette. It affects 14 % of population under the age of 18 years. Beyond 18 years, symptoms wane reducing its prevalence in adult life. Diagnosis of Tourette's syndrome requires presence of multiple motor and vocal tics, and these tics for one year and in a person under 18 years of age.

Tics in Tourette's syndrome and tics can be treated with tetrabenazine, clonazepam, clonidine and botulium toxin.

20.21 Cerebellar Disorders

Pramod Kumar Pal

INTRODUCTION

The functions of cerebellum include control of muscle tone, coordination of movements, and control of posture and gait. It also co-ordinates the movements of eye and body with respect to gravity and movement of the body in space. Recent evidence suggests that cerebellum probably plays a role in learning.

Cerebellum and or its connections to other parts of the central nervous system (CNS) may be affected in several ways. The aetiology can be congenital (hereditary or non-hereditary) or acquired (**Table 1**). The most common disorder is degeneration of cerebellum and/or its connections, often affecting other parts of the nervous system.

Table 1: Classification of Cerebellar Ataxias

Hereditary ataxias
- Autosomal recessive ataxias
- Autosomal dominant ataxias
  - Spinocerebellar ataxias (SCA)
  - Episodic ataxias (EA)
- Mitochondrial disorders

Non-hereditary ataxias
- Idiopathic late onset cerebellar ataxia
- Multiple system atrophy
- Symptomatic ataxias

Congenital or developmental disorders, cerebellar malformations
- Non-genetic
- Genetic

CLINICAL MANIFESTATIONS OF CEREBELLAR DISORDERS

Ataxia, a term attributed to disturbances of coordinated muscle activity, is the hallmark of disorders of cerebellum, its afferent or efferent connections. Manifestations include truncal ataxia, unsteadiness of gait and stance and ataxia of intended limb movements. The ataxic limb movements are irregular, jerky, tend to overshoot the target (past-pointing), often accompanied by rhythmic side-to-side movements as the target is approached (intention tremor). There is impaired judgement of the distance to the target (dysmetria), movements tend to be broken down at various joints (dyssynergia) and inability to perform rapid alternating movements (dysdiadocokinesia).

In neurodegenerative disorders other areas of the nervous system may be variably involved resulting in pyramidal signs, peripheral neuropathy, ophthalmic changes, bulbar and brainstem dysfunction, posterior column dysfunction, extrapyramidal manifestations, dysautonomia and cognitive decline.

DIAGNOSTIC APPROACH TO CEREBELLAR DISORDERS

The first step in the evaluation of cerebellar disorder is to distinguish focal from non-focal cerebellar disorders. In the former, symptoms are usually acute to subacute in onset, cerebellar signs are usually unilateral in early stage and there may be signs of raised intra-cranial tension or systemic manifestations (e.g. in cerebellar abscess). Non-focal cerebellar disorders (e.g. degenerative ataxias), are usually insidious in onset, chronic in evolution, and may have a positive family history.

The next step is to identify disorders with a highly characteristic phenotype that can be diagnosed easily on clinical grounds and confirmed by specific laboratory tests, e.g. Friedreich's ataxia (FA), ataxia telangiectasia, cerebrotendinous xanthomatosis, etc.

Finally it is important to look for extra-neural manifestations in patients with cerebellar ataxias, which may provide clues to the aetiology.

An outline of important steps in eliciting history and neurological examination in a patient with cerebellar dysfunction is given in **Table 2**. Further diagnostic tests will depend on the mode of inheritance, age at disease onset, rate of progression, accompanying symptoms, etc.

HEREDITARY ATAXIAS

In hereditary ataxias, an autosomal recessive (AR) inheritance is characterised by several affected members in one generation with healthy parents. Presence of consanguinity in parents strongly favours such inheritance. Typically these disorders manifest in childhood, adolescence or early adulthood. Presence of ataxia in subsequent generations, particularly if both sexes are affected, is highly suggestive of autosomal dominant (AD) transmission. The onset of symptoms is usually later than in AR disorder, though early onset can be seen in subsequent generations due to anticipation (discuses later in the chapter). Finally there are ataxic syndromes, which may have mitochondrial inheritance. However, a negative family history does not always rule out a hereditary disorder. An erroneous conclusion of 'sporadic' disorder may occur in the following situations: (i) unreliable history, (ii) social stigma attributed to a positive family history, (iii) mild symptoms of degenerative disorders in relatives ignored by informants, (iv) family members not examined and (v) strong anticipation in index patient (onset of symptoms at early age even before a parent is symptomatic).

Classifications

Classifications of hereditary ataxias have undergone changes over past several decades. Greenfield (1954) was the first to classify heredoataxias based on pathological criteria. In 1970 Konigsmark and Weiner classified olivopontocerebellar atrophics (OPCAs) into five categories based on genetic, clinical and pathologic data. The genetic loci ascribed for autosomal dominant cerebellar ataxias (ADCAs) are increasing steadfastly, and till date include SCA1 to SCA31, dentato-rubro-pallido-luysian atrophy (DRPLA), and episodic ataxias (EA-1 to EA-7). An updated classification of ADCAs described by Harding based on SCA genetic loci (symptomatic classification of SCAs) is given in **Table 3**. A genetic classification of AR ataxias is given in **Table 4**.

Table 2: Clinical Examination in Cerebellar Disorders

Neurological examination

a. Cerebellar signs: Ataxia of gait, stance, impaired tandem walking, dysdiadochokinesia, incoordination in upper limbs (finger-to-nose test) and lower limbs (heel-knee-shin test), rebound phenomenon, hypotonia and hyporeflexia (if pure cerebellar syndrome, sometimes with pendular knee jerks), dysarthria (scanning, slurred, explosive or a combination), and nystagmus.
b. Determine if the disorder is 'pure' cerebellar or mixed with other neurological signs
c. Whether the cerebellar signs are:
   Bilaterally symmetrical
   Unilateral
   Bilateral, but asymmetrical
d. Other neurological signs often associated with ataxic syndromes:
   Abnormalities of ocular movements:
      Jerky pursuit
      Hypometric and sometimes hypermetric saccades
      Impaired optokinetic nsytagmus
      Vertical gaze palsies (often supranuclear)
      Downbeat nystagmus associated with anomalies of craniovertebral junction
   Head thrust sign
   Reduced visual acuity, optic atrophy, retinal degeneration, macular degeneration
   Papilloedema in ataxic disorders resulting from space occupying lesions in cerebellum
   Extrapyramidal features, such as tremor (rest or action), rigidity, bradykinesia, 'bulging eyes' (as a result of facial dystonia), choreoathetosis and dystonia, myoclonus, etc.
   Deafness
   Bulbar signs, pyramidal signs, sensori-motor peripheral neuropathy, impaired proprioception, etc.
   Autonomic dysfunction
   Mental retardation and cognitive decline
e. Does the neurological syndrome fit in to a well defined disease entity (such as Friedreich's ataxia, or SCA7 characterised by dominant cerebellar ataxia with retinal degeneration?

General physical examination

a. Musculoskeletal abnormalities-kyphosis, scoliosis, pes cavus, contracture of tendoachilles, etc.
b. Telangiectasias (conjunctiva, oral mucous membrane, external ear lobe, eyelids, exposed part of neck, antecubital and polpliteal spaces)
c. Ichthyosis
d. Neurocutaneous markers
e. Neck-to-body ratio and low hair line especially in sporadic ataxias where craniovertebral anomalies are suspected

Systemic examination

a. Cardiac abnormalities (e.g. hypertrophic cardiomyopathy in Friedreich's ataxia)

Autosomal Dominant Cerebellar Ataxias

As discussed earlier, most of the ADCAs are now labelled as SCAs. The types of nucleotide repeat abnormalities in SCAs are shown in **Table 3**. The most common abnormality found in SCAs is abnormal cytosine-adenine-guanine (CAG) repeat. CAG encodes glutamine, and therefore CAG triplet repeat expansions result in expanded polyglutamine proteins, known as ataxins, which cause a toxic gain of function. These abnormal proteins result in neuronal loss with gliosis in a specific pattern according to the genetic mutation. 'Anticipation' is common in these disorders, characterised by an earlier age of onset and more aggressive disease in subsequent generations due to further expansion of the CAG triplet repeat and increased polyglutamine number in the mutant ataxin. Certain clinical findings can give a clue to the type of SCA genotype. Direct genetic testing is currently available for a large number of SCAs including SCA1, SCA2 to SCA8, SCA10, SCA12, SCA14, SCA17, DRPLA and some of the episodic ataxias (EAs). The most common genetically defined SCAs worldwide as well in India are SCA1, SCA2, and SCA3. In India, SCA2 has been reported to be the most common SCA in Northern and Western India, and SCA1 in Southern India. The clinical features of the common SCAs are discussed below.

SCA1

The frequency of SCA1 varies from 6% to 27% of the ADCAs. SCA1 results from mutated Ataxin-1 protein as a result of increased CAG trinucleotide repeats of the SCA1 gene located at chromosome 6p23. The clinical features are quite variable, with age of onset from 4 to 74 years (average around 4th decade) and anticipation is common. Pancerebellar involvement results in gait, trunk and limb ataxia, dysarthria and less frequently nystagmus. Ophthalmologic signs are prominent later in the disease, include slow or absent saccades and gaze paresis. Other manifestations are upper motor neuron signs (spasticity-most common in lower extremities, exaggerated stretch reflexes-especially knees, extensor plantar responses), extrapyramidal signs (later in disease include dystonia and chorea), sensory or sensory-motor polyneuropathy (especially large fibre), and bulbar dysfunction (vocal cord paralysis and stridor). Most patients are disabled by five years, bedridden by 10 years, and death by 10 to 20 years after onset of symptoms.

SCA2

SCA2 is a common ADCA (13% to 18% of the ADCAs), caused by mutated Ataxin-2 due to extra CAG trinucleotide repeats in reading frame of ataxin-2 gene located on chromosome 12q 24.1. There is clinical overlap with SCA1 and SCA3 and significant intrafamilial variability. The age of onset of symptoms is variable, ranging from 6 to 67 years (average around 20 years), and anticipation is also common. Apart from progressive limb and gait ataxia, and dysarthria, SCA2 is characterised by slow saccades (almost 100%) and polyneuropathy. Extrapyramidal features are often seen and include tremor, titubation, dystonia, chorea and myoclonus. Occasionally, dopa-responsive young-onset Parkinsonism may be the presenting or dominant feature in the family. Other features may include bladder dysfunction (~40%), pyramidal signs (~ one-third), fasciculations and amyotrophy (approximately 20%), and dysphagia. MRI findings of atrophy of pons, cerebellum, middle cerebellar peduncles, and medulla can be appreciated in **Figure 1**.

SCA3

SCA3, also known as Machado-Joseph disease (MJD) is another common ADCA (23% to 63%). It results from mutated ataxin-3, due to extra CAG trinucleotide repeats of ataxin-3 gene on chromosome 14q32.1. Male parent transmits the mutant allele about 73% of time. Anticipation is common, and clinical features are variable among different families, as well as within the same family depending on the CAG repeat lengths. Apart from cerebellar signs, patients can have extrapyramidal, pyramidal

Table 3: Autosomal Dominant Cerebellar Ataxias

Type	Notation	Locus	Mutation/Gene
ADCA			
Type I	SCA1	6p23	CAG>39 (Ataxin-1)
	SCA2	12q24.1	CAG>32 (Ataxin-2)
	SCA3	14q32.1	CAG>54 (Ataxin-3)
	SCA4	16q22.1	Mutation at PLEKHG4; (Puratrophin-1)
	SCA8	13q21	CTG repeats, noncoding
	SCA9	?	?
	SCA12	5q31-33	CAG>66 (Protein phosphatase 2A
	SCA17	6q27	CAG>44
	SCA27	13q34	Point mutation at Fibroblast Growth Factor (FGF) 14
	SCA28	18p11.22-q11.2	Unknown
Type II	SCA7	3p14.1-p21.1	CAG>37 (Ataxin-7)
Type III	SCA5	11q13	Mutation of β-III Spectrin (SPTBN2)
	SCA6	19p13	CAG>19 (α_{1A} voltage-dependent calcium channel subunit-CACNA1A)
	SCA10	22q13	ATTCT repeat (Ataxin-10)
	SCA11	15q15.2	Tau tubulin kinase 2 (TTBK2)
	SCA14	9q13.4	Protein kinsae C gamma (PKC γ)
	SCA15	3p24.2-3pter	Inositol 1,4,5-triphosphate receptor, type 1 (ITPR1)
	SCA22	1p21-q23	
	SCA26	19p13.3	
	SCA30	4q34.3-q35.1	
	SCA 31	16q22.1	Pentanucleotide (TGGAA) n repeat insertion
Other			
	SCA13	19q13.3-q13.4	Potassium channel, voltage-gated, shaw-related subfamily, member 3 (KCNC3)
Dentato-rubro-pallido-luysian atrophy		12p13	CAG>48 (Atrophin)
Episodic Ataxias (EA)			
	EA-1	12p13	Missense point mutation in the potassium voltage-gated channel gene KCNA-1
	EA-2	19p13	Stop codon nonsense mutation of the α_{1A} voltage-dependent calcium channel subunit gene CACNA1A
	EA-3	1q42	
	EA-5	2q22	Mutation at CACNB4β4
	EA-6	5p13	Missense mutation of SLC1A3 gene (EAAT1 protein)

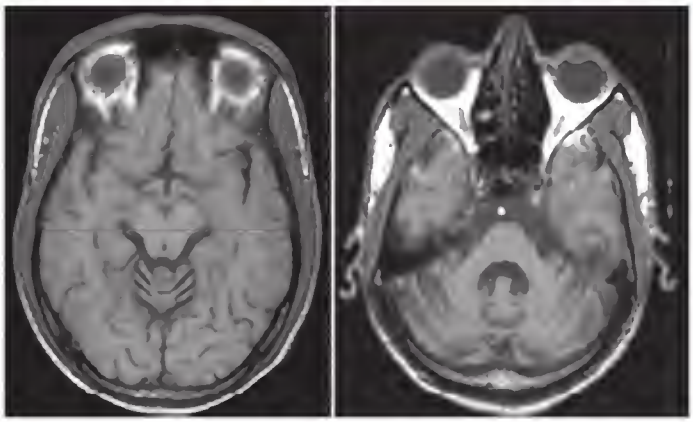

Figure 1: T1 weighted MRI scans of a patient with SCA2 showing severe cerebellar (vermian and hemispheric) and brainstem atrophy.

or polyneuropathy signs. Accordingly, MJD has been classified into three clinical types:

(a) In type I MJD (amyotrophic lateral sclerosis-parkinsonism-dystonia type) the symptoms appear early, at 10 to 30 years. Dystonia of face, neck, trunk and limbs is prominent, along with increased tone and weakness of limbs, pyramidal signs, dysarthria, dysphagia, and abnormalities of eye movements (horizontal and vertical nystagmus, paresis of upward gaze, hypometric and hypermetric saccades).

(b) Type II MJD (ataxic type) is the commonest form of MJD, have an intermediate age of onset (20 to 50 years) and progression and present with prominent cerebellar ataxia and pyramidal signs without any significant extrapyramidal signs.

(c) Type III MJD (ataxic-amyotrophic or neuropathic type) has a later age of onset (40 to 75 years) and slowest progression. There is pancerebellar involvement with ataxia, dysarthria and incoordination of limbs along with prominent peripheral neuropathy. The latter includes distal sensory loss, amyotrophy, fasciculations and weakness.

SCA5

In SCA5 there is mutation of the β-III Spectrin; SPTBN2 gene on chromosome 11q13. The disease is a relatively 'pure' cerebellar syndrome with disease onset in the 4th decade and the course is slowly progressive. Apart from ataxia, incoordination and dysarthria, abnormalities of eye movements are common.

SCA6

SCA6 is a relatively 'pure' cerebellar ataxia with family history of AD transmission in approximately three-fourths of the patients; the rest are sporadic. There is CAG repeat expansion in the gene

for α_{1A} voltage-dependent calcium channel subunit (CACNL1A4, also known as CACNA1A gene) at chromosome 19p13.

SCA7

The characteristic finding in SCA7 is retinal degeneration. There is expanded CAG repeat at chromosome 3p14.1 to p21.1. The mutant protein is Ataxin-7. The age of onset of symptoms is variable, the average being around 20 years. Marked anticipation may be present especially with paternal inheritance. The initial symptoms may be ataxia, dysarthria or visual. The early visual abnormalities are blue-yellow colour blindness, which proceed to frank visual loss and macular degeneration. Other features are variable and may include pyramidal signs, ophthalmoparesis, and hearing loss.

SCA12

SCA12 has been reported from India and Germany. There is expanded CAG repeat in 5' untranslated region of gene protein phosphatase 2 regulatory subunit B, β (PPP2R2B) on chromosome 5q31-q33. The mean age of onset of symptoms is in the 4th decade (vary from 8 to 55 years), and characterised by tremor of arm, or gait ataxia and dysarthria.

Dentato-Rubro-Pallido-Luysian Atrophy (DRPLA)

DRPLA is a CAG repeat disorder most often reported from Japan. There is expansion of the CAG triplet of the DRPLA gene mapped to chromosome 12p13.31. The DRPLA gene product is *atrophin*. The age of onset is variable (1st to 6th decade) depending on the size of expansion, with paternal transmission resulting in stronger anticipation. The clinical picture consists of progressive ataxia, myoclonus, seizures, choreoathetosis, dystonia, and dementia. The patients with larger CAG expansion have younger onset with myoclonus, epilepsy and dementia, while those with smaller CAG expansion have older onset and symptoms of ataxia, chorea and dementia.

Episodic Ataxias (EA)

These are genetically determined ion channel disorders, also known as 'channelopathies' and are characterised by intermittent ataxias. These are rare disorders and to date at least five types of EA have been described (EA-1 to EA-5). Of these EA-1 and EA-2 are the most important (**Table 3**).

EA-1

It is an episodic ataxia/myokymia syndrome caused by a missense point mutation in the potassium voltage-gated channel gene KCNA-1 on chromosome 12p13. The onset of symptoms is in childhood to second decade. The patients have brief episodes of ataxia and myokymia around the eyes and hands lasting for few minutes. There may be choreoathetotic movements during the attack. The attacks may be precipitated by sudden change of posture, emotion, vestibular stimulation, and exercise. There is no ataxia between attacks. Acetazolamide or anticonvulsants may reduce the frequency of attacks.

EA-2

There is stop codon nonsense mutation of the α1A voltage-dependent calcium channel subunit gene CACNA1A on chromosome 19p13, similar to SCA6. The onset of symptoms is in early childhood or in adolescence, and is characterised by episodes of ataxia, nystagmus and truncal instability lasting for 30 minutes to 6 hours. Other associated symptoms may include vertigo, nausea, vomiting, headache and generalised weakness. The attacks may be provoked by stress, exercise or fatigue. Interictal cerebellar signs may be present and some patients may later develop progressive ataxia. As in EA-1, acetazolamide may be helpful in preventing attacks.

Episodic ataxias should be differentiated from metabolic disorders, described earlier, which can also cause intermittent ataxia.

AUTOSOMAL RECESSIVE ATAXIAS

Autosomal recessive cerebellar ataxias (ARCA) are a group of neurological disorders, usually manifesting before 20 years of age, characterised by degeneration or abnormal development of cerebellum and spinal cord. Based on clinicogenetic criteria ARCA can be classified into four main categories (**Table 4**): (i) congenital ataxias (developmental disorders), (ii) degenerative

Table 4: Autosomal Recessive Spinocerebellar Ataxias (ARSCA) with Known Genetic Defect or Identified Loci

Congenital and developmental
- Joubert syndrome
- Gillespie's syndrome

Degenerative ataxias
- Friedreich's ataxia
- Early onset cerebellar ataxia with retained tendon reflexes (EOCARR)
- Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSCAS)
- Marinesco-Sjögren syndrome
- Infantile-onset spinocerebellar ataxia (IOSCA)
- Mitochondrial recessive ataxic syndrome (MIRAS)
- Spinocerebellar ataxia with axonal neuropathy (SCAN)
- Coenzyme Q_{10} deficiency with cerebellar ataxia
- Posterior column ataxia with retinitis pigmentosa

DNA repair defects
- Ataxia Telangiectasia (AT)
- Ataxia Telangiectasia-like disorder (ATL)
- Ataxia with oculomotor apraxia (types 1 and 2) (AOA1 and AOA2)
- Spinocerebellar ataxia with axonal neuropathy (SCAN1)
- Xeroderma pigmentosum

Metabolic ataxias
- Progressive ataxias
  - Ataxia with isolated Vitamin E deficiency (AVED)
  - Abetalipoproteinaemia
  - Cerebrotendinous xanthomatosis (CTX)
  - Refsum's disease
- Disorders associated with intermittent ataxias
  - Hyperammonaemic syndromes (urea cycle disorders)
  - Aminoacidurias
    - Maple syrup urine disease
    - Hartnup's disease
    - Isovaleric aciduria
  - Disorders of pyruvate and lactate metabolism
    - Pyruvate dehydrogenase deficiency
    - Pyruvate carboxylase deficiency
    - Multiple biotin dependent carboxylase deficiency
- Metabolic disorders in which ataxia occurs as a minor feature
  - Hexosaminidase deficiency
  - Metachromatic leucodystrophy
  - Adrenoleucodystrophy
  - Neuronal ceroid lipofuscinosis
  - Sialidosis
  - Wilson's disease

ataxias, (iii) ataxias with a DNA repair defect, and (iv) ataxias associated with metabolic disorders.

Friedreich's Ataxia

Friedreich's ataxia (FA) is the most common inherited degenerative ataxia (~50%), and constitutes approximately 75% of those with onset <25 years. It was first described by Nikolaus Friedreich in 1863. The estimated prevalence is one person in 30,000 to one in 50,000 in most populations; however, no data is available from India. It is inherited as an AR disorder, and consanguineous marriages increase the frequency of the disease. The classic form of FA (about 98% of patients) maps to 9q13 to 9q21, and the mutant gene *frataxin* contains expanded GAA triplet repeats (200 to 900 repeats, whereas the normal is 7 to 22). More than 95 % of patients are homozygous for the expanded GAA repeats, whereas a small percentage of patients are compound heterozygotes who have one copy of the GAA expansion and a point mutation of the *frataxin* gene. *Frataxin* is a mitochondrial protein required for iron homeostasis and prevents free radical toxicity in the tissues. Mutant *frataxin* gene results in loss of iron transporter with resultant accumulation of oxidised intramitochondrial iron, free radical injury and finally irreversible cell injury. In patients with FA *frataxin* mRNA is extremely low or undetectable. There is neuronal degeneration of the posterior columns, spinocerebellar tracts (especially cervical segments), corticospinal tracts, dorsal root ganglia, Clark's column and peripheral nerves.

The mean age at onset of symptoms is 15.5±8 years (usually <20 years) but ranges from 2 to 51 years. The late onset type (after 20 years) is referred to as LOFA (late onset FA). The common presenting symptoms are ataxia of gait, frequent falls and titubation. However, scoliosis and cardiomyopathy may be present before neurological symptoms. Speech and co-ordination of upper limbs may be normal in the first few years. At an advanced stage there is incoordination in both upper and lower limbs, stance and gait ataxia, truncal titubation, dysarthria, wasting of distal muscles of lower limbs and later upper limbs, hyporeflexia in upper limbs and areflexia in lower limbs, Babinski's sign, normal tone, weakness (greater distally than proximally), and decreased vibration sensation at the ankles. Musculoskeletal abnormalities are common and include kyphoscoliosis and pes cavus. Cardiac involvement occurs in 90% of patients and manifested by hyper-trophic cardiomyopathy, murmurs and conduction defects. Approximately 20% of patients have diabetes mellitus. Nerve conduction studies show presence of axonal sensory neuropathy. Neuroimaging shows presence of cervical cord atrophy without cerebellar atrophy. Patients are usually wheelchair bound by a mean age of 25 years, and the median age of death is 35 years. Women have a significantly better prognosis than men. Genetic testing confirms a clinical diagnosis of FA.

Ataxia Telangiectasia

Ataxia Telangiectasia (AT), also known as Louis-Bar syndrome, is an AR progressive ataxic disorder with onset in early childhood. It is caused by mutations in the single ATM (ataxia telangiectasia mutated) gene located on chromosome 11 (11q22 to 23). The protein product of this ATM gene is a kinase, which is a key regulator of multiple signalling cascades, forms a part of the synaptonemal complex and plays a role in meiotic and mitotic recombination, probably by sensing the double-strand breaks in DNA.

The neurological manifestations of AT include cerebellar ataxia, dysarthria, extrapyramidal manifestations. Ataxia is first manifested when the child learns to walk. As the disease progresses mild polyneuropathy, hyporeflexia, distal muscle wasting can be present. Cognition is usually normal, though later mild cognitive decline can be present. Extraneurological manifestations include oculocutaneous telangiectasias, recurrent sinopulmonary infections, endocrine alterations (absence of secondary sexual characters and type 1 diabetes mellitus), and thymic hypoplasia causing variable immunodeficiency state involving humoral and cellular immune systems. The characteristic telangiectatic lesions appear at the age of 3-5 years and consist of transversely oriented subpapillary venous plexuses most prominent over the outer parts of the bulbar conjunctiva (**Figure 2**). Other cutaneous changes include premature greying of hair, vitiligo, loss of subcutaneous fat, and café-au-lait spots. There is an increased incidence of malignancies, such as lymphomas, acute leukaemias, breast cancer, etc. Laboratory investigations show cerebellar atrophy on neuroimaging, absence or decrease of immunoglobulins such as IgA and IgE, elevated levels of alpha fetoprotein, chromosomal instability especially those of chromosome 7 and 14, abnormal sensitivity to ionizing radiation, and characterisation of mutations in the ATM gene. There is no specific treatment except prevention and control of infections and treatment of malignancies and avoidance of diagnostic tests involving radiation.

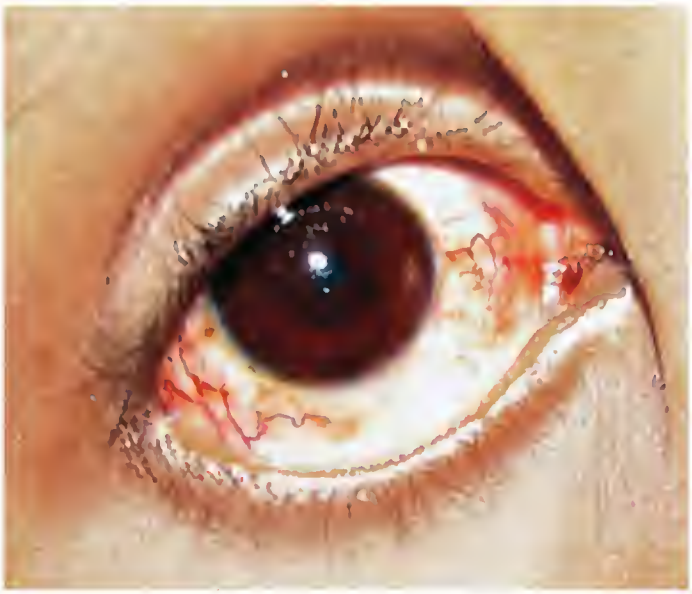

Figure 2: Transversely oriented subpapillary venous plexuses most prominent over the outer parts of the bulbar conjunctiva, in a patient with ataxia telangiectasia.

Other Ataxias

There are other ataxic syndromes associated with DNA repair defects and where either the abnormal gene or locus is known. These are xeroderma pigmentosum (ataxia, choreoathetosis, spasticity, deafness, progressive mental deterioration, skin photosensitivity), Cockayne syndrome (psychomotor retardation, skin photosensitivity, cataract, retinitis pigmentosa, blindness, sensorineural deafness, and ataxia), ataxia telangiectasia-like disorder (ATLD), Nijmegen breakage syndrome (NBS), ataxia with oculomotor apraxia (types 1 and 2), and SCA with axonal neuropathy.

Ataxias Associated with Metabolic Disorders

Progressive or intermittent ataxia is an important feature in several metabolic disorders described below. There are several other rare AR metabolic disorders in which ataxia occurs as a minor feature. The progressive metabolic ataxia of importance are briefly discussed below.

Ataxia with isolated vitamin E deficiency (AVED)

Vitamin E or its major active form-α-tocopherol, is a major liposoluble antioxidant molecule in the body. Vitamin E deficiency results in reduced protection against oxidative stress caused by free radical toxicity, leading to neurological dysfunction manifested by ataxia and neuropathy. In ataxia with isolated AVED, the only abnormality is very low vitamin E level. This is a genetically determined disorder (AR) resulting from mutation in the α-tocopherol transfer protein (α-TTP) gene on chromosome 8q13. The mutated α-TTP gene causes an inability to incorporate a-tocopherol into lipoproteins for transport to various tissues. The onset of symptoms range from 2 to 52 years. The main clinical manifestations of AVED are progressive sensory and cerebellar ataxia. Other findings include dysarthria, areflexia and loss of vibration and position sensations in the lower limbs, bilateral Babinski's sign, scoliosis and pes cavus. Cardiomyopathy is the most common systemic finding but is probably less common than in FA. Moreover, patients with AVED have more head titubation, less neuropathy and a slower course of disease than patients with FA. Electrophysiological studies show axonal sensory neuropathy and MRI may show mild cerebellar atrophy. Laboratory tests reveal low level of vitamin E and diagnosis is confirmed by genetic analysis. In AVED, therapeutic doses of vitamin E should be initiated at the earliest. The treatment can result in cessation of progression of neurological symptoms and signs and amelioration of established neurological abnormalities.

Cerebrotendinous xanthomatosis

Cerebrotendinous xanthomatosis (CTX) is an AR lipid storage disorder with predominant accumulation of cholestanol and cholesterol in almost every tissue of the body. Extraneurological manifestations begin in childhood and include bilateral cataracts, chronic diarrhoea, and tendon xanthomas found in achilles tendon and over the extensor tendons of fingers, toes, on the tibial tuberosities and in the triceps. Neurological manifestations, which generally start around 20 years of age, may include progressive mental retardation, presenile dementia, behavioural changes, convulsions, pyramidal or extrapyramidal signs, cerebellar signs specifically ataxia and dysarthria, sensorimotor peripheral neuropathy, and bulbar palsy with dysphagia. Diagnostic tests include measuring cholestanol in serum, elevated cholesterol/cholestanol in the tissues. Neuroimaging studies show cerebral, cerebellar and cervical cord atrophy, cerebral and cerebellar white matter hypodensities. Management includes early diagnosis and treatment with chenodeoxycholic acid to lower the cholesterol levels.

Refsum's disease

Refsum's disease or heredopathia atactica polyneuritiformis, an AR disorder, has characteristic clinical and biochemical features. In most patients, there is mutation of the gene for the peroxisomal enzyme phytanoyl CoA hydroxylase, *PHYH*, on chromosome 10 resulting in disturbed peroxisomal function and phytanic acid storage. There is accumulation of phytanic acid in serum and tissues. In addition there is impaired calcium homeostasis and mitochondrial dysfunction. The onset of symptoms is between 10 and 20 years, characterised by retinitis pigmentosa resulting in night blindness, restricted peripheral vision and often blindness. Anosmia and sensorineural deafness are also initial symptoms. At a later stage patient develops ataxia that results from neuropathy, cerebellar and motor involvements. Neuropathy, which first manifests in lower limbs, initially involves propioception and later other modalities. There is diminution and later loss of knee and ankle reflexes. Thickening of nerves and wasting and weakness may be present in severe disease. In stressful conditions, such as rapid weight loss or illness, there can be mobilisation of phytanic acid from fat stores which can lead to acute worsening of symptoms. Extraneurological manifestations include ichthyosis, cardiac involvement, nephropathy and skeletal abnormalities (such as pes cavus, shortening of terminal phalanges of thumb, symmetrical short fourth metatarsals and over-riding of toes). The course of the disease is progressive, often with exacerbations and remissions of symptoms. Laboratory investigations show elevated levels of serum phytanic acid, demyelinating type of neuropathy on electrophysiological tests, elevated CSF protein and elevated levels of creatine kinase in some patients. Management strategies include dietary restriction of food containing high content of phytanic acid such as, fish and milk products. In acutely ill states, where there is sudden increase of serum phytanic acid, plasmapheresis has been reported to be beneficial.

Abetalipoproteinaemia

This is a rare AR disorder initially described by Bassen and Kornzweig in 1950. There is mutation in the gene for the large subunit of microsomal triglyceride transfer protein located on chromosome 4q22 to 24. This gene functions in the assembly of apolipoprotein-B containing very low-density lipoproteins and chylomicrons. This leads to intestinal malabsorption of lipids and all fat soluble vitamins. Vitamin E deficiency may be a pathogenic factor in producing the neurological manifestations. The initial symptoms start in infancy or early childhood with inability to thrive and chronic diarrhoea resulting from malabsorption of fat. The neurological symptoms occur later (6 to 12 years of age), characterised by weakness of limbs and ataxia. The ataxia is initially a result of sensory neuropathy, and later cerebellar component is added. Loss of night vision and hyporeflexia may be early manifestations, and at a later stage there is progressive diminution of vision resulting from retinal degeneration (retinitis pigmentosa). Muscle contractures are common, and in some cases Babinski's sign and mental retardation have been reported to be present. The laboratory findings include acanthocytes in peripheral blood smear (>50% of erythrocytes in a fresh smear), low erythrocyte sedimentation rate, marked reduction of serum low-density lipoprotein, cholesterol (<70 mg/dL) and very low density lipoprotein, and low levels of vitamin E. Pathologic studies reveal foamy vacuolated epithelial cells in intestinal mucosa. Treatment with large doses of vitamin E can prevent progression of neurological dysfunction. Concomitant administration of vitamin A is recommended.

Familial hypolipoproteinaemia

Familial hypolipoproteinaemia is an AD disorder characterised by hypocholesterolaemia, acanthocytes in peripheral blood smear, retinitis pigmentosa, and pallidal atrophy (HARP syndrome). Most patients are asymptomatic. Treatment includes vitamin E supplementation and restriction of dietary fat.

ATAXIA IN MITOCHONDRIAL DISORDERS

Mitochondrial disorders result from mutations in the mitochondrial genome or mutations of the nuclear genes that code for a component of the mitochondrion. Accordingly they are transmitted exclusively by maternal inheritance (maternal genome) or by Mendelian inheritance (nuclear genome). The disorders are sometimes referred to as mitochondrial encephalomyopathies due to frequent involvement of brain and muscle tissues. The syndromes often have elevated lactate or lactate-to-pyruvate ratio in the blood and CSF due to respiratory chain abnormalities. In disorders with muscle involvement 'ragged-red' muscle fibres can be seen on Gomori trichrome stains in sections of frozen muscle. The common syndromes which can have ataxia as one of the prominent manifestations are Kearns-Sayre syndrome (KSS), myoclonic epilepsy with ragged red fibres (MERRF), mitochondrial encephalomyopathy, lactic acidosis, with stroke-like episodes (MELAS), subacute necrotising encephalomyelopathy (Leigh's disease), and the syndrome of neuropathy, ataxia, retinitis pigmentosa (NARP).

NON-HEREDITARY ATAXIAS

Idiopathic Late Onset Degenerative Cerebellar Ataxia

Idiopathic cerebellar ataxia of adult onset is characterised by progressive cerebellar ataxia without evidence of a focal or non-focal symptomatic cause of the disorder, absence of any neurodegenerative disorders in the relatives and no history of consanguinity of parents. Some of these disorders remain as pure cerebellar disorders, do not fit the criteria of multiple system atrophy (see below) and investigations rule out any secondary causes (as discussed below).

Multiple System Atrophy

Multiple system atrophy (MSA) is a sporadic disorder characterised by varying degrees of cerebellar ataxia, parkinsonism, signs of corticospinal involvement and autonomic failure. The onset of symptoms is usually in the around 50 years and the median survival is 6 to 9 years. According to the predominant clinical manifestations, MSA is subgrouped into three broad phenotypes: (i) striatonigral degeneration (SND), (ii) OPCA, and (iii) progressive autonomic failure (PAF). However, at a later stage of the disease, there may be overlap of symptoms.

Symptomatic Ataxias

This group includes progressive symmetrical cerebellar ataxia with evidence of non-focal symptomatic origin (**Table 5**) and focal cerebellar ataxias with focal or multifocal cerebellar lesions (**Table 6**).

Symptomatic symmetrical (non-focal)

Ataxias due to drugs and toxins: Acute and reversible ataxias include those caused by acute alcohol intoxication, and exposure to several drugs and toxins described below. Chronic exposure over years may lead to irreversible cerebellar damage. Cerebellar degeneration resulting from chronic

Table 5: Symptomatic Ataxias: Symmetrical

Acute syndrome (hours to days)
- Infections (para-or post-infectious):
  - Acute viral cerebellitis (chickenpox, coxsackie, enteroviral, etc.)
  - Slow viral infections
  - Falciparum malaria
  - Enteric fever
  - Post vaccinial
- Toxic
  - Acute alcoholic intoxication
  - Overdosage of drugs such as phenytoin, lithium, barbiturates, etc.
- Hyperthermia (e.g. hyperpyrexia, neuroleptic malignant syndrome, heat stroke, etc.)
- Hypoxia

Subacute syndrome (days to weeks)
- Toxic
  - Alcohol
  - Drugs (e.g. phenytoin, lithium, chemotherapeutic) agents
  - Heavy metals, solvents, organochlorine compounds, etc.
- Nutritional/alcohol as a result of deficiencies of vitamins B1, B12, E.
- Metabolic/endocrinal
  - Hypoglycaemia
  - Hepatic encephalopathy
  - Hyponatraemia
- Paraneoplastic

Chronic syndrome (months to years)
- Drugs such as anticonvulsants (especially phenytoin) and lithium
- Paraneoplastic
- Anti-gliadin antibody syndrome
- Hypothyroidism
- Associated with antibodies to glutamic acid decarboxylase (GAD)
- Ataxia due to acquired vitamin E deficiency

Table 6: Symptomatic Ataxias: Focal, Unilateral or Asymmetric Bilateral

Acute syndrome (hours to days)
- Vascular
  - Infarction
  - Haemorrhage
- Infections
  - Cerebellar abscess

Subacute syndrome (days to weeks)
- Neoplastic
  - Cerebellar gliomas
  - Metastatic
- Demyelination
- Infections
  - Granulomas, e.g. tuberculomas, neurocysticercosis
- Multifocal leucoencephalopathy

Chronic syndrome (months to years)
- Stable gliosis secondary to causes mentioned in (A) and (B) above
- Congenital lesions such as Arnold-Chiari or Dandy-Walker malformations

alcoholism is probably the commonest form of chronic cerebellar ataxia.

Several drugs and toxins predominantly affects the cerebellum, and include phenytoin, barbiturates, carbamazepine, lithium, cytosine arabinoside, and 5-fluorouracil, exposure to methylmercury and bismuth, toluene, carbon tetrachloride, thallium, gasoline sniffing, glue sniffing, spray painting, organochlorine compounds, etc. Phenytoin, unlike other anti-epileptic drugs, can cause permanent cerebellar damage.

Hypoxia, ischaemia, hyperthermia and trauma: Purkinje cells of the cerebellum are highly vulnerable to deleterious effects of hypoxia, ischaemia and hyperthermia. In survivors of hypoxic insults there may be cerebellar signs along with prominent extrapyramidal manifestations. Often the cerebellar signs may be overshadowed by generalised cerebral dysfunction associated with the hypoxic states. Hyperthermia associated with heat strokes, neuroleptic malignant syndrome and even transient hyperpyrexia due to infections can lead to cerebellar damage.

Nutritional, metabolic and endocrine causes: Deficiencies of vitamin B1, B12 and E may result in cerebellar ataxias. Wernicke's encephalopathy caused by thiamine deficiency affects oculomotor and cognitive systems as well as cerebellum. The most common cause of thiamine deficiency is alcohol abuse. Gaze paresis, nystagmus, papillary dysfunction, dysautonomia, confusion and varying degree of altered sensorium, severe stance and gait ataxia characterise the syndrome. There may be seizures, hypotension and hypothermia. Vitamin B12 deficiency causes the classic syndrome of subacute combined degeneration of cord, but may rarely present with cerebellar ataxia. Vitamin E deficiency can lead to a progressive spinocerebellar syndrome with peripheral neuropathy and retinal degeneration.

Among the endocrine causes, hypothyroidism is the most important disorder associated with chronic cerebellar ataxia. Ataxia may be the only sign. All cases of sporadic ataxia should be screened for hypothyroidism. Replacement of thyroid hormone results in a striking therapeutic effect even after several years of cerebellar dysfunction.

Paraneoplastic syndromes: Paraneoplastic cerebellar degeneration (PCD) occurs as a result of remote effects of systemic cancer, and is probably an immune mediated disorder. Features include dizziness, nausea, blurry or double vision, sometimes associated with oscillopsia, instability of gait, variable degree of ataxia of upper and lower limbs, dysarthria and dysphagia. A flu-like illness may precede these symptoms. Tumours most frequently associated with PCD are cancer of lung, ovary, breast and Hodgkin's lymphoma, small-cell lung cancer being the most frequent. Treatment of PCD is usually unsatisfactory. Rarely patients may respond to plasma exchange, intravenous immunoglobulins or steroids if given early.

Infections of cerebellum: Disorders of cerebellum could be related to neuroinfections either directly, which usually cause focal signs described below, or by immune-mediated mechanisms.

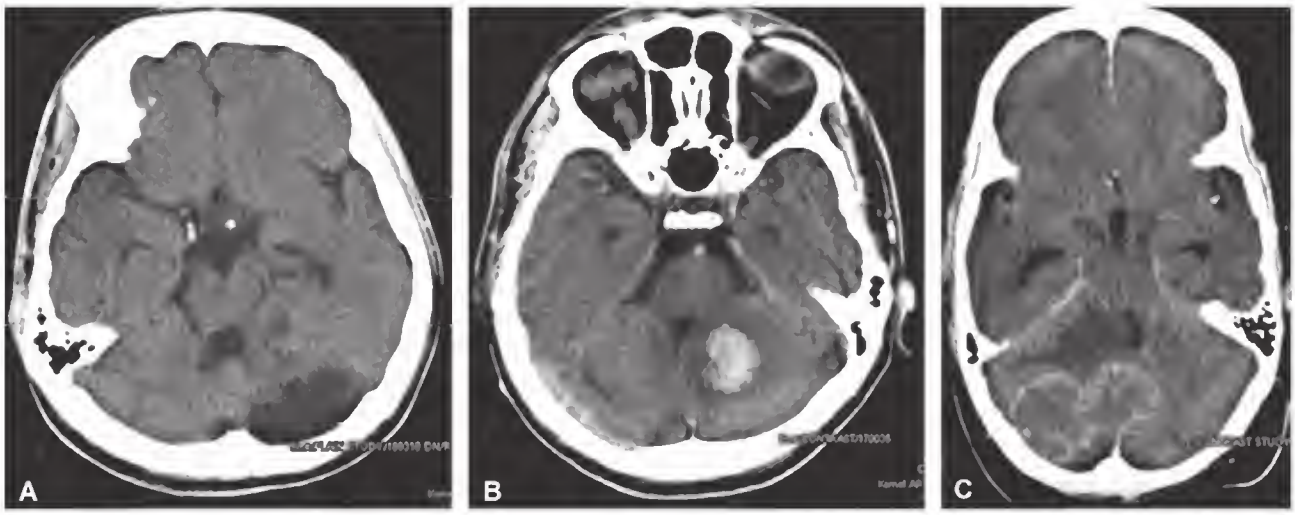
In immune-mediated injuries, there is diffuse cerebellar involvement. The majority of the acute ataxias in childhood, related to infections are associated with chickenpox. Other infections associated with acute or subacute 'meningo-cerebellitis' include infections due to enterovirus (Coxsackie), Epstein-Barr virus (EBV), cytomegalovirus (CMV), and measles. A similar syndrome can occur after vaccinations, and can be associated with enteric fever, and falciparum malaria. In enteric fever, ataxia usually appears in the second week of illness, may have other neurological manifestations, and is usually self-limited. Acute ataxic syndrome associated with falciparum malaria may be rarely a presenting manifestation or more commonly an ataxic syndrome occur 3 to 4 weeks after the illness. There is progression up to 2 weeks usually followed by a complete recovery.

Subacute or chronic cerebellar ataxia related to infections has been reported with slow viral infections or prion diseases, such as chronic progressive rubella panencephalopathy of children, Creutzfeld Jakob disease (CJD), and the new variant CJD, i.e. bovine spongiform encephalopathy (BSE). Meningovascular syphilis and tabes dorsalis can cause chronic ataxia due to degeneration of the posterior column and spinocerebellar pathways in the spinal cord.

Focal cerebellar ataxias

A large number of disorders (**Table 6**) can cause focal unilateral ataxia or asymmetric bilateral ataxia due to involvement of only one cerebellar hemisphere or asymmetrically of both hemispheres with or without the vermis (**Figures 3A to C**). According to the nature of lesion, the onset of ataxia may be acute or subacute, and the deficit may be maximum at the onset or progress.

CEREBELLAR ATAXIAS DUE TO CONGENITAL ANOMALIES AND MALFORMATIONS



There are well-recognised intrauterine insults (radiation, certain drugs, viral infections, ischaemia) and many chromosomal and genetic disorders which affect the cerebellar growth and development, resulting in syndromes of nonprogressive cerebellar hypoplasias, often improving with age.

The important soft tissue abnormalities include syndromes resulting from agenesis or dysgenesis of vermis and that of midline malformation. The important syndromes with midline malformation include Dandy-Walker malformation and Arnold-Chiari malformations, which are mostly sporadic. These may be associated with bony (craniovertebral) malformations (basilar invagination/impression and atlantoaxial dislocation) and vascular malformations (arteriovenous malformations and aneurysms) of the posterior cranial fossa.

The bony and soft tissue abnormalities of the posterior cranial fossa, foramen magnum and upper cervical cord are often referred to as craniovertebral junction anomalies. Patients may present with adult onset sporadic ataxia.

Arnold-Chiari Malformations

In *Type I*, there is protrusion of cerebellar tonsils through the foramen magnum into the upper cervical spinal canal. It is sometimes associated with basilar impression where there is upward displacement of the foramen magnum an occipital bony floor, resulting in a small posterior fossa. Syringomyelia of upper cervical cord, or sometimes syringobulbia can be associated with *Type I* Arnold-Chiari malformation (**Figure 4**). The symptoms include a progressive cerebellar ataxia, headache due to increased intra-cranial pressure, progressive spastic quad-riparesis, downbeating nystagmus, and signs of cervical syringomyelia

Figures 3A to C: CT scan of patients with unilateral cerebellar ataxia resulting from (A) infarction, (B) haemorrhage, and (C) granulomas (tuberculoma).

(dissociated sensory loss), and lower cranial nerve palsies. In *Type II* Arnold-Chiari malformation there is downward displacement of medulla oblongata, inferior vermis and tonsils that impinge on the foramen magnum causing hydrocephalus. Associated lumbar meningomyelocele is common. In *Type III* Arnold-Chiari malformation, there is midline bony defect with displacement of cerebellar and brainstem tissue into an infratentorial meningoencephalocele. *Type IV* Arnold-Chiari malformation is uncommon and is characterised by cerebellar hypoplasia.

Dandy-Walker Malformations

In this syndrome there is failure of development of the midline portion of the cerebellum and partial or complete agenesis of the vermis. These result in a large posterior fossa cyst as a result of the dilatation of the posterior half of the fourth ventricle. The cyst causes significant obstructive hydrocephalus.

MANAGEMENT

There is no specific drug that has been scientifically documented to improve cerebellar functions. For episodic ataxias 1 and 2, carbonic anhydrase inhibitors such as sulthiame and acetazolamide (Diamox), and anti-epileptic drugs, such as, carbamazepine and phenytoin have been used to prevent attacks. In ataxias with predominant extrapyramidal manifestations, such as SCA3/MJD, dopaminomimetic drugs have been used. Other drugs reported to provide some symptomatic benefit in ataxias, include propranolol, amantadine, buspirone, 5-hydroxytryptophan, topiramate, zolpidem, and coenzyme Q_{10}. Uncontrolled open label studies using a combination of coenzyme Q_{10} and vitamin E have shown improvement of cardiac function and possible stabilisation of neurological symptoms in FA, and low-dose idebenone (a synthetic analogue of coenzyme Q_{10}) probably reduces cardiac hypertrophy without improvement of neurological functions. Metabolic ataxias and other symptomatic ataxias should be managed according to the primary cause.

The mainstay of treatment for progressive cerebellar ataxia is balance training and regular balance exercises to increase the performance of the remaining functioning cerebellar neurons. In FA, management of kyphoscoliosis, exercises to improve respiratory muscle strength and early detection and therapy of cardiac abnormalities are important.

Figure 4: T1 weighted MRI showing Arnold-Chiari malformation Type I with syringomyelia. There is caudal displacement of cerebellar tonsils into the cervical canal.

20.22 Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases

BK Bajaj

INTRODUCTION

Motor neurons are the neurons through which the brain exerts control over skeletal muscles of the body. They are classified into upper and lower motor neurons. The upper motor neurons (UMN) are the motor neurons which have their cell bodies in the cerebral cortex and which form the corticobulbar and corticospinal tracts. These neurons exert direct or indirect control over the lower motor neurons. Lower motor neurons (LMN) are the motor neurons which directly innervate skeletal muscles and which have their cell bodies in the brainstem or spinal cord. The term 'motor neuron disease' (MND) was first coined by Lord Russell Brain in 1969 to refer to the specific disorder of both the upper and the lower motor neurons. The term 'amyotrophic lateral sclerosis' (ALS) has been in vogue for the same presentation since the first descriptions of the disorder by Jean Martin Charcot in the 19th century. It is important to differentiate the terms MND and ALS from the 'motor neuron disorders or diseases' which is used for a heterogeneous group of diseases or disorders of neurons of varied aetiology having in common the involvement of upper and/or lower motor neuron systems (**Table 1**).

AMYOTROPHIC LATERAL SCLEROSIS (ALS)

Amyotrophic lateral sclerosis is a progressive neurodegenerative disorder of undetermined aetiology characterised by progressive motor paralysis due to degeneration of primarily the motor neuron (UMN and LMN) population in the motor cortex, brainstem and spinal cord. The term 'amyotrophy' refers to atrophy of muscle fibres consequent to denervation of muscles due to anterior horn cell degeneration and 'lateral sclerosis' refers to sclerosis or hardening of anterior and lateral corticospinal tracts which are replaced by progressive gliosis. The celebrated neurologist of the 19th century, Jean Martin Charcot is credited with the first detailed descriptions of the disorder 'la sclérose latérale amyotrophique' which affects both the lower motor neurons and upper motor neurons. ALS is also known as Lou Gehrig's disease after the name of the famous baseball player of the United States, Lou Gehrig, who was diagnosed with the disease at the peak of his career in the 1930's. When there is presence of both the upper and the lower motor neuron features at presentation, this is referred to as classic or Spinal or Charcot's ALS. Modern clinical practice recognises the existence of several variants or syndromes related to the spectrum of presentation of ALS including primary lateral sclerosis (PLS), progressive bulbar palsy (PBP), progressive muscular atrophy (PMA), flail arm syndrome (Vulpian-Bernhardt syndrome), flail leg syndrome (Pseudopolyneuritic form) and ALS with multisystem involvement (**Table 2**). The underlying common molecular and cellular pathology of all these syndromes, along with characteristic ubiquitin-immunoreactive (Ub-IR) and TAR DNA binding protein-43 (TDP-43) reactive intraneuronal inclusions, are considered the unifying characteristics of these disorders. Other motor neuron diseases like spinal muscular atrophy, bulbospinal atrophy have molecular pathology distinct from ALS and, while being motor neuron disorders, are not included as ALS or MND.

This is pertinent to note that the terms 'motor neuron disorders' or 'motor neuron diseases' include inflammatory and immune disorders, sporadic and familial disorders and disorders of undetermined cause. ALS or MND is one of the motor neuron diseases or disorders.

Table 1: Classification of Motor Neuron Disorders

- **Upper motor neuron disorders**
  - Neurodegenerative disorders
    - Primary lateral sclerosis
  - Toxins
    - Neurolathyrism
    - Konzo
  - Infection related/Immune mediated
    - HTLV-1 associated myelopathy
    - HTLV-2 associated myelopathy
  - Inherited disorders
    - Hereditary spastic paraparesis
    - Adrenomyeloneuropathy
- **Lower motor neuron disorders**
  - Neurodegenerative disorders
    - Progressive muscular atrophy
    - Benign focal amyotrophy/brachial monomelic amyotrophy/hirayama disease
  - Infections/immune mediated
    - Poliomyelitis
    - Post-polio syndrome
    - Subacute motor neuronopathy in lymphoproliferative disorders
  - Inherited disorders
    - Spinal muscular atrophy
    - X-linked bulbospinal neuronopathy (Kennedy)
    - Heredity bulbar palsy with deafness (Brown-Vialetto-van Laere)
    - Hereditary bulbar palsy without deafness (Fazio-Londe)
    - Hexosaminidase deficiency
  - Physical agents/toxins
    - Postirradiation lower motor neuron disease
- **Upper and lower motor neuron disorders**
  - Amyotrophic lateral sclerosis
    - Sporadic ALS
    - Familial ALS

Progressive muscular atrophy*
Juvenile ALS
Western Pacific ALS†
Madras variant MND†

**Nat included in El Escarial Criteria for ALS.*
†These have features in additian ta UMN & LMN invalvement and as yet not strictly considered ta be presentatian af ALS.

EPIDEMIOLOGY

The incidence and prevalence of ALS are fairly uniformly distributed throughout the world. The classic or spinal ALS has an annual incidence of around 1 to 2.7 per 100,000 population per year and a prevalence of around 2.7 to 7.4 per 100,000 population. In hospital based studies from different regions of India, there are reports that motor neuron disease constitutes around 0.11% of all neurological cases seen in outpatient departments of a tertiary care centre. There is male predominance in sporadic spinal ALS with male to female ratio of 1.2 to 1.5:1. Hospital based studies from India have reported higher male to female ratio of 2:1 to 7:1. These studies included atypical forms of motor neuron disease as well. The male preponderance has been variously attributed to putative protective effects of female hormones, increased likelihood of exposure to possible risk factors in males and under ascertainment of female patients. There are reports of female predominance in bulbar onset variety of ALS. While there are no such reports from India, internationally there is some recent data suggesting that the gender ratios for ALS might be approaching equality. There is notable clustering of cases of ALS in certain regions like Chamorro people of Guam and Kii peninsula of Japan. ALS has a peak age of onset in the sixth and seventh decades with reports of onset as early as in the second decade. Most of the available data suggests earlier onset of ALS in Indian population by one to two decades. The mean age of onset of 46.5 years is reported from NIMHANS, Bengaluru, India. Worldwide, the reported mean duration of disease from symptom onset to death is around 3 years. Around 20% and 10% of patients with ALS (PALS) survive for 5 and 10 years, respectively. Indian studies report longer survival of patients with one study reporting an unusually long median survival of 9.5 years. The younger age of onset is possibly the reason for the longer survival in the Indian population. The younger population with greater neuronal reserve have longer survival.

Sporadic ALS constitutes 90% to 95% of cases and the rest are familial ALS with predominantly autosomal dominant pattern of inheritance. While there are no comprehensive Indian epidemiological studies available, familial ALS is probably rarer in India than in the west. There are reported differences in the pattern of presentation of MND in India, with Madras variant of MND (MMND) being commoner in Southern states of Tamil Nadu, Karnataka, and Andhra Pradesh. MMND was first described by Meenakshisundaram from Madras (now renamed Chennai). This variant of MND has been reported subsequently from Thailand, China and in an Italian of South Indian origin. MMND has younger age of onset with mean age of 15.8 ± 7.9 years and has a few peculiar presenting features. Because of the presence of additional neurological features, MMND is usually not clubbed with ALS. Future research may reveal the exact place of the various presentations in the taxonomy of the motor neuron disease.

AETIOPATHOGENESIS

The aetiology of ALS remains undetermined. The most favoured hypothesis is that it is the result of complex genetic-environmental interactions as the causal factor for motor neuron degeneration. There is insufficient evidence to implicate any of the earlier proposed hypotheses of motor neuron degeneration secondary to viral infections, exogenous toxins, immune activation, and hormonal dysfunctions. The molecular pathway causing motor neuron degeneration is likely a complex interplay of multiple cellular mechanisms including excitotoxicity, oxidative stress, mitochondrial dysfunction, impaired axonal transport, neurofilament aggregation, protein aggregation, and deficits of neurotrophic factors and signalling pathways on a possible background of genetic predisposition. Various proposed ALS susceptibility genes include APOE, SMN, peripherin, vascular endothelial growth factor, and paraoxonase.

ALS Parkinsonism dementia complex (Western Pacific ALS) is a disorder of ALS with a combination of Parkinsonism and Dementia of Alzheimer type. It was described from the Chamorro population of the Western Pacific Island of Guam and subsequently from New Guinea and the Kii peninsula of Japan. Accumulated epidemiological evidence suggests an environmental factor, a toxin in native cycad seed.

In familial ALS (FALS), mutation in Cu-Zn Superoxide mutase (SOD-1) has been reported in 20% of cases. Mutation in ALSIN gene has been recognised in recessively inherited juvenile ALS of North African origin. FALS types 1 to 10 are reported. Of these FALS type - 2 and 5 are autosomal recessive, the rest have autosomal dominant inheritance except that the mutation SOD-1 (Asp90-Ala) leads to autosomal recessive FALS-1 and missense mutation of SOD-1 gene results in autosomal dominant inheritance. X-linked dominant mutation and other rare mutations have also been documented in some families. ALS-frontotemporal dementia has an autosomal dominant pattern of inheritance.

Histopathology

Degeneration and loss of motor neurons with astrocytic gliosis and presence of intraneuronal inclusions, such as Bunina bodies (small eosinophilic, hyaline intra-cytoplasmic inclusions staining positive for cystatin, and transferrin) ubiquitinated inclusions (UBIs) or ubiquitin – immunoreactive inclusions (Ub-IR), and hyaline conglomerate inclusions are observed in patients with ALS. There is relative sparing of motor nucleus of Onufrowicz and oculomotor nuclei. Bunin bodies are present in 70% to 100% of ALS cases and UBIs/Ub-IR inclusions are seen in 95% of patients.

CLINICAL PRESENTATION

About two thirds of patients may have typical or spinal form of ALS and present with focal muscle weakness of distal or proximal upper or lower limbs. There is spread of weakness to contiguous muscles in the same region before another region is involved. Initially there may be involvement of muscles in the apparent distribution of a peripheral nerve, the pseudoneuritic pattern, or one limb may be affected first, the monomelic presentation. Some patients present with weakness in both the distal lower limbs as is seen in a length dependent neuropathy and is called pseudopolyneuritic presentation. Approximately 25% of patients present with bulbar symptoms like dysarthria, dysphonia, and dysphagia. Weakness that is restricted to one side of body, Mills' hemiplegic variant, may sometimes be the presenting pattern of involvement. In one to two per cent of patients, weakness starts in the respiratory group of muscles and they either present with dyspnoea on exertion or the disease is suspected when there is failure to wean a patient off ventilator support for another incidental unrelated condition or situation. Up to 10% of patients

present with bilateral upper limb weakness and wasting, flail arm or flail person in barrel syndrome. Patients may present with bulbar or pseudobulbar presentation (**Table 3**). Head drop may be the initial presentation of the disease in a small minority of patients. Peculiarly, fasciculations are usually not the initial presenting symptom of ALS. However, these are present in almost all patients at presentation. Absence of fasciculation should lead to consideration of other possible diagnoses. Patients with ALS may complain of cramps in unusual muscles such as thighs, abdomen, back or even tongue. In addition to motor symptoms, patients with ALS often have non-motor associated symptoms including sleep disturbance, subtle cognitive dysfunction and mood changes.

Table 3: Salient Features of Pseudobulbar Palsy (Involuntary emotional expression disorder)

Corticobulbar tracts involvement
Spastic dysarthria, dysphonia, dysphagia (usually milder than in bulbar palsy)
Emotional lability (inappropriate or forced crying or laughter)
Brisk jaw jerk
Hyperactive gag reflex

DIAGNOSIS

The diagnosis of ALS can be made by clinical history, examination and electrophysiological assessment. The condition must be differentiated from other 'ALS mimickers' which may present like ALS or one of its variants. It is prudent to do laboratory investigations to rule out other conditions and the extent of such investigation should be guided by clinical history and examination findings. All patients over 50 years of age and those who are smokers should have a chest X-ray to look for neoplastic lesions. Thyroid function tests should be done in patients to exclude hyperthyroidism or thyrotoxicosis which can present with multi-segmental fasciculations with brisk reflexes and weakness. Parathormone dysfunction and hypovitaminosis B12 should be excluded, as dictated by the clinical presentation. Appropriate neuroimaging, like MRI of spine or brain, may be required when there is suspicion of other conditions like cervical spondylotic myelopathy or myeloradiculopathy, craniovertebral junction anomalies, multiple sclerosis, paraneoplastic disorder, and various other suspected cerebral and spinal lesions according to the appropriate clinical setting. Flail arm syndrome may be a presentation of HIV infection. Muscle biopsy is not required for the diagnosis. It may be fruitful to exclude suspected inclusion body myositis in appropriate cases. World Federation of Neurology established diagnostic criteria for ALS at El Escorial, Spain in 1990. These were further modified in 2000 at Airlie House, Virginia, USA. These criteria are known as El Escorial Airlie House criteria for ALS. These criteria, while essential for research on ALS, should only serve as a guide for diagnosis of ALS in day-to-day practice. ALS is divided into definite, probable, laboratory supported definite, and possible ALS based on history and examination findings of 4 regions including bulbar, cervical, thoracic, and lumbosacral. The diagnosis of ALS requires clinical, electrophysiological, or pathological evidence of lower motor neuron degeneration, and clinical evidence of upper motor neuron degeneration with evidence of progressive spread of symptoms and signs within a region or other regions.

Neuroimaging Studies

Role of MRI is in excluding the ALS 'mimickers'. There are reports of signal changes in corticospinal tracts on MRI of PALS. 'Garland sign' and 'Wine-glass sign' have been reported in Indian literature. 'Garland sign' is garland like appearance of T2 hyperintensity in corticospinal tract and corpus callosum as visualised on coronal section images of MRI Brain. 'Wine-glass appearance' is white matter hyperintensity involving corticospinal tracts from internal capsule to brainstem on T2 images in coronal section MRI Brain.

Electrophysiology

Neuroelectrophysiology, including nerve conduction study and electromyography, are invaluable adjuncts for diagnosis of ALS. These are particularly useful in evaluation or documentation of lower motor neuron disease. Nerve conduction study is normal in PALS except for low amplitude of compound muscle action potential (CMAP) which is due to wasting of muscles being recorded. Distal latency and nerve conduction velocity are normal in all patients except when there is associated incidental or consequential neuropathy due to other cause or pressure palsy of a predisposed nerve. Sensory nerve conduction study is also normal in patients. EMG examination reveals increased insertional activity, fibrillations, and positive sharp waves suggestive of active denervation. Chronic denervation and reinnervation is suggested by motor unit potentials of increased amplitude and duration with polyphasia. Fasciculations with abnormal and complex morphology are seen in patients. On electromyography, one may observe 'split hand' phenomenon wherein there are severe changes in the lateral hand or thenar eminence and the medial part or hypothenar eminence is relatively spared. Electrodiagnosis should be carried out in at least 3 of the 4 regions of neuraxis, i.e bulbar, cervical, thoracic, and lumbosacral.

Motor unit number estimation (MUNE) may be helpful in quantitative assessment of progressive motor axon loss and is a useful endpoint for clinical trials. Transcranial magnetic stimulation to measure central motor conduction can help document upper motor neuron involvement (involvement of corticospinal tracts), but is not routinely required.

MANAGEMENT

While there is no cure available for ALS, there have been considerable advances in the management of PALS. The goal of therapy at present remains improvement in the quality of life of patients. To achieve this goal multidisciplinary care comprising of a neurologist, physician, rehabilitation specialist, and paramedics is required. The patient with ALS should be appropriately disclosed the diagnosis and options available should be discussed. Repeated meetings may be required to make the patient and his relatives fully comprehend the problems and possible choices. Issues relating to end of life care, nutritional, and respiratory management should be discussed with patient and relatives at the earliest possible.

Disease modifying agents/specific therapy

Riluzole is the first specific drug approved for use in ALS. It results in modest effect on survival of PALS. Cochrane meta-analysis of controlled riluzole trials have shown that the drug results in 9% increment in probability of survival for one year. It probably prolongs the survival by 2 to 3 months, when taken for 18

months in clinically probable or definite ALS, with symptoms for less than 5 years, FVC more than 60% and age less than 75 years. The uncommon side effects of the drug include fatigue, gastrointestinal upset, deranged liver function tests, and dizziness. Liver function tests should be regularly monitored during therapy. The recommended dosage of Riluzole is 50 mg once a day for two weeks, followed by 50 mg twice daily.

There are more than 100 neuroprotective agents, besides riluzole, which have been studied in animal models and humans. Subcutaneous recombinant human insulin-like growth factor, glial cell line derived neurotrophic factor, ciliary neurotrophic factor, oral xaliproden, minocycline, ceftriaxone, Coenzyme Q-10, Vitamin E, celecoxib, L-deprenyl, N-acetylcysteine, calcium channel blockers, and various other agents have been tried and found not to be significantly effective. There is a currently ongoing trial on the role of memantine in PALS.

Gene therapy approach to deliver neurotrophic factors directly to neurons, using genetically engineered adeno-associated viruses expressing neurotrophic factors, have been used in SOD-1 mouse models. No such studies have taken place for humans. Autologous stem cell transplantation is still in experimental state and cannot be applied as a practice as yet.

Supportive care

While there is no specific curative therapy available for ALS, this must not mean denial of the available advanced supportive measures to improve quality of life of patients and a dignified living. Nutritional support, respiratory support, prevention of aspiration, management of speech, treatment of spasticity, pain, cramps, constipation, insomnia, and depression with appropriate pharmacotherapy and non-pharmacological measures must be given to all the patients.

Nutrition management

Oral intake of PALS progressively declines and, dysphagia and aspiration are dangerous imminent realities. History of choking, weight loss and total daily intake should be checked in all the patients. Initially, changes in the form and texture of food items and use of high calorie supplement are adequate for proper nutrition. Eventually enteral feeding, percutaneous endoscopic gastrostomy (PEG), percutaneous radiologic gastrostomy (PRG), and in some cases Percutaneous Jejunostomy has to be done in order to maintain proper nutrition. PEG is the standard procedure for PALS. It is advisable to consider this before FVC drops to less than 50%. PRG is better and safer in those with FVC less than 50%. It is important to note that aspiration is a continued risk for patients on PEG. When aspiration becomes problematic, percutaneous jejunostomy should be done.

Management of speech and communication

Problems in communication are an important hindrance in patients' daily living and often a source of great frustration for both the patient and family members. Speech therapist referral should be done early in the course to maintain independent communication as long as possible. Various communication devices including alphabet boards, picture boards, and voice synthesizers can be used for improved communication.

Respiratory management

All PALS eventually develop respiratory failure and require ventilator support. Dyspnoea on exertion or talking, orthopnoea, excessive day time somnolence, headaches and confusion may all indicate respiratory failure. Clinical signs including tachypnoea, prominent use of accessory muscles of respiration, paradoxical breathing and weak cough are evident in these patients. Forced vital capacity (FVC), sniff nasal inspiratory pressure (SNIP) and overnight pulse oxymetry are helpful in deciding about their management. FVC of less than 50%, SNIP value less than 32% is highly predictive of respiratory failure. Such patients are usually provided with non invasive ventilation. Bilevel positive airway pressure (BIPAP) ventilation improves symptoms and prolongs the survival. BIPAP does not prolong the life indefinitely; decision about invasive ventilation has to be made at some point of time.

Other symptomatic treatments

Treatment of symptoms like spasticity (with Baclofen/ Tizanidine), cramps (with vitamin B-complex, calcium channel blockers, levetiracetam), sialorrhoea (anticholinergics, tricyclic anti-depressants), depression (selective serotonin reuptake inhibitors/tricyclic anti-depressants) and fatigue with appropriate pharmacotherapy and physiotherapy should be offered to all the patients.

PROGRESSIVE MUSCULAR ATROPHY

This motor neuron disorder is not included in the El Escorial Criteria for ALS. However, for practical purposes, it is appropriate to consider the LMN syndrome, PMA at one end of the spectrum of ALS and the UMN syndrome, PLS at the other (**Tables 4 and 5**). The disorder comprises 8% of all adult onset motor neuron diseases. Most authors agree that one cannot conclude that PMA presentation will not progress to ALS subsequently until after 4 years after onset. Laboratory testing reveals raised creatine kinase (CK) levels to less than 10 times the normal. Exclusion of other diagnostic possibilities such as chronic inflammatory demyelinating polyradiculopathy, multifocal motor neuropathy with conduction block (MMNCB) and a myopathy should be done before concluding PMA. Treatment of PMA is similar to that of ALS.

Table 4: Salient Features of Progressive Muscular Atrophy

Age of onset earlier than ALS by a decade
LMN involvement during entire course
Diagnosis not made until 3 to 4 years (lest UMN signs appear)
Focal asymmetric weakness in distal extremities with gradual spread
Bulbar and respiratory involvement eventually develops in later stages
Better 5 year survival than ALS (2/3rd survive beyond 5 years)

Table 5: Reasons for Considering PMA as a Variant of ALS Representing One End of Spectrum (PMA is not recognised as a variant of ALS as per El Escorial Criteria)

Motor conduction studies may reveal corticospinal tract involvement (2/3rd of patients in one series)
PMA presentation in some cases of FALS described
Pyramidal tract pathology seen in sporadic PMA
Subset of PMA presentation progress rapidly, like ALS

PRIMARY LATERAL SCLEROSIS

PLS accounts for 2% to 4% of all ALS cases and is conventionally distinguished from ALS by the absence of LMN involvement.

The salient features of the condition are mentioned in **Table 6**. Other features like fasciculations, cramps, bladder dysfunction, cognitive deficits, and abnormal voluntary eye movements have all been observed, rarely, in this group of patients. Median disease duration is 19 years and survival of 6 years to 40 years has been reported in two separate series. Pathological changes include a striking loss of Betz cells in layer 5 of frontal and prefrontal cortex with laminar gliosis of layers 3 and 5 and degeneration of corticospinal tracts. The disease is diagnosed by exclusion of other conditions like Hereditary Spastic Paraparesis, HTLV-1 Associated Myelopathy, Hex-A deficiency, multiple sclerosis and high cervical region compressive myelopathy.

Table 6: Salient Features of Primary Lateral Sclerosis

Diagnosis of exclusion
Onset: a decade earlier than ALS (Early 50s')
UMN involvement during entire course
Diagnosis not confirmed until 4 years after onset
Slowly evolving spastic paraparesis later involving upper limbs
Median disease duration:19 years
Reports of development of LMN signs in some as late as 27 years after onset. Diagnosis needs to be revised to ALS in such cases

MADRAS VARIANT MND

This variant of MND has been reported from Southern India. Majority of reported cases are sporadic and a few familial cases have been documented by a study from NIMHANS, Bengaluru. The pattern of inheritance in Familial MMND appears to be mostly autosomal recessive with a case of autosomal dominant pattern reported in Indian literature.

Salient features of MMND are given in (**Table 7**). The Madras Motor Neuron Disease can be classified as sporadic MMND, sporadic MMND variant, Familial MMND and Familial MMND variant. Clinical and audiological evidence of sensorineural impairment is an important criterion for diagnosing MMND. The MMND variant has evidence of optic atrophy, in addition to the features common for MMND. A few cases with mild cerebellar signs, principally mild gait ataxia, are seen. Features in MMND are like ALS except very young onset, facial palsy and deafness. These are the reasons that the entity is not clubbed with ALS.

Table 7: Salient Features of Madras Variant MND

Younger age of onset (1st and 2nd decade)
Wasting and weakness of predominantly distal muscles of limbs
Bulbar dysfunction (predominantly IX to XII cranial nerve nuclei) and facial muscle involvement
Pyramidal dysfunction
Sensorineural hearing impairment
Optic atrophy in small group of patients (when present, called Madras MND variant)

JUVENILE ALS

This is another young onset motor neuron disorder presenting in less than 25 years of age with UMN and LMN symptoms and signs. This is different from MMND as patients often develop additional neurological features like choreic movements, cerebellar ataxia, and mental retardation in the absence of deafness. The patients do not have bulbar manifestations till late in the course of disease.

POSTPOLIO SYNDROME

The patients who suffer poliomyelitis, after a prolonged period of relative stability, may develop new disabilities affecting activities of daily living. Patients develop progressive muscular atrophy, weakness, pain, and fatigue. This is called postpolio syndrome.

The prevalence of postpolio syndrome has been variously reported as 20% to 85% of people who were earlier afflicted with acute poliomyelitis. The wide variation is possibly due to different diagnostic criteria used.

Diagnosis of postpolio syndrome is of exclusion. The triad of fatigue, weakness, and pain are the most common manifestation. Cold intolerance, dysphagia, muscle twitching and cramps, respiratory distress, and voice changes are the other symptoms. The diagnosis is supported by electromyography which demonstrates longstanding neurogenic changes. Macro EMG can help in precise quantification of motor units and their size.

Symptomatic treatment of fatigue, underlying depression, and use of analgesics for pain are important aspect of management. Surgery for correction of joint deformities, arthosis, and limb length inequality can help. Orthopaedic braces and assistive devices, as per individual patient needs, should be provided. Lifestyle management including weight management, avoidance of over exertion and group therapy may improve the symptoms.

Intravenous immunoglobulins have been tried with some success in individual patients, and small open-label studies. Lamotrigine has been reported as promising for pain, fatigue, and improvement of quality of life.

20.23 Demyelinating Diseases of Nervous System

Man Mohan Mehndiratta, Rohit Kumar Garg

Demyelinating diseases comprise of diseases of central and peripheral nervous system in which disruption of myelin is a dominant feature. Diseases affecting central nervous system (CNS) myelin can be classified on the basis of whether a primary biochemical abnormality of myelin exists (dysmyelinating) or whether some other process damages the myelin or oligodendroglial cells (demyelinating). Demyelinating diseases include autoimmune, infectious, toxic, metabolic, and vascular processes; dysmyelinating diseases in which a primary abnormality of the formation of myelin exists include several hereditary disorders (**Table 1**). The present chapter concentrates on inflammatory demyelinating diseases of central and peripheral nervous system that are presumably immune-mediated.

Table 1: Diseases of Myelin

Central nervous system
- Autoimmune
  - Acute disseminated encephalomyelitis (ADEM)
  - Acute haemorrhagic leucoencephalopathy (AHLE)
  - Multiple sclerosis (MS)
- Infectious
  - Progressive multifocal leucoencephalopathy (PML)
- Toxic/metabolic
  - Carbon monoxide
  - Vitamin B12 deficiency
  - Mercury intoxication
  - Alcohol/tobacco amblyopia
  - Central pontine myelinolysis
  - Marchiafava-Bignami syndrome
  - Hypoxia
  - Radiation

Vascular
- Binswanger's disease

Hereditary disorders of myelin metabolism (dysmyelinating)
- Adrenoleucodystrophy
- Metachromatic leucodystrophy
- Krabbe's disease
- Alexander's disease
- Canavan-van Bogaert-Bertrand disease
- Pelizaeus-Merzbacher disease
- Phenylketonuria (PKU)

Peripheral nervous system
- Acute inflammatory demyelinating neuropathy (AIDP)
- Chronic inflammatory demyelinating neuropathy (CIDP)
- Multifocal motor neuropathy (MMN)

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

ADEM is a demyelinating syndrome most commonly affecting young adults and children and occurs in association with vaccination (post-vaccination) or systemic infection (para-infectious encephalomyelitis) (**Tables 2 and 3**). Unlike multiple sclerosis (MS), ADEM is almost always monophasic. Salient differences between ADEM and MS as given in **Table 4**.

Table 2: Acute Disseminated Encephalomyelitis (ADEM) and Related Disorders

- ADEM
  - Uniphasic, para/post-infectious or post-vaccination inflammatory demyelinating disorder of CNS
- Acute haemorrhagic leucoencephalitis (AHLE)
  - Hyperacute form of ADEM, usually occurring after non-specific upper respiratory infections, more tissue destructive
- Site restricted forms of monophasic acute inflammatory demyelinating disorders
  - Transverse myelitis
  - Optic neuritis
  - Cerebellitis
  - Brainstem encephalitis
- Chronic or recurrent forms of parainfectious or post-vaccination encephalomyelitis
- Multiphasic form of ADEM
- Combined central and peripheral nervous system inflammatory demyelinating disorders
  - Post-vaccination : Rabies, Influenza
  - Post-infectious : Measles

Table 3: Triggering Events of ADEM

Infections

Viral

Measles	Rubella
Mumps	Epstein-Barr virus
Influenza A or B	Cytomegalovirus
Hepatitis A or B	Coxsackie
Herpes simplex	Dengue
Human herpes virus E	Human immunodeficiency virus (HIV)
Varicella	

Bacterial

Mycoplasma pneumoniae	*Streptococcus pyogenes*
Chlamydia	*Salmonella typhi*
Legionella	*Leptospira*
Lyme's disease	*Mycobacterium tuberculosis*
Campylobacter	*Brucella*

Vaccines

Rabies	Japanese B encephalitis
Diphtheria, tetanus, pertussis	Polio
Smallpox	Hepatitis B
Measles	Influenza
Mumps	Meningococcal A and C
Rubella	

Drugs

Gold	Sulphonamides
Arsenical compounds	Streptomycin/ PAS

Clinical Manifestations

The hallmark clinical feature is the development of a focal or multifocal neurological disorder following exposure to virus or receipt of vaccine. The onset of the CNS disorder is usually rapid, with peak dysfunction within several days. Initial features include encephalopathy ranging from lethargy to coma,

seizures, and focal and multifocal signs reflecting cerebral (hemiparesis), brainstem (cranial nerve palsies), and spinal cord (paraparesis) involvement. Other reported findings include movement disorders and ataxia.

Table 4: Differences between ADEM and Multiple Sclerosis

Characteristics	ADEM	Multiple Sclerosis
Onset	Abrupt	Subacute
Age group	More common in children	Young adults
Sex distribution	Possible male preponderance	1.7:1 to 2:1 (F/M)
Triggering event	Preceding infection/ vaccination in 70%	Uncommon
Temporal profile	Monophasic; rarely relapsing	Relapsing
Clinical features		
Altered sensorium	More common	Rare
Seizures	More common	Rare
Neurologic deficits	Multifocal	Usually single deficit
Optic neuritis	Bilateral	Unilateral
Transverse myelitis	Complete myelopathy	Incomplete
Headache	More common	Rare
Meningismus	More common	Rare
Cerebrospinal fluid (CSF)		
Cell count	Mild to moderate pleocytosis	Normal or mild pleocytosis (never >75 cells/ µL)
Proteins	Modestly elevated (50 to 150 mg/dL)	Normal or slightly elevated (never >100 mg dL)
Oligoclonal bands	Uncommon, transient	Common and persistent
Magnetic resonance imaging (MRI)		
Distribution of lesions	Bilateral confluent, extensive lesions	Scattered asymmetric lesions
White matter lesions	Confluent, ill-defined, periventricular, and subcortical white matter lesions	Well-defined, periventricular preponderance, juxtacortical
Grey matter lesions	Thalamic and basal ganglia involvement common (**Figure 1**)	Uncommon
Corpus callosum lesions	Rare	Common (Dawson fingers) (**Figure 2**)
Oedema and mass effect	May be present	Usually absent
Follow up MRI	No new lesion or lesion resolution	New lesions - dissemination in time and space
Mortality	10% to 25%	Rare

Pathologic Features and Pathogenesis

ADEM is characterised by perivascular inflammation, oedema, and demyelination within the CNS. The pathology of encephalomyelitis following infections and vaccines is indistinguishable from each other. ADEM results from an aberrant immune attack on the brain and/or spinal cord, triggered by temporally related infections or vaccinations.

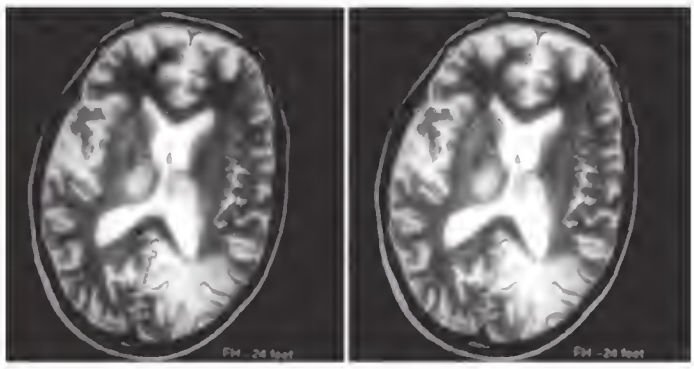

Figure 1: MRI brain T2W image in a 28 years man showing postinfectious ADEM showing hyperintense bilateral lesions in thalami and in the left parieto-occipital area.

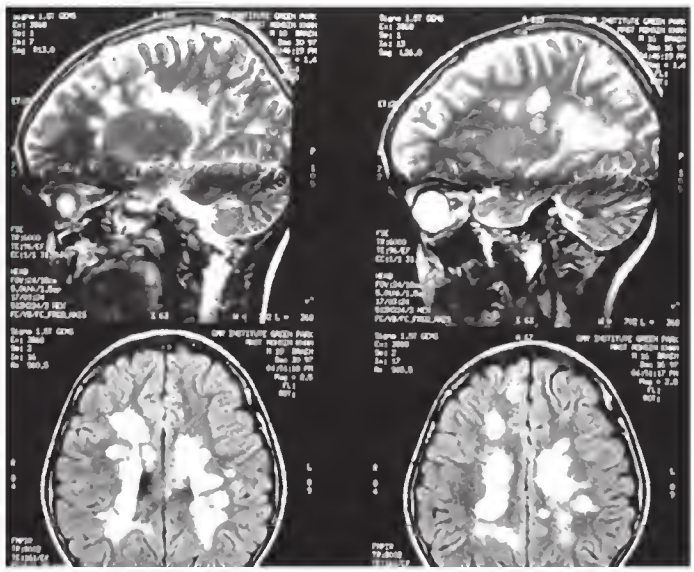

Figure 2: Multiple white matter lesions perpendicular to the lateral ventricles and in and around corpus callosum suggestive of multiple sclerosis. Patient had relapsing-remitting MS and visual evoked potentials (VEP) were markedly prolonged.

Treatment

An initial regime of high-dose intravenous methylprednisolone (3 to 5 g over a period of five days), is followed by a prolonged oral prednisolone tapered over 3 to 6 weeks. If a patient does not respond adequately to corticosteroids, therapy should be escalated, preferentially with intravenous immunoglobulin (Ig) (0.4 g/kg/d over 5 days). Alternatively, or if this approach fails, plasmapheresis can be considered. In very severe cases, immunosuppression with cyclophosphamide or mitoxantrone should be attempted.

MULTIPLE SCLEROSIS (MS)

MS is the most common inflammatory-demyelinating disease of the CNS and the most frequent cause of non-traumatic neurologic disability in young and middle-aged adults.

Epidemiology

MS affects ~350,000 individuals in the United States (US) and 2.5 million individuals worldwide. It is approximately threefold more common in women than men. The age of onset is typically between 20 and 40 years (slightly later in men than in women), but the disease can present across the lifespan. Approximately 10% of cases begin before 18 years of age, and with onset as early as 1 to 2 years of age or as late as the eighth decade have

been described. Whites are especially vulnerable, particularly those of Northern Europe, Northern US, and Canada. By contrast, prevalence is low in Japan (6 per 100,000), in other parts of Asia, in Equatorial Africa, and in the Middle East. MS was considered to be uncommon in Indian subcontinent, but the widespread availability of magnetic resonance imaging (MRI) has led to an increased recognition of MS in India. Optico-spinal form is seen more commonly in India.

MS risk also correlates with high socioeconomic status, which may reflect improved sanitation and delayed initial exposures to infectious agents.

Genetic Considerations

Though not clearly inherited in a simple Mendelian pattern, MS tends to cluster within families (**Table 5**). Susceptibility to MS is polygenic.

Table 5: Risk of Developing MS

Risk of developing MS	
1 in 3	If an identical twin has MS
1 in 15	If a fraternal twin has MS
1 in 25	If a sibling has MS
1 in 50	If a parent or half-sibling has MS
1 in 100	If a first cousin has MS
1 in 1000	If a spouse has MS
1 in 1000	If no one in the family has MS

Clinical Manifestations

The onset of MS may be abrupt or insidious. Symptoms of MS are extremely varied and depend on the location and severity of lesions within the CNS (**Tables 6 and 7**). Examination generally reveals evidence of neurologic dysfunction, often in asymptomatic locations.

Table 6: Initial Symptoms of MS

Symptom	Per Cent	Symptom	Per Cent
Sensory loss	37	Lhermitte	3
Optic neuritis	36	Pain	3
Weakness	35	Dementia	2
Paraesthesias	24	Visual loss	2
Diplopia	15	Facial palsy	1
Ataxia	11	Impotence	1
Vertigo	6	Myokymia	1
Paroxysmal attacks	4	Epilepsy	1
Bladder	4	Falling	1

Table 7: Common Clinical Features of MS

Clinical Features Suggestive of MS	Clinical Features not Suggestive of MS
Onset between ages 15 and 50	Onset before age 10 or after 60
Relapses and remissions	Steady progression
Optic neuritis	Early dementia
Lhermitte's sign	Rigidity, sustained dystonia
Internuclear ophthalmoplegia Fatigue	Cortical deficits such as aphasia, apraxia, alexia, neglect
Worsening with elevated body temperature	Deficit developing within minutes

Pathogenesis

The lesions of MS (plaques) vary in size from 1 or 2 mm to several centimetres. Acute MS lesions are characterised by perivenular cuffing with inflammatory mononuclear cells, predominantly T cells and macrophages, with disruption of the blood-brain barrier. In many lesions, myelin-specific autoantibodies are present, presumably promoting demyelination directly with prominent astrocytic proliferation (gliosis) as the lesions evolve. Surviving oligodendrocytes may partially remyelinate the surviving naked axons, producing so-called shadow plaques.

The signs and symptoms of MS are the manifestations of CNS demyelination. Although relative sparing of axons is typical of MS, partial or total axonal destruction can also occur, especially within highly inflammatory lesions. Evidence also suggests that axonal loss is a major contributor to irreversible neurologic disability in MS.

Disease Course

Four clinical types of MS have been described:

1. *Relapsing/remitting MS (RRMS)* – accounts for 85% of cases at onset and is characterised by discrete attacks with often complete recovery over ensuing weeks to months.
2. *Secondary progressive MS (SPMS)* – always begins as RRMS. At some point, however, the clinical course changes so that the patient experiences a steady deterioration in function un associated with acute attacks. For a patient with RRMS, the risk of developing SPMS is ~2.5% each year.
3. *Primary progressive MS (PPMS)* – accounts for ~15% of cases. These patients experience a steady functional decline from onset.
4. *Progressive/relapsing MS (PRMS)* – accounts for ~5% cases. These patients experience a steady deterioration from disease onset, along with occasional attacks super-imposed.

Diagnostic Criteria

The current diagnostic criteria for MS has been proposed by McDonald and colleagues in 2005 (**Tables 8 and 9**).

Table 8: Revised McDonald *et al* Diagnostic Criteria for MS

Clinical (Attacks)	Objective Lesions	Additional Requirements to Make Diagnosis
2 or more	2 or more	None
2 or more	1	Dissemination in space by MRI ***or*** 2 or more MRI lesions consistent with MS plus positive CSF ***or*** await further clinical attack implicating other site
1	2 or more	Dissemination in time by MRI ***or*** second clinical attack
1	1	Dissemination in space by MRI ***or*** 2 or more MRI lesions consistent with MS plus positive CSF ***or*** await further clinical attack implicating other site ***AND*** dissemination in time by MRI ***or*** second clinical attack
0 (progression from onset)	1 or more	Disease progression for 1 year (retrospective or prospective) ***AND*** 2 out 3 of the following: Positive brain MRI (9 T2 lesions ***or*** 4 or more T2 lesions with positive VEP), Positive spinal cord MRI (2 or more focal T2 lesions), Positive CSF

Table 9: Paraclinical Evidence in MS Diagnosis

What is positive MRI

Three out of four of the following:

(i) One Gadolinium-enhancing lesion or cord lesion ***or*** 9 T2 hyperintense brain and/or cord lesions if no Gd-enhancing lesion

(ii) 1 or more brain infratentorial or cord lesions

(iii) 1 or more juxtacortical lesions

(iv) 3 or more periventricular lesions

MRI evidence of dissemination in time

A Gd-enhancing lesion demonstrated in a scan done at least 3 months after onset of initial clinical event at a site different from initial event, ***or***

A new T2 lesion detected in a scan done at any time compared to a reference scan done at least 30 days after initial clinical event

Positive CSF

Oligoclonal IgG bands in CSF (and not serum) ***or*** elevated IgG index

Positive VEP

Delayed but well preserved waveform

Table 10: Currently Approved Disease-Modifying Drugs for MS

DMD	Use in MS
IFN-β IFN-β-1a, 30 μg IM once weekly (Avonex) IFN-β-1a, 22 or 44 μg SC three times weekly (Rebif) IFN-β-1b, 250 μg SC every other day (Betaseron)	Considered first-line treatment for RRMS
Glatiramer acetate, 20 mg SC once daily (Copaxone)	Considered first-line treatment for RRMS
Natalizumab 300 mg IV once monthly (Tysabri)	Generally recommended only for patients who have had suboptimal response to, or are unable to tolerate, other MS therapies, or those with rapidly evolving severe RRMS. Requires careful monitoring due to increased risk of PML
Mitoxantrone, 12 mg/m^2 IV every three months, lifetime maximum dose 140 mg/m^2	Second-line treatment for worsening RRMS. Also used for treatment of PRMS or SPMS. Requires careful monitoring due to serious safety concerns (leukaemia and cardiomyopathy)

Treatment

Therapy for MS can be divided into several categories: (1) treatment of acute attacks, (2) treatment with disease-modifying agents that reduce the biological activity of MS, and (3) symptomatic therapy. Treatments that promote remyelination or neural repair do not currently exist but would be highly desirable.

Acute attacks or initial episodes

Glucocorticoids are used to manage either first attacks or acute exacerbations. They provide short-term clinical benefit by reducing the severity and shortening the duration of attacks. Intravenous methylprednisolone 500 to 1000 mg/dL for 3 to 5 days, is given, either without a taper or followed by a course of oral prednisone beginning at a dose of 60 to 80 mg/d and gradually tapered over two weeks.

Plasma exchange (seven exchanges: 40-60 mL/kg per exchange, every other day for 14 days) may benefit patients with fulminant attacks of demyelination (not only MS) that are unresponsive to glucocorticoids.

Relapsing forms of MS (RRMS, SPMS with exacerbations)

Table 10 shows the currently approved disease-modifying therapies for MS. **Table 11** outlines the treatment paradigm used currently.

A key aspect of treatment in MS is to begin therapy with disease-modifying drugs (DMDs) as early as possible to minimise further axonal damage and irreversible disability.

Novel therapies in development for MS

Emerging parenteral therapies include the anti-CD52 monoclonal antibody alemtuzumab, MBP8298, anti-CD20 monoclonal antibodies, and the anti-CD25 monoclonal antibody daclizumab. Several promising oral agents are also in phase III development [BG-12, Cladribine, Fingolimod (FTY720), Laquinimod, Teriflunomide].

Symptomatic treatment

There have been no recent major breakthroughs in the symptomatic therapies for MS except in the management of spasticity. Recently, intrathecal delivery of baclofen has dramatically altered the way such patients are managed. Intrathecal baclofen pump device allows a constant flow of baclofen into the spinal fluid at lumbar region, which brings about a dramatic relief from spasticity in lower extremities.

PROGRESSIVE MULTIFOCAL LEUCOENCEPHALOPATHY (PML)

PML is a CNS disease characterised by multiple foci of demyelination that progressively increase in size and number. It is now recognised as a form of opportunistic viral infection of oligodendrocytes by JC virus (papova virus group) resulting from impaired cell mediated immune response. It is usually seen in association with acquired immunodeficiency syndrome (AIDS), malignancies, particularly leukaemia and lymphomas, granulomatous diseases like tuberculosis and sarcoidosis and therapeutic immunosuppression (e.g. collagen vascular disorders, organ transplantation).

In the pre-AIDS era, the most common age of onset was the sixth to seventh decade but it is now reported even in children as young as seven years who are HIV positive.

The clinical presentation of PML is of a focal neurological deficit, which typically evolves over hours or days. The onset can be abrupt in which case it can be confused with stroke. The most common site of affliction is the cerebrum (80% to 90%). Cerebellum and brainstem (10% to 20%) and spinal cord is rarely involved.

Diagnosis is based on a high index of suspicion, on clinical grounds in subjects with neurological deficit developing in the background of depressed immunity. Polymerase chain reaction (PCR) technique is now available for the diagnosis. MRI brain is paramount for the diagnosis (**Figure 3**).

Table 11: Multiple Sclerosis Treatment Strategies

Disease Course/Stage	Treatment Options	Evidence
Monosymptomatic (e.g. optic neuritis) – acute attack	IV methylprednisolone, 1000 mg for 5 days, without oral taper, or with oral prednisone tapered over two weeks	Class I evidence
Relapsing-remitting, no disease activity for several years, and/or no activity on MRI	IV corticosteroids if acute attack occurs	Class I evidence
Relapsing-remitting, current disease activity, and/or activity on MRI	IV corticosteroids for acute attacks, plus for prevention (1) IFN-β-1a (Avonex), or (2) IFN-β-1a (Rebif), or (3) IFN-β-1b (Betaseron), or (4) glatiramer acetate	Class I evidence
Relapsing-remitting, disease activity while on interferon or glatiramer acetate, or intolerance to either agent	Switch to natalizumab	Class I evidence
Relapsing-remitting, accumulating disability while on interferon or glatiramer acetate	Switch to natalizumab or mitoxantrone	Class I evidence for mitoxantrone, no studies for natalizumab in this population
Rapidly progressing disability	Switch or add mitoxantrone	
Secondary progressive multiple sclerosis (SPMS)	Mitoxantrone	Class I and II evidence
Primary progressive multiple sclerosis (PPMS)	No established therapy. Trials of mitoxantrone and rituximab are currently underway	

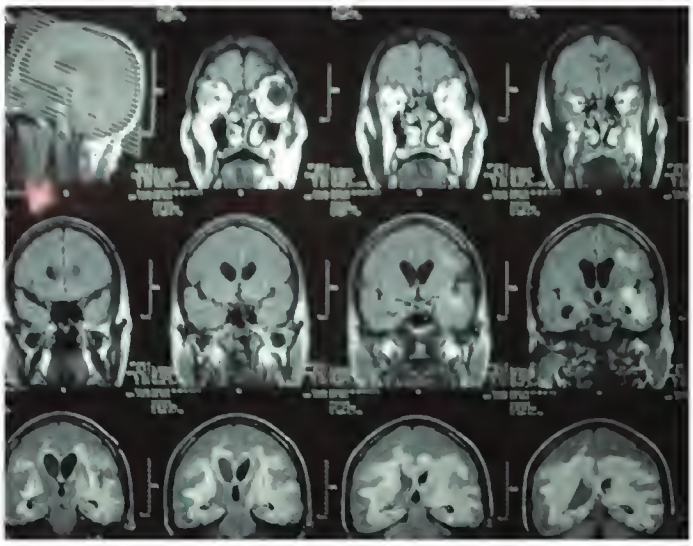

Figure 3: MRI brain showing bilateral extensive white matter lesions in an elderly individual suggestive of PML. Tissue histopathology confirmed the diagnosis.

Usually this disease has a relentless progressive course and most of the patients usually die within 3 to 6 months. No specific therapy. is available though there are some reports of improvement with cytosine arabinoside and cidofovir. HIV associated PML has been reported to show good response to highly active anti-retroviral therapy (HAART) therapy.

ACUTE INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY (AIDP)

AIDP is considered to be an immunological disorder with an acute, often fulminant evolution characterised by a syndrome of rapidly progressive flaccid paralysis, areflexia and albuminocytological dissociation in the CSF. It is popularly referred to as Gullain-Barre syndrome (GBS) after the French army neurologists, Georges Guillain and Jean Alexandre Barre, who described this entity in 1916.

Epidemiology

AIDP is a non seasonal illness that affects persons of all ages. With the decline of acute anterior poliomyelitis, AIDP is the most common acute paralytic disease in Western countries. The mean annual incidence is 1.8 per 100,000 population. Incidence rates increase with age from 0.8 in those younger than 18 years to 3.2 for those 60 years and older.

Antecedent Events

Approximately two thirds of patients report a preceding event, most frequently an upper respiratory or gastrointestinal infection, surgery, or immunisation 1 to 4 weeks before the onset of neurological symptoms. Specific infections implicated include cytomegalovirus, Epstein-Barr virus, varicella zoster virus, hepatitis A and B, HIV, *Mycoplasma pneumoniae*, and *Haemophilus influenzae*. The most common bacterial organism linked to GBS and particularly its axonal forms is *Campylobacter jejuni*. Vaccinations implicated include New Jersey influenza vaccine, tetanus and diphtheria toxoids, rabies and oral polio; and drugs include streptokinase, suramin, gangliosides, and heroin. Several cases have occurred in immunocompromised hosts with Hodgkin's lymphoma or in pharmacologically immunosuppressed patients after solid organ or bone marrow transplantation.

Clinical Features

Patients commonly present with acute onset sensory symptoms in the form of paraesthesias followed by rapidly ascending (rarely descending) weakness. In some patients there may be severe pain in the limbs and back. Involvement of limbs is usually symmetrical and respiratory involvement can occur in a period of three to four weeks. Cranial nerves may be affected, most commonly the facial (50%), bulbar (30%), and ocular (10%). The deep tendon reflexes may be diminished or absent. Sensory loss is uncommon but occasional patients may develop glove and stocking

distribution of sensory loss. Papilloedema may be present in 1% of cases. Sphincter disturbances may occur in 15% cases especially early in the course. Autonomic dysfunction has been reported in 65%, and includes persistent tachycardia (50%), systolic hypertension, sinus bradycardia and severe postural hypotension.

A tentative classification of GBS subtypes has been proposed (**Table 12**).

Table 12: Classification of GBS Subtypes

Acute inflammatory demyelinaring polyradiculoneuropathy (AIDP)
Acute motor axonal neuropathy (AMAN)
Acute motor sensory axonal neuropathy (AMSAN)
Millar-Fisher syndrome
Acute pandysautonomia
Sensory GBS

Course

Approximately 30% reach maximum deficit in seven days, others progress up to four weeks. Neurological disability can be graded according to Hughes' grading scale (**Table 13**). Respiratory involvement occurs in 50% patients with 20% to 30% requiring assisted ventilation. Common causes of death include respiratory failure, pulmonary embolism, infection and autonomic disturbances. Relapses occur in 2% of patients.

Table 13: Neurological Disability Grading in GBS

Grade 0	:	Healthy
Grade 1	:	Minor signs or symptoms of neuropathy but capable of manual work
Grade 2	:	Able to walk without support of a stick but incapable of manual work
Grade 3	:	Able to walk with a stick, appliance, or support
Grade 4	:	Confined to bed or chair bound
Grade 5	:	Requiring assisted ventilation
Grade 6	:	Dead

Investigations

The CSF findings consist of an elevated protein level (100 to 1000 mg/dL) without accompanying pleocytosis. It is often normal when symptoms have been present for ≤48 h; by the end of the first week the level of protein is usually elevated. A transient increase in white cell count (10 to 100/μL) occurs occasionally; however, a sustained CSF pleocytosis suggests an alternative diagnosis (viral myelitis) or a concurrent diagnosis such as HIV infection.

Electrophysiological studies (nerve conduction) may reveal prolonged distal motor and F-wave latencies, absent or impersistent F waves, conduction block, reduction in distal compound muscle action potential (CMAP) amplitudes with or without temporal dispersion, and slowing of motor conduction velocities. In cases with primary axonal pathology, reduced amplitude of CMAP is seen.

Lumbosacral spinal MRI may demonstrate gadolinium enhancement of lumbar roots.

Diagnostic Criteria

Diagnostic criteria for GBS is given in **Table 14**.

Table 14: Asbury and Cornblath Diagnostic Criteria for GBS

Features required for diagnosis
Progressive weakness in both arms and both legs
Areflexia
Features supportive of diagnosis
Progression of symptoms over days to four weeks
Relative symmetry of symptoms
Mild sensory symptoms or signs
Cranial nerve involvement especially bilateral weakness of facial muscles. Recovery beginning 2 to 4 weeks after progression ceases
Autonomic dysfunction
Absence of fever at the onset
Laboratory features supportive of diagnosis
Elevated concentration of proteins in the CSF with <10 cells/μL
Typical electrodiagnostic features

Treatment

Treatment should be initiated as soon as possible after diagnosis, as immunotherapy is no longer effective two weeks after the first motor symptoms. Either high-dose intravenous immunoglobulin (IVIg) or plasmapheresis can be initiated, as they are equally effective. A combination of the two therapies is not significantly better than either alone. Careful observation of cardiorespiratory function, prevention of complication due to prolonged immobilisation and analgesia are other aspects to be taken care of.

Glucocorticoids have not been found to be effective in GBS. Occasional patients with very mild forms of GBS, especially those who appear to have already reached a plateau when initially seen, may be managed conservatively without IVIg or plasma exchange (PE).

Specific Treatment

Intravenous immunoglobulin (IVIg)

IVIg is indicated in subjects who are unable to walk unassisted. The dose recommended is 0.4 gm/kg/day for 5 days intravenously (total of 2.0 g/kg body weight). Ideally IgA deficiency should be ruled out before the administration of IVIg.

Plasmapheresis/plasma exchange

Plasmapheresis means separation of whole blood into plasma and cellular components and PE means same process with replacement by fluids. Several factors like antimyelin antibodies, cytokines, complement components, and other inflammatory mediators, which are potentially pathogenic factors, are removed by PE from the circulation.

A course of plasmapheresis usually consists of 40 to 50 mL/kg PE four times over a week. Meta-analysis of randomised clinical trials indicates that treatment reduces the need for mechanical ventilation by nearly half (from 27% to 14% with PE), and increases the likelihood of full recovery at one year (from 55% to 68%).

Liquorpheresis

Liquorpheresis (CSF filtration) is a new technique developed to purify CSF from pathological factors (probably responsible for manifestation of GBS).

IVIg is preferred mode of treatment over PE because of easy administration and less of haemodynamic fluctuations (**Table 15**).

Table 15: Complications and Side Effects of PE and IVIg

Plasma exchange	Intravenous Immunoglobulin
Haemodynamic and cardiovascular Hypotension Acute respiratory distress syndrome Acute cardiac insufficiency Myocardial infarction Arrhythmias	Headache including precipitation of migraine Back pain Fever Tachycardia Aseptic meningitis
Complications due to vascular access Septicaemia Thrombosis	Rash (erythema multiforme, purpuric erythema, maculopapular, petechial)
Associated with replacement fluids/anticoagulants Allergic reactions Hepatitis, HIV (FFP) Citrate toxicity Bleeding	Alopaecia Eczema Reversible neutropaenia Haemolysis Immune complex arthritis, Thromboembolism Transmission of Hepatitis C
Depletion of plasma components Loss of clotting factors, globulins Loss of protein bound drugs	Deep venous thrombosis Congestive cardiac failure Acute hypotension
Technical complications Clotting in the tubing Air embolism Haemolysis	Oligaemic renal failure Cerebral vasospasm Anaphylaxis
Death (0 to 0.3%)	

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY (CIDP)

CIDP is a common, albeit underdiagnosed and potentially treatable disease with an estimated prevalence of about 1 to 2 per 100,000 in adults. It causes progressive or relapsing weakness and numbness of the limbs.

Patients with AIDP reach their maximum deficit in less than four weeks whereas in CIDP progression lasts more than eight weeks. It is always necessary to exclude alternative diagnoses, such as hereditary, metabolic, vasculitic, paraneoplastic, and paraproteinaemic neuropathies.

Clinical Features

CIDP has a peak incidence in fifth and sixth decades with a male preponderance. About 65% have a relapsing course and 35% a progressive or monophasic course. There is a significant earlier onset in patients with relapsing disease. About 35% have a history of preceding infection or some other possible antecedent event. Weakness is present in both proximal and distal muscles, while paraesthesia and sensory loss are usually distal. Weakness of lower cranial nerves and intercostal muscles may occur. Hyporeflexia or areflexia develop in almost all. Papilloedema is present in 7%, and thickened nerves in 11%.

Pathology and Pathogenesis

CIDP is a multifocal demyelinating disease of peripheral nervous system, with myelin destruction mediated by macrophages that attack myelin without disturbing the integrity of Schwann cells.

Laboratory Studies

The CSF protein is elevated at some stage of the illness in almost every case of CIDP. Mononuclear cells, usually <10/μL are present, but in CIDP associated with HIV disease, a moderate pleocytosis is usual. The electrophysiological findings include multifocal nerve involvement with slowing of conduction velocity, temporal dispersion of compound action potentials, and conduction block.

Treatment

Corticosteroids, PE and IVIg are the modalities of choice. Corticosteroids (prednisone) regimen consists of an initial high daily dose of 1 to 1.5 mg/kg for one month, which is gradually tapered to an alternate day regimen of the same dose over a period of six months. If improvement commences, dose levels are lowered steadily, if weakness increases, the dose must be increased.

PE is used in some centres as the initial therapy. It produces striking benefit in patients with relapsing disease, often needing only a small number of exchanges for a brief period of time. Patients with progressive type of CIDP may require at least four weeks of alternate day pheresis for improvement to start. If no improvement occurs after 12 weeks, PE is stopped and corticosteroids are instituted. PE is not the initial treatment in older individuals because of risks of volume depletion and hypotension.

IVIg (400 mg/kg body weight for 5 days) is similar in efficacy with PE. The limiting factor is its cost and that the beneficial effect is short-lived.

Immunosuppressive therapy with azathioprine, cyclophosphamide, cyclosporine A, or lymphoid radiation, autologous stem cell transplantation is advocated for patients unresponsive to the above treatment strategies.

DISTAL ACQUIRED DEMYELINATING SYMMETRIC NEUROPATHY

Features of the disorder include an increased prevalence in men and in persons over the age of 50 years, a predominantly distal sensory loss, a mild distal weakness (as opposed to the more generalised motor deficits in classic CIDP), and an unsteady gait. IgM paraproteinaemia is present in nearly two-thirds of patients with this condition. IgM-associated cases seem to respond poorly to immunosuppressive therapy.

MULTIFOCAL MOTOR NEUROPATHY (MMN)

MMN is characterised by asymmetric weakness without sensory loss, often starting in distal arm muscles (**Figure 4**). A partial motor conduction block at multiple sites is a characteristic electrophysiologic feature. CSF protein and cell counts are usually normal. Although corticosteroids and plasmapheresis are ineffective treatments, MMN improves with IVIg or cyclophosphamide.

Figure 4: Asymmetric progressive weakness and wasting of five years duration in 40 years male in the left thenar eminence. Nerve conduction studies revealed pure motor involvement with conduction block suggestive of MMN. The patient's disease process halted following IVIg therapy.

MULTIFOCAL ACQUIRED DEMYELINATING SENSORY AND MOTOR NEUROPATHY

Multifocal acquired demyelinating sensory and motor neuropathy (Lewis-Sumner syndrome) has similarities to both CIDP (i.e. motor and sensory deficits, an elevated CSF protein content, and abnormal results on motor and sensory nerve conduction studies) and multifocal motor neuropathy (i.e. asymmetrical presentation of symptoms, and conduction block). A reasonably good response to treatment with IVIg or cyclophosphamide is seen.

20.24 Nutritional and Toxic Disorders of the Nervous System

UK Misra

Nutritional deficiency is a global problem and is common in the developing countries contributed by poverty, dietary deficiency, and coexisting infections. Protein energy malnutrition and vitamin B complex deficiency are important in the context of neurological involvement. Nutritional deficiencies are often multiple and may affect different organs such as skin, mucous membrane, hair, and the nervous system. All the parts of the nervous system such as cerebrum, cerebellum, spinal cord, peripheral nerves, and muscles may be affected independently or in various combinations. The important nutritional disorders of the nervous system are presented in **Table 1**.

Table 1: Important Nutritional Deficiencies Affecting the Nervous System

Vitamin B complex deficiency syndrome (B1, B6, B12, folic acid deficiency)
Vitamin D deficiency—osteomalacic myopathy
Vitamin E deficiency
Protein-energy malnutrition
Iodine deficiency disorders

VITAMIN B COMPLEX DEFICIENCY SYNDROME

Vitamin B12 Deficiency

The neurological manifestations of vitamin B12 deficiency are caused by defective production of intrinsic factor as a result of autoimmune gastritis produced by anti-parietal cell antibodies or as a result of gastrectomy, malabsorption syndrome, surgical resection, and blind loop syndromes. Drugs like colchicine produce vitamin B12 deficiency. Vegetarians with inadequate milk are also at risk of vitamin B12 deficiency. Nearly 20% of AIDS patients have low vitamin B12. Nitrous oxide exposure can result in a clinical syndrome similar to vitamin B12 deficiency. The daily requirement of vitamin B12 is 1 to 2µg and is present in meat, fish, eggs, milk, and fortified cereals.

Pathology

The pathological changes of vitamin B12 deficiency have been described as subacute combined degeneration of spinal cord characterised by swelling of myelin sheath followed by demyelination and astrocytic gliosis. The changes begin in lower cervical and upper thoracic spinal cord and spread up and down. The lateral columns are also affected. Papillomacular bundles of optic nerve reveal degeneration. Demyelination is also seen in cerebral white matter. Axonal degeneration without significant demyelination is seen in peripheral nerve.

Clinical features

The neurological manifestations of vitamin B12 deficiency evolve generally in subacute or chronic manner. The initial symptoms are paraesthesia, weakness, and ataxic gait due to sensory ataxia. A quarter of patients may have Lhermitt's sign. Motor deficits which appear later are limited to the legs and manifest with weakness, spasticity, hyperreflexia, extensor plantar response and gait ataxia.

In vitamin B12 deficiency, myelopathy is more common (80%) than neuropathy (20%). Neurobehavioural changes such as irritability, mental slowing, depression, confusion, delusion, hallucination, personality change, and dementia may occur. Visual impairment, loss of taste, and dyspepsia may also occur. Optic atrophy, brainstem, and cerebellar signs have been rarely reported. Anaemia is usually mild to moderate and may even be absent.

Laboratory tests

Haematological investigations reveal mild to moderate anaemia, macrocytosis, hypersegmented neutrophils, and megaloblastic bone marrow. Antibodies to intrinsic factor have replaced Schilling test because of non availability and radiation exposure. Estimation of serum B12 level provides confirmatory evidence of vitamin B12 deficiency in appropriate clinical setting. If serum B12 is normal in a strongly suspected patient with B12 deficiency syndrome, serum homocysteine and methyl malonic acid should be done which are raised. Electroencephalography (EEG) may be normal or reveal non-specific slowing. Visual evoked potential reveals prolongation of P100 latency even with normal visual functions. Tibial somatosensory evoked potentials are abnormal more frequently than motor, which may be slow or unrecordable. Peripheral nerve conductions are abnormal in minority of cases. Magnetic resonance imaging (MRI) reveals hyperintense signal changes on T2 sequence in subcortical white matter. Spinal MRI shows T2 hyperintensity in the posterior region of the cervico-thoracic spinal cord and spinal cord atrophy in advanced cases (**Figure 1**).

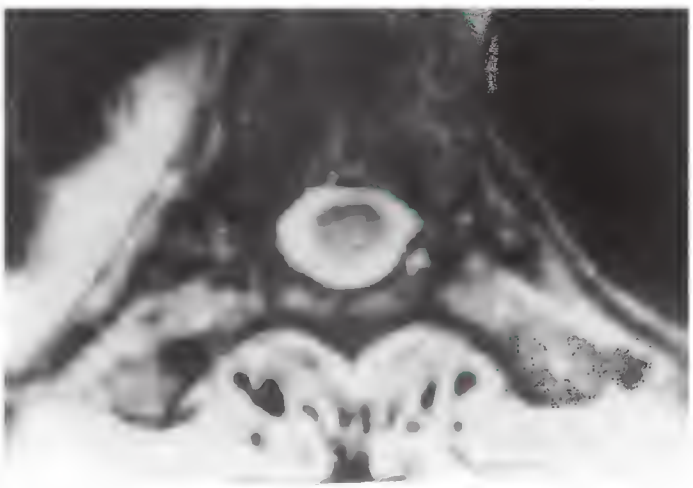

Figure 1: Spinal MRI axial section of a patient with vitamin B12 deficiency showing posterior hyperintensity.

Treatment

The patient with vitamin B12 deficiency should be treated with vitamin B12 1000 µg IM daily for 5 to 10 days followed by weekly dose for 1 month and then monthly for the rest of life. Symptomatic improvement occurs in first 6 months, though it may not be complete for 1 year or more. Recovery depends on early diagnosis and prompt treatment. The underlying cause of vitamin B12 deficiency should be addressed.

Folate Deficiency

Folate deficiency usually results in megaloblastic anaemia and neurological involvement is rare. The daily requirement of folate is 1 mg and is present virtually in all foods. The neurological syndrome in folate deficiency is similar to vitamin B12 deficiency and may occur due to inadequate intake, alcoholism, addiction, increased demand, such as haemolytic anaemia, pregnancy, malabsorption and drugs, such as 5-fluorouracil, cytosine arabinoside, phenytoin, pentamidine, nitrous oxide, etc. The patients with folic acid deficiency are more likely to be malnourished than vitamin B12. The neurological abnormalities include subacute combined degeneration, peripheral neuropathy and dementia though have been reported with folate deficiency, but are controversial. The usual therapeutic dose of folic acid is 1 mg but up to 5 mg may be required in patients with malabsorption. Duration of therapy depends on the underlying cause of deficiency.

Nicotinic Acid Deficiency (Pellagra)

Nicotinic acid can be synthesised in the body from tryptophan. Nicotinic acid is available in meat and starchy cereals. Daily requirement of niacin is 5 to 20 mg. Dietary deficiency of niacin causes pellagra (rough skin) which has been reported from Deccan plateau of India and Udaipur where consumption of maize, millet or jowar is high. High consumption of maize or millet results in imbalance of dietary amino acids, or a complex deficiency state of niacin or tryptophan. Pellagra is characterised by classical triad of diarrhoea, dermatitis, and dementia. The main gastrointestinal manifestations include, stomatitis, diarrhoea, and abdominal discomfort. The neuropsychiatric manifestations are fatigue, irritability, depression, apathy, confusion, dementia, hallucination, and eventually organic psychosis. In acute nicotinic acid deficiency, impaired consciousness, extrapyramidal signs, grasp, and sucking reflex may be present. Polyneuropathy may occur due to deficiency of other vitamins. The skin lesions are hyperkeratotic, hyperpigmented, and desquamated. Dermatitis is symmetrical and present in sun-exposed areas due to photosensitivity.

Diagnosis of pellagra is based on clinical picture, therapeutic response to niacin, and low urinary excretion of nicotinic acid metabolite and tryptophan. Plasma tryptophan and RBC nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate levels are also reduced. For treatment of endemic pellagra, niacin 10 mg orally daily is required but 40 to 200 mg daily or 25 mg 2 to 3 times daily parenterally may be needed in severe deficiency.

Thiamine Deficiency

Thiamine has specific role in nervous system independent of its function in general metabolism. Daily requirement of thiamine is 0.3 to 1.6 mg and it is widely present in vegetables and cereals. Cooking above 100°C, results in loss of thiamine. Thiamine requirement increases with high carbohydrate diet, pregnancy, lactation, and thyrotoxicosis. Excessive loss of thiamine occurs in diarrhoea, dialysis, and diuretic phase of renal failure. Defective absorption of thiamine occurs in malabsorption syndrome, alcoholism, and folate deficiency. In thiamine deficiency, nervous and cardiovascular systems are affected and result in three distinct syndromes; beriberi, Wernicke's encephalopathy and Korsakoff's syndrome.

Beriberi

Beriberi occurs due to consumption of milled rice or food containing thiaminase, such as raw fish, shrimps and raw animal tissue. Thiamine deficiency occurs in alcoholics, food faddists and patients who are starving, on dialysis or on diuretics. Neuropathy in beriberi progresses over several weeks and manifests with paraesthesia, cramps, tenderness, and leg weakness. Cardiac syndromes such as palpitation, tachycardia, dyspnoea, fatigue, and pedal oedema may also be present. On examination there is evidence of symmetric distal sensory, motor, and reflex dysfunction. Nerve conduction study and histopathology are consistent with axonal neuropathy.

Thiamine 50 to 100 mg intramuscularly daily is prescribed for 3 weeks followed by daily oral dose of 2.5 mg. Recovery occurs gradually over weeks to months. Infantile beriberi occurs in infants who subsist on mother's milk who consume polished rice as staple diet. The infant manifests with cardiac symptoms and heart failure which can be fatal. Central nervous system involvement includes drowsiness, ophthalmoplegia and convulsions. Infantile beriberi is a medical emergency and requires thiamine 5 to 25 mg parenterally.

Wernicke's encephalopathy

Wernicke's encephalopathy comprises of acute syndrome of amnesic confusional state, ophthalmoplegia and gait ataxia due to haemorrhage around aqueduct, third and fourth ventricle. Wernicke's encephalopathy is most commonly associated with chronic alcoholism, hyperemesis gravidarum, malignancy, diabetes, prolonged parenteral nutrition, starvation and anorexia nervosa. The incidence of Wernicke's encephalopathy has been estimated to be 0.8% to 2.8% and 20% of these patients are undiagnosed during their lifetime.

MRI reveals atrophy of mamillary bodies with T2 hyperintense signal changes in medial thalamus and mamillary bodies. Wernicke's encephalopathy is treated by thiamine 50 to 100 mg intravenously daily in acute stage followed by oral administration. Ocular signs respond within hours but horizontal nystagmus may persist indefinitely. Apathy and lethargy improve over days or weeks followed by gait ataxia which improves slowly. Many patients are left with persistent amnesia.

Korsakoff's psychosis

Korsakoff's psychosis refers to an amnesic confusional state where memory is impaired out of proportion to cognitive functions. Most patients are disoriented to time and place in the early stage with prominent confabulatory state. Like Wernicke's encephalopathy, Korsakoff's syndrome is best known with chronic alcoholism and has been attributed to thiamine deficiency resulting in changes in diencephalon and temporal lobe. The histopathological changes are similar to Wernicke's encephalopathy. In addition, there is involvement of medial nucleus of thalamus which is responsible for amnesia.

Pyridoxine (Vitamin B6) Deficiency

Pyridoxine is widely and uniformly available in meat, liver, vegetables and whole grain cereals. Daily requirement of pyridoxine is 0.3 to 2.1 mg which increases during pregnancy, dialysis, and high protein intake. A number of drugs, such as isoniazid, cycloserine, and penicillamine result in vitamin B6 deficiency by inhibiting the function of coenzymes. Several genetic defects also cause abnormality in pyridoxine metabolism resulting in convulsion, brain damage and death. Isolated pyridoxine deficiency in adults is rare as it is amply present in food. The clinical picture of pyridoxine deficiency comprises of following syndromes; sporadic infantile seizure, hereditary pyridoxine seizure, and peripheral neuropathy.

Sporadic infantile seizure

Sporadic case of infantile seizures due to vitamin B6 deficiency occurs in developing countries as a result of breast feeding by malnourished mothers. The infants have a normal birth history and development until irritability, exaggerated auditory startle and recurrent convulsions develop. Seizures respond dramatically to pyridoxine administration and the child has normal development.

Hereditary pyridoxine seizures

Several genetic disorders cause abnormality of vitamin B6 metabolism. In one group, infants develop brain damage and die if not treated with pyridoxine. In contrast to dietary deficiency, infant develops seizures within days of birth and requires a larger dose of pyridoxine supplementation to control seizures. In any patient with undiagnosed seizures with poor response to anticonvulsants, pyridoxine therapy should be considered.

Peripheral neuropathy

Patients receiving hydralazine, isoniazid and penicillamine without vitamin B6 supplementation may develop neuropathy. Peripheral neuropathy occurs in 50% patients who are slow acetylators of isoniazid. Tingling, numbness, and burning sensation in the feet are initial symptoms. Distal weakness, absent ankle reflex, and impaired sensations are noted. Hypervitaminosis of pyridoxine is also reported to result in predominantly sensory neuropathy.

VITAMIN E DEFICIENCY

Daily requirement of vitamin E is 3 to 10 mg and it acts as antioxidants. Neurological complications of vitamin E deficiency occur almost exclusively in patients with fat malabsorption and rarely due to congenital defect in intestinal vitamin E transport and in abetalipoproteinaemia. Pathological studies reveal degeneration of large myelinated fibres of peripheral nerve, posterior column and sensory roots. Accumulations of lipoproteins are seen in neurons of spinal cord, cerebellum, and endothelial cells. Vitamin E deficiency following malabsorption manifests after 15 to 20 years though may occur at earlier age of 2 to 3 years because of poor reserve. The clinical presentation includes ataxia and weakness, decreased proprioception and gaze paresis, resembling spinocerebellar ataxia; 50% patients have nystagmus and external ophthalmoplegia. Diagnosis is confirmed by low serum vitamin E levels. Nerve conduction studies are consistent with mild axonal neuropathy, somato-sensory and visual evoked potentials are abnormal and serum CK is mildly raised. Oral supplementation of vitamin E in a dose of 50 to 100 mg daily is most effective, if started early in course of the disease. If there is no improvement, higher dose or parenteral administration may be tried.

VITAMIN D DEFICIENCY

The patients with vitamin D deficiency may present with osteomalacic myopathy which has been described in females with poor nutrition, multiple pregnancies, continued lactation, especially in Muslims with *Purdah*. Osteomalacic myopathy can be found even in unmarried young females. In a study on 628 patients with osteomalacia from New Delhi, 84% patients had dietary vitamin D deficiency, 98% were females, 79% unmarried. Pelvic muscle weakness often follows bone pain. Shoulder girdle muscle weakness is rare. Bone tenderness, lumbar lordosis, waddling gait, Gower's sign, and brisk tendon jerks are characteristics of osteomalacic myopathy. Carpopedal spasm occurs in 50% and paraesthesia in 25% of patients. The diagnosis of osteomalacia is based on radiological (looser's zone, codfish vertebrae, triradiate pelvis, pseudo-fracture in adults and cupping of lower end of radius and ulna in children) and biochemical findings (high alkaline phosphatase, low serum calcium, phosphorus and mildly elevated serum CK). Electromyography may show myopathic features. Muscle histology is normal or shows non-specific fibre atrophy which is attributed to disuse or malnutrition rather than myopathy.

Treatment of osteomalacic myopathy is calciferol 2,000 to 4,000 IU for 6 to 12 weeks followed by daily supplementation of 200 to 400 IU. In dietary deficiency calcium supplementation 500 to 1,000 mg daily is also recommended. The laboratory parameters return to normal after a short period of vitamin D supplementation, pain disappears quickly and muscle weakness improves slowly over a period of several months.

PROTEIN ENERGY MALNUTRITION (PEM)

PEM is common in the developing countries, insufficient consumption of protein and calories results in loss of body mass and fat, though in a particular patient either may predominate. Two polar forms of PEM are found—marasmus and kwashiorkor.

Marasmus manifests with stunted growth, loss of adipose tissue, wasting, absence of oedema and pronounced weight loss (<60% of normal expected weight for the age). Kwashiorkor manifests with growth failure, oedema, hypoalbuminaemia, fatty liver, and preservation of subcutaneous fat. Kwashiorkor is attributed to selective protein malnutrition. It is associated with relative preservation of body weight between 60% and 80% expected for the age. PEM occurs in both adults and children and differentiation between the two polar terms has little clinical significance.

Acute Effects

PEM results in signs and symptoms related to both central and peripheral nervous system and muscles. Neuropsychological symptoms include apathy, irritability, attention deficit, slow learning, language deficit, and poor social skills. Rarely features of myelopathy have been reported in juvenile PEM. Soft neurological signs in rural malnourished children have correlated with degree of malnutrition. Peripheral nerve involvement is more pronounced in PEM, especially during vulnerable period, but effect is negligible if PEM occurs later. Generalised weakness, hyperreflexia, occasional sensory abnormalities, and autonomic dysfunction have been reported in PEM.

Delayed Effects

The intellectual consequences of PEM have been difficult to define because of concurrent social deprivation. The neurological and cognitive sequel of PEM depends on age, severity and duration, malnutrition on one hand and neurological reserve and plasticity on the other. Impairment of reasoning and organisation of knowledge, memory and perception have been reported in children 8 years after being rescued from Kwashiorkor. These changes further improved after dietary supplementation. Changes in motor nerve conduction velocity and motor unit potential are reversible but sensory nerve action potential may recover partially. Cognitive evoked potentials were normal in children who suffered malnutrition in infancy, but the amplitude of P3 was significantly higher compared to controls and this was regarded as a compensatory phenomena following earlier PEM. The laboratory tests reveal evidence of malnutrition, such as anaemia and hypoalbuminaemia. EEG and nerve conduction studies reveal non-specific changes.

IODINE DEFICIENCY DISORDERS

Nutritional iodine deficiency affects large population in developing countries of Asia, Africa and Latin America. In India iodine deficiency is endemic in sub-Himalayan regions. About two million people live in iodine deficient areas and one-third of them have goitres. Neurons are especially susceptible to iodine deficiency. Thyroid dysfunctions in pre-natal and post-natal period often results in irreversible brain damage. Endemic Iodine deficiency, results in two polar forms of cretins, viz. neurologic cretin and myxoedematous cretin.

Neurologic cretins have profound mental retardation, deaf mutism, lesser degree of hearing loss, rigidity and bradykinesia, less frequently strabismus, kyphoscoliosis and frontal lobe release signs. Signs of hypothyroidism may or may not be present. Myxoedematous cretinism is associated with profound intellectual impairment, growth retardation, delay in bone age, and features of hypothyroidism. Early diagnosis of iodine deficiency and hypothyroidism in the neonate may be difficult because of paucity of physical signs. Early diagnosis is critical, because delay in treatment may result in irreversible brain damage. Hence, a high index of suspicion is required especially in iodine deficiency areas.

CHEMICALS AFFECTING THE NERVOUS SYSTEM

The ever increasing list of chemical toxins is linked to industrialisation of society. Some of the important industrial neurotoxins, their use, important source of intoxication, salient clinical features and specific therapies are mentioned in **Table 2**. The toxicity of some of the chemicals which are especially relevant in the Indian context is briefly discussed.

Arsenic

Acute arsenic poisoning occurs due to high dose of inorganic arsenic compounds. The neurological symptoms include headache, vomiting, confusion, visual symptoms, convulsions, and features of raised intra-cranial tension. Skin changes occur 1 to 6 weeks after exposure and include hyperkeratosis and raindrop pigmentation and Mee's lines in the nails. Chronic arsenic poisoning occurs through contamination of food and water and results in non-specific symptoms, such as malaise,

Table 2: Some Important Industrial Chemicals and their Neurotoxicity

Chemicals	Use or Source of Exposure	Clinical Picture	Treatment
Acrylamide	Printing, paper making	Sensory motor neuropathy	—
Arsenic	Rats poison, pesticide, paint, glass, enamel	Encephalopathy, neuropathy	DMSA
Carbon disulphide	Rayon, cellophane and rubber industry	Acute: headache, irritability, delirium	
		Chronic: polyneuropathy, Parkinsonism	—
Carbon tetrachloride	Solvent, fire extinguisher	Acute: stupor, coma convulsions Chronic: headache, vertigo, visual phenomena, optic atrophy, Parkinsonism, peripheral neuropathy	—
DDT	Pesticide	Tremor, seizures, irritability, ataxia	
Ethylene glycol	Antifreeze	Stupor, coma, convulsion	Ethanol
Hydrogen sulphide	Rayon and tanneries	Delirium, seizures, coma	
Lead	Storage battery, polishing, soldering, silver refining	Encephalopathy, neuropathy	BAL, Ca-EDTA penicillamine,
Manganese	Mining, smelting, dry batteries	Hallucination, confusion, psychosis, Parkinsonism, dystonia, spastic paraplegia	Ca-EDTA
Methyl bromide	Fumigant, insecticide, refrigerant	Acute psychosis, convulsions	BAL
Methyl alcohol	Solvent, antifreeze	Visual symptoms, blindness, polyneuropathy	Ethanol
Methyl-N-butyl ketone	Solvent, plastic industry	Polyneuropathy	—
Methyl mercury	Industrial effluent	Neuropsychiatric, cerebellar, choreoathetosis, Parkinsonism, visual and hearing loss	BAL, penicillamine
Organophosphate: Tri-o-cresyl phosphate, Mepafax	In petrol to control pre-ignition	Peripheral neuropathy	—
Thallium	Extraction from ore, pesticide, firework, optical lens industry	Acute: confusion, delirium, coma, neuropathy, autonomic dysfunction, hair loss, memory loss, ataxia, tremor, foot drop	Prussian blue, potassium chloride

nausea, vomiting and diarrhoea. Arsenic neuropathy is the commonest peripheral neuropathy caused by metal. Acute or subacute form of arsenic neuropathy which is a symmetrical sensorimotor neuropathy resembling Guillain-Barre syndrome. Nerve conduction studies reveal slowing of sensory conduction and sensory nerve action potentials may not be recordable in majority of patients. Urine and nail clippings are useful for monitoring recent exposure (above 25 µg/L). Arsenic neuropathy results in distal axonopathy. Large myelinated fibres are especially involved in axonal degeneration. Evidence of segmental demyelination has been reported in some cases.

The antidotes for arsenic poisoning are dimercaprol (British anti-lewisite, BAL) and dimercaptosuccinic acid. Chelation may not significantly alter the course of neuropathy which improves slowly and spontaneously once further exposure is prevented.

Thallium

Thallium is used as insecticide, rodenticide and intentional poison. It is absorbed from dermal, gastrointestinal and through inhalation. Its clinical picture is similar to arsenic poisoning but for alopecia which manifests after 2 weeks of poisoning (**Figure 2**). The diagnosis of thallium poisoning is confirmed by blood thallium levels. Prussian blue prevents absorption from intestine and is given orally 250 mg/kg in divided doses. Induced emesis and gastric lavage are indicated within 4 to 6 hours of poisoning. Activated charcoal is used to interrupt enterohepatic circulation. Forced diuresis and potassium chloride enhance renal excretion. Role of haemodialysis, laxative and vitamin B complex therapy has been highlighted in the management of thallium poisoning.

Figure 2: Total alopaecia in a patient with thallium poisoning.

Fluoride

In India, fluorosis is endemic in Andhra Pradesh, Punjab, Haryana, Tamil Nadu, Karnataka, Gujarat, Uttar Pradesh, Maharashtra and Kerala. Neurological complications occur in about 10% of patients of fluorosis and include compression of the spinal cord or nerve roots or both. Rarely entrapment of peripheral nerves also occurs. There is no specific medical treatment for the neurological complications of fluorosis. In selected cases of myeloradiculopathy, surgical decompression has been tried with limited success.

Lead

The clinical features of lead poisoning in children are dominated by encephalopathy and in adults by neuropathy and rarely there may be illness like motor neuron disease. Symptomatic lead poisoning is characterised by abdominal pain, irritability, lethargy, anorexia, ataxia, slurred speech, convulsions, and coma. Visual loss may occur due to post-papilloedematous optic atrophy. In adults, the clinical picture comprises of lead colic, headache, joint pain, fatigue, anaemia, and peripheral neuropathy. Wrist drop and foot drop are common manifestations of lead neuropathy. Chelation therapy is recommended in all children with blood lead exceeding 55 µg/dL and 25 to 55 µg/dL if associated with encephalopathy or urinary excretion exceeds 200 µg/dL 8 hours after a single dose of Ca EDTA. In adults chelation is recommended if blood lead exceeds 80 µg/dL.

Manganese

The initial stage of intoxication is marked by a prolonged confusional hallucinatory state. Extrapyramidal symptoms include mask-like facies, drooling, monotonous dysarthric speech, stiffness, rigidity, and tremors. Corticospinal and cerebellar signs may follow. Rarely axial rigidity and dystonia have been reported. Sham-mirth or pathological laughter is considered a common feature. Spinal cord involvement in manganese poisoning was reported for the first time from India; the clinical picture is similar to that of amyotrophic lateral sclerosis. The neuropathological changes include neuronal loss and gliosis mainly affecting the pallidum, striatum, frontoparietal and cerebellar cortex, and hypothalamus. Calcium disodium edetate has been tried in the treatment of manganese poisoning with variable results. In the dystonic form of manganese poisoning, levodopa has been more useful than other anti-parkinsonian drugs.

Pesticides

A large number of pesticides are used in India, of which organochlorine (DDT, hexachlorocyclohexane, endosulphan), organophosphate (malathion, fenthion DDVP) and carbamate (Carbaryl, Baygon, Aldicarb) are most commonly used.

The syndrome of delayed organophosphate neurotoxicity follows poisoning with compounds, such as tri-ortho-cresyl phosphate, mepafox and liptophos. Ten to 20 days after the poisoning following a well-defined cholinergic phase, predominantly motor neuropathy develops. Mild sensory loss and spasticity may also be present. Pathologically, axonal degeneration and myelin loss are present distally in the largest fibres, which show dying back phenomenon. Delayed neurotoxicity is attributed to inhibition of neurotoxic esterase in the CNS.

Ethyl Alcohol

Ethyl alcohol is the commonest external toxin which affects the nervous system. Acute alcohol intoxication manifests with slurred speech, ataxia, diplopia, nystagmus, and uninhibited behaviour. These symptoms appear in a beginner at blood alcohol level below 100 mg/dL but in a chronic alcoholic these may appear at 200 mg/dL or above. At blood alcohol level of 300 mg/dL, coma may set in. Severe intoxication may result from rapid drinking which may be fatal due to a direct inhibitory effect on the brain. There is no specific therapy for acute alcoholic coma; prevention of aspiration and maintenance of oxygenation of the brain are of primary importance.

Sudden withdrawal of alcohol from a physically dependent patient can be dangerous. Many alcoholics are tremulous and irritable on waking up in the morning but they improve on drinking. If deprivation is prolonged, the symptoms may aggravate and hallucinations may appear; which are commonly auditory. Delirium tremens is a more serious condition. Besides tremor and hallucination, there may be confusion, sleepiness, restlessness, and autonomic over-activity. The patient is flushed, sweating with tachycardia, fever, dilated pupils, and tremulousness. The patient is apathetic but mutters or screams unintelligibly. Most attacks of delirium tremens subside in 1 to 2 days but mortality is 15%. Treatment includes control of infection, maintenance of fluid and electrolytes (over-enthusiastic fast correction may lead to central pontine myelinolysis) and parenteral vitamin B complex. Of the many sedatives recommended, benzodiazepines are most useful. Alcohol withdrawal can lead to seizure which may vary from a single fit to status epilepticus which is managed by lorazepam or diazepam. Regular anti-epileptic is not required.

Chronic alcoholism is often associated with nutritional deficiencies especially of vitamin B complex group. This is because of poor intake due to gastritis and high energy content of alcohol. The common nutritional syndromes include peripheral neuropathy, amblyopia, Wernicke's encephalopathy, and Korsakoff's psychosis.

Alcoholic cerebellar degeneration has a distinctive clinical picture. There is subacute or gradual onset of gait ataxia with relatively slight in co-ordination of arms. There are no ocular signs or mental changes. Nystagmus, dysarthria, and tremors are rare. Pathologically, there is atrophy restricted to the anterior lobe of the cerebellum. It has been thought to be due to nutritional deficiency. This condition remains unchanged or is slowly progressive. Remissions do not occur.

20.25 Metabolic Disorders of Nervous System

Vrajesh Udani

The age of molecular genetics has seen an explosion of gene mapping and identification of mutations responsible for the disease. Finally, abnormal gene products like receptors, neurotransmitters, cytoskeletal and signalling proteins responsible for the diseased state are being identified and should help in understanding the pathophysiology, paving way for rational therapy.

GENETICS

Most of these conditions are genetically transmitted and there is usually a risk of recurrence. Autosomal recessive (AR) inheritance is by far the most common and consanguinity is a significant risk factor. The risk of an affected offspring is about 25% in each pregnancy while the risk of a carrier is 50 per cent. Anticipation is (successive generations are affected earlier and more severely) another characteristic of these disorders. Fifty per cent of the offsprings are at risk. In the less common X-linked recessive inheritance (XLR), the mother is an asymptomatic or minimally symptomatic carrier with 50% of the male offsprings having a full-blown disease and 50% of the females being carriers. Mitochondrial inheritance (MI) is recognised since the last 2-3 decades. Here mitochondrial DNA transmits the disease. This is maternally inherited as mitochondria come from the ovum. There is a great deal of phenotypic heterogeneity because of heteroplasmy (variable numbers of wild and mutant mitochondria in different tissues).

CLASSIFICATION

There are several different classifications with both advantages and limitations. We will highlight the most commonly used.

Grey versus White Matter Disease

This is an old classification used for mainly chronic progressive storage disorders (**Table 1**). It was before the imaging era and may have limited relevance today.

Table 1: Examples of Disease Predominantly Affecting Grey or White Matter

Degenerative disorders of grey matter	Degenerative disorders of white matter
Neuronal ceroid lipofuscinosis	Globoid cell leucodystrophy
Menke's disease	Metachromatic leucodystrophy
Alper's disease	Maple syrup urine disease
	Alexander's disease
	Canavan's disease
	Adrenoleucodystrophy

Subcellular Organelle Affected

Here the classification is according to the predominant subcellular organelle affected, e.g. Lysosomal or peroxisomal disorders (**Table 2**). Usually a metabolic block results in an accumulation of products or depletion of necessary metabolites leading to disturbances in neuronal function or survival.

Table 2: Examples of Lysosomal and Peroxisomal Disorders

Lysosomal Disorders	Peroxisomal Disorders
GM1/GM2 Gangliosidosis Mucopolysaccharidosis	Zellweger's spectrum disorder (multiple enzyme defects)
Metachromatic leucodystrophy Gaucher's disease Niemann-Pick's disease	Adrenoleucodystrophy (defect of single peroxisomal enzyme)

Intermediary Metabolism Defects

Here the metabolic block does not lead to storage disease. However, there is intoxication with unwanted metabolites as in aminoacid disorders and organic acidaemias or failure of energy production as in mitochondrial disorders and fatty acid oxidation defects.

Disorders of Mineral Metabolism

Wilson's (excess copper) and Menke's (copper deficiency) diseases are classic examples.

Acute versus Chronic Diseases

Typically, the acute encephalopathies are seen in infants and toddlers and are usually due to diseases causing metabolic intoxication like organic acidaemias or energy failure, e.g. mitochondrial disorders. Chronic encephalopathies come at any age and are typically slowly progressive or static. They are seen in the lysosomal, peroxisomal, mitochondrial disorders and disorders of metal metabolism (**Table 3**).

Table 3: Examples of Diseases Presenting Acutely

Disease	Presentation
Ornithine transcarbamylase deficiency (urea cycle disorder)	Hyperammonaemia
Maple syrup urine disease (aminoaciopathy)	Neonatal encephalopathy
Proprionic acidaemia (organic acidaemia)	Encephalopathy-ketotic hyperglycinaemia

DIAGNOSTIC INVESTIGATIONS

One should reach a working clinical diagnosis before ordering tests. Non-directed investigations in every case are certainly not cost effective in our country.

Biochemical Tests

Screening tests are listed in **Table 4**. They are useful in screening for the aminoacidopathies, organic acidaemias, fatty acid beta-oxidation defects and mitochondrial disorders. In developed nations and now increasingly in India as well, these have been replaced by tandem mass spectroscopy (TMS) which can screen

blood and urine samples for >100 disorders. In India, further refinements like quantitative aminoacids in plasma and organic acids in urine are available by HPLC, GCMS and Gas chromatography (Table 4).

Table 4: Screening Tests for Inborn Error of Metabolism (IEM)

Blood	Urine
Complete blood count, peripheral smear examination	pH
Glucose	Ketones
Ketones	Gas Chromatography
Calcium	Mass Spectroscopy (GCMS)
Electrolytes	organic acid analysis
Blood gas	
Anion gap	
Ammonia	
Aminotransferases	
Lactate, pyruvate	
Uric acid	
Caeruloplasmin	
Phenylalanine	
Tandem Mass Spectrometry (TMS)	

Role of TMS

Tandem Mass Spectrometry (TMS, also called MS/MS) is very specific and accurate in identification of compounds in blood. It can measure very small amounts of material with excellent precision. Mass spectrometers can be thought of as very sensitive weighing scales or instruments that weigh molecules. TMS can analyse a filter paper dried blood spot specimen for 45+ metabolic disorders including organic acid, amino acid and fatty acid oxidation disorders in a single two minute analyses.

Radiology

MRI should be the primary imaging modality in patients with suspected inborn error of metabolism (IEM). It is in most cases sensitive as well as on various occasions specific for neurometabolic disorders. White matter changes (leucodystrophies) are easily identified while grey matter diseases (poliodystrophies) can be diagnosed by demonstrating progressive cortical atrophy on sequential imaging. Myelination is best noted by MRI.

Certain disorders like Leigh's disease may have variable neuroimaging findings like cerebellar atrophy; cavitatory lesions in the basal ganglia and brainstem as well as diffuse leucoencephalopathy; Occasionally malformations of cortical development (MCDs) can be seen as well.

Contrast enhanced MRI may be helpful in differentiating among leucodystrophies, e.g. post-contrast rim enhancement in Alexander's disease. MR spectroscopy (MRS) identifies the biochemical state of the central nervous system. Metabolites measured by MRS include n-acetyl aspartate (NAA), creatine, choline, lactate, glutamate , myoinositol and likewise. Canavan's disease has a larger than normal NAA peak, while mitochondrial disorders have abnormally high lactate peak. Diffusion tensor imaging and tractography is helping in diagnosis of hypomyelinating disorders like Pelizaeus-Merzbacher disease (PMD).

Advancement in MRI has made it mandatory for every patient with cryptogenic neurological disability or suspicion of metabolic disorder to undergo cranial MRI and if needed MRS/diffusion tensor imaging.

Neurophysiology

EEG is rarely specific for a particular disorder. However, epileptic abnormalities suggest grey matter disease. Nerve conduction velocity (NCV) studies demonstrate, evidence of demyelinating peripheral neuropathy in certain leucodystrophies (metachromatic leucodystrophy, Krabbe's disease) or the mitochondrial disorders like Leigh's disease. Electroretinogram (ERG) is abnormal in neuronal ceroid lipofuscinosis and peroxisomal disorders while brainstem auditory-evoked responses (BAER) confirm deafness in some of the mucopolysaccharidosis (MPS), peroxisomal diseases and Refsum's disease. Giant visual-evoked potential (VEP)/somatosensory-evoked potential (SSEP) scalp potentials suggest the possibility of progressive myoclonic epilepsy syndromes [Lafora Body disease, neuronal ceroid lipofurcinosis (NCL), myoclonic epilepsy with ragged red fibres (MERRF), etc.]

Histology

Biopsies of affected organs have nowadays been replaced by more specific enzymatic and molecular tests. Ultrastructural skin and conjunctival biopsies are still useful in neuronal ceroid lipofuscinosis and Lafora Body disease; ragged red fibres in mitochondrial disorders as well as glycogen and lipid storage disorders are identified on muscle biopsy. Brain biopsy would now seem unethical.

Molecular Diagnosis

Molecular techniques are now available to diagnose many of the mitochondrial syndromes like mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes, myoclonic epilepsy with ragged red fibres (MERRF), spinocerebellar atrophies (SCAs), including Friedreich's Ataxia, Huntington's disease and the leucodystrophies (Canavan's disease, Pelizaeus-Merzbacher disease). This helps to make a very specific diagnosis not only in the patient but also in presymptomatic children, carriers and in the unborn foetus. After sequencing of the entire human genome this diagnostic technique may ultimately replace all others.

The next section deals with specific neurometabolic diseases with emphasis on those commonly seen in the Indian subcontinent.

NEONATAL-ONSET DISEASES

Neonates usually have acute encephalopathies because most illnesses presenting at this time have a complete deficiency of the enzyme. Manifestations occur only after birth. All toxic metabolites are cleared by the placenta in utero.

Disorders Presenting as an Acute Encephalopathy

The neonate becomes lethargic and hypotonic, feeds poorly, vomits, and finally develops seizures. Diagnosis needs a high index of suspicion as many diseases of the neonate like hypoglycaemia, bilirubin encephalopathy, meningitis/encephalitis and even hypoxic-ischaemic encephalopathy develop similar symptoms albeit with some differences. Consanguinity and history of prior neonatal deaths must alert the physician to the possibility of metabolic diseases.

Examination reveals stupor, poor cry, hypotonia, poor neonatal reflexes, tremor, occasionally ophthalmoplegia and sometimes evidence of other system involvement like respiratory distress and jaundice. In patients with partial deficiencies, presentation is in later life with intermittent ataxia, encephalopathy, vomiting and acidosis during illnesses or high protein loading.

Urea cycle disorders

The prevalence is estimated at 1 in 30,000 live-births. Common conditions include the X-linked ornithine transcarbamylase (OTC) deficiency, carbamyl phosphate synthetase deficiency and citrullinaemia.

All the symptoms of acute encephalopathy are seen. Seizures are prominent later and are often intractable. Cerebral oedema causes vomiting and a full fontanel. Tachypnoea leads to respiratory alkalosis. In organic acidaemias, on the other hand tachypnoea is due to metabolic acidosis – an important differentiating point between the two.

Diagnosis rests on a marked elevation of ammonia with respiratory alkalosis. Orotic aciduria is seen in OTC deficiency and high citrulline is noted in citrullinaemia. Specific enzyme estimations can be carried out in leucocytes or hepatic cells.

Treatment includes urgent peritoneal or haemodialysis followed by protein restriction and use of sodium benzoate or phenylacetic acid. Arginine should be supplemented. If left untreated or improperly managed, death or severe disability is inevitable.

Disorders of branched chain aminoacids

Maple syrup urine disease (MSUD) and the organic acidaemias (isovaleric acidaemia, propionic acidaemia and methylmalonic acidaemia) are caused by different enzyme deficiencies in the catabolism of branched chain amino acids - leucine, isoleucine and valine (**Figure 1**).

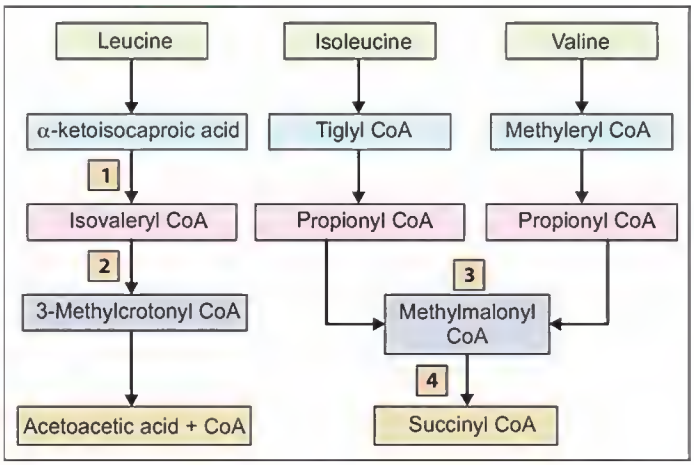

Figure 1: Branched chain aminoacid metabolism. *(1) Branched chain A - ketoacid dehydrogenase (MSUD); (2) Isovaleryl - CoA dehydrogenase (isovaleric acidaemia); (3) Propionyl - CoA carboxylase (propionic acidaemia); (4) Methylmalonyl - CoA mutase (methylmalonic acidaemia).*

Maple syrup urine disease (MSUD)

MSUD is due to a complete deficiency of ketoacid dehydrogenase and has a frequency of 1 in 200,000. An acute encephalopathy with a maple syrup smell in the urine is characteristic. Cerebral oedema can be lethal. Diagnosis is suggested by a deep blue colour in the $FeCl_3$ and a yellow precipitate in the 2,4 DNPH test.

Isovaleric acidaemia

This is a rare disorder caused by a deficiency in the enzyme isovaleryl CoA (**Figure 1**). The clinical picture is similar with a strong smell of sweaty feet. Mortality is high. Protein restriction, leucine free foods, carnitine and glycine supplements may help to a degree.

Diseases Presenting with Early Prominent Seizures

Nonketotic hyperglycinaemia

An acute encephalopathy with hiccups and persistent myoclonia is seen. These are distal and fragmentary. The seizures are initially intractable but diminish over time. The infant is left severely handicapped.

Pyridoxine-dependent seizures

Defective binding of glutamate decarboxylase with its co-factor pyridoxal-5-phosphate leads to a deficiency of g-aminobutyric acid (GABA), a major inhibitory neurotransmitter. Intrauterine convulsions are on record and clonic seizures are persistent from the initial days. The babies are jittery, irritable and have feeding difficulties. Characteristically crying continues during the seizures. IV pyridoxine 40 to 300 mg abolishes the seizures and normalises the electroencephalogram (EEG). This has to be continued life-long.

Disorders Presenting with Severe Hypotonia

Peroxisomal disorders

Zellweger's syndrome and neonatal adrenoleucodystrophy are AR prototype disorders of the first type. The incidence is estimated at 1 in 50,000.

Zellweger's syndrome presents with dysmorphic facies, severe hypotonia, hepatomegaly, increased hepatic enzymes, hearing loss, retinal pigmentary degeneration, severe retardation and seizures. There are feeding difficulties and the babies are poorly responsive. There is arthrogryposis (contractures of the fingers, knee and ankle) and areflexia. Brain malformations, renal cysts and sometimes biliary cirrhosis are noted. Life span is only a few months to a year. Neonatal adrenoleucodystrophy is a milder variant with subclinical adrenal insufficiency and failure to thrive.

The diagnosis is made by elevations of very long chain fatty acid (VLCFA), pipecolic, phytanic and bile acids in leucocytes.

Galactosaemia

This disorder is caused by a deficiency of galactose-1-phosphate uridyl transferase or its epimerase. It is now localised to 9pl3 and the frequency is 1 in 6,200. It presents with hyperbilirubinaemia vomiting and diarrhoea and if untreated children either die of sepsis or develop retardation and cataracts.

Disorders of Early Infancy (Onset usually before 6 months) with Seizures as a Prominent Symptom

Biotinidase deficiency

Refractory seizures start between 1.5 and 3 months. Hair becomes sparse, easily pluckable and alopecia results (**Figure 2**). Skin rash with seborrhoea is characteristic. Candidial infections occur due to immune dysfunction. Hypotonia, psychomotor regression, visual and hearing deficits occur later. Acidosis with alterations in sensorium are life threatening. If untreated most die within a year of onset.

Figure 2: Infant with biotinidase deficiency showing sparse hair.

Diagnosis rests on the characteristic clinical picture, high plasma lactate, ammonia and acidosis. A prompt cessation of seizures within 48 hours with biotin therapy confirms the diagnosis. Biotinidase assay done on a blood spot is now part of neonatal screening of metabolic disorders in even in India. The children remain completely normal with early treatment. Mutations in the BTD gene, located on 3p25 is responsible for partial or complete biotinidase deficiency.

Menke's disease

This X-linked disorder is due to a primary defect in the intestinal transport of copper leading to a deficiency of copper containing enzymes. In early infancy and sometimes from in the first month, males present as psychomotor regression/delay and myoclonic jerks. The infants are poorly reactive and develop sparse, hypopigmented wiry hair, which breaks easily. Hypothermia is characteristic. Microcrania is usual. Subdural haematomas may develop due to rapid brain shrinkage and paradoxically infants present as macrocrania. Tortuous intra-cranial vessels and temporal lobe changes are seen on MRI. A low ceruloplasmin and copper and a high lactate/ammonia is characteristic. Early treatment with Copper Histidine may improve an otherwise downward course.

Alper's disease

This is a heterogeneous group of conditions with spongy degeneration of the cerebral grey matter. Mutations within polymerase gamma gene (POLG) are associated with the disease. The liver is variably involved and many die of chronic hepatitis and cirrhosis. Developmental delay, refractory myoclonic or generalised seizures (**Figure 3**), status epilepticus and acute regression are manifestations. Raised liver enzymes, low albumin and abnormal liver histology of hepatitis or cirrhosis are characteristic.

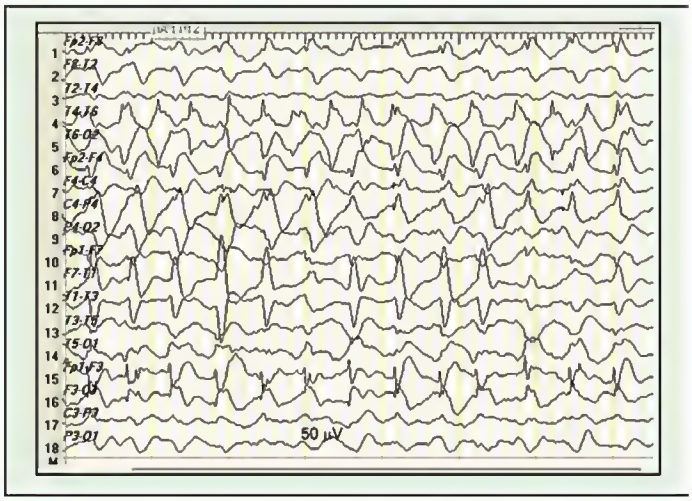

Figure 3: Typical EEG findings in a patient with POLG mutation proven Alper's disease.

Disorders Presenting as Psychomotor Retardation/Regression

Krabbe's disease

The gene of this AR leucodystrophy maps to chromosome 14. Beta-galactocerebrosidase is deficient and leads to storage of sphingosine in globoid cells in the brain and in the Schwann cells of the peripheral nerve.

Onset is below 3 months sometimes as early as in the neonatal period. Hyperacusis - increased startle response and later opisthotonus and spasticity are prominent. There are reduced or absent reflexes due to the associated demyelinating neuropathy. Infantile spasms and severe hypotonia are atypical presentations.

Early cord stem cell transplant or bone marrow transplant may be useful in less symptomatic children.

Tay-Sachs disease

This AR condition is due to a deficiency of hexosaminidase A and the gene has been localised to chromosome 15. Sandhoff disease is due to a deficiency of both Hexosaminidase A and B and is due to a mutation on chromosome 5q13. These two diseases are common in India (**Table 5**). Onset is below 3 months with delay or regression. Early hyperacusis is universal. Hypotonia, later spastic tetraparesis and a macular cherry red spot are very suggestive. Macrocephaly and seizures are other manifestations. Sandhoff's' disease has additional hepato-splenomegaly.

Pelizaeus-Merzbacher disease

This X-linked leucodystrophy is caused by deletions in the gene for proteo-lipid protein, which is a constituent of normal myelin. It is localised to Xq21-22. Rotatory nystagmus and roving eye movements are initially seen. Hypotonia, developmental delay and later cerebellar signs and spasticity supervene. Mental functions are less affected. Progression occurs later and many succumb by 5 to 7 years though prolonged survival is common.

Phenylketonuria

This AR aminoacidopathy is seen with a frequency of 1 in 10,000 and was one of the first disorders screened in normal newborns. It seems uncommon in Western India though it occurs with high frequency from South India. There is a deficiency of phenylalanine hydroxylase resulting in hyperphenylalaninaemia. In untreated

infants, developmental delay and later regression becomes apparent in early infancy. Diagnosis is suggested by a green colour in the $FeCl_3$ test. Treatment with a phenylalanine-restricted diet as soon as possible prevents mental retardation if levels are maintained between 5 and 10 mg/dL for life.

Table 5: Frequency of Common Metabolic Disorders in India (1,042 children)

Leucodystrophies	N = 118
Metachromatic leucodystrophy	47%
Megalencephalic leucoencephalopathy	29%
Krabbe's disease with subcortical cysts	14%
Other lysosomal storage diseases	N = 496
Mucopolysaccharidosis	64%
Tay Sachs/Sandhoff's disease	14%
Niemann-Pick type A	10%
GM1 gangliosidosis	6%
Gaucher's disease	4%
Aminoacid disorders	N = 206
Phenylketonuria	45%
Homocystinuria	22%
Maple syrup urine disease	21%
Organic acidaemias	N = 41
Glutaric aciduria Type 1	29%
Propionic acidaemia	19%
Methylmalonic acidaemia	19%
Mitochondrial disorders	N = 57
Leigh's disease	30%
KSS/MERRF/MELAS	11%
Others	
Wilson's disease	N = 81
Urea cycle defects	N = 21
Biotinidase deficiency	N = 21

Courtesy: Data mainly from KEM Hospital, Mumbai, PD Hinduja Hospital, Mumbai, AIIMS, New Delhi, NIMHANS, Bangalore, Bombay Hospital, Mumbai and others.

Disorders Presenting with Visceromegaly

Niemann-Pick disease types A, B, C

Types A, B are due to a deficiency of sphingomyelinase and type C is a cholesterol metabolism disorder (discussed separately). For Type A the gene has been mapped to chromosome 11. Onset is between 3 and 6 months with feeding problems, failure to thrive and predominantly hepatomegaly. A cherry red spot is seen in 50% of patients. Emaciation, opisthotonus, spasticity and blindness are end-points. Vacuolated lymphocytes and histiocytes in the blood or bone marrow, so called foam cells, are suggestive. Sphingomyelinase reduction/absence is diagnostic and readily available.

Gaucher's disease

This AR disease has a deficiency of beta-glucocerebrosidase and the gene coding the enzyme is at 1q21 to 31. Type I usually occurs in adult life, but childhood presentations are known. Clinical phenotype includes visceromegaly, bone disease and pulmonary manifestations. Type 3 occurs in later life as a spinocerebellar syndrome and dementia. Type 2 occurs in early infancy.

Onset is around 3 to 5 months of life with characteristic neck retraction, bulbar palsy, ophthalmoplegia and developmental regression. Massive splenomegaly and pancytopaenia are seen. PAS-positive cells ('Gaucher' cells) in the bone marrow and enzyme estimation clinch the diagnosis.

Though enzyme replacement is effective against Type 1, it is extremely costly and probably has little effect on neurological manifestations. Splenectomy and bone marrow transplant have also been tried in Type I.

Disorders with Macrocephaly

Canavan's disease

This AR leucodystrophy is due to a deficiency in aspartoacylase which leads to accumulation of N-aspartic acid in the white matter. It has been mapped to chromosome 17. Onset is with macrocephaly and delayed development before six months of age. The disease progresses rapidly with spasticity, seizures, cortical blindness.

Megalencephalic leucoencephalopathy with subcortical cysts (MLC)

The first reports were from the Netherlands. In the same year, Singhal from India described 30 patients, majority from the Agrawal community. AR inheritance is likely.

Macrocrania is noticed at birth or early infancy and is often misdiagnosed as hydrocephalus. After a rapid increase in the first couple of years, it stabilises. Initial development is normal or only mildly delayed. Motor problems in the form of mild clumsiness become obvious in a few patients in the preschool years. Cognitive functions appear normal in most. Later spastic ataxia occurs and may progress. Learning problems are frequent. Minor head injuries precipitate seizures followed often by a sudden deterioration in motor functions. Prognosis is variable with some children remaining stable and others becoming nonambulant. In some MRI changes may actually regress.

Alexander's disease

This sporadic disorder of the white matter is due to astrocytic dysfunction and is due to mutations in the glial fibrillary acidic protein (GFAP) gene. Rosenthal fibres are the pathological hallmark of the disease. The infantile form affects predominantly males who have psychomotor arrest/regression, macrocephaly and later spasticity and seizures. MRI shows evidence of predominantly frontal white matter demyelination with contrast enhancement. Outcome is poor with death by 2 to 3 years in most.

Disorders Characterised by Hypotonia and Weakness

Infantile pompe disease

This AR glycogen storage disorder type IIa is caused by deficiency of lysosomal acid maltase (now called alpha-glucosidase). The defective gene is localised to 17q. Macroglossia, hypotonic weakness, areflexia and cardiomyopathy are characteristic. The latter may be fatal.

Congenital disorders of glycosylation (previously called carbohydrate deficient glycoprotein syndrome)

This recently described disorder is characterised by a deficiency of carbohydrates in sialoproteins. The deficient enzyme in the common Type I is phosphomannomutase and the gene is linked to chromosome 16.

Disorders with Late Infantile Onset

These disorders have their onset between 6 months and the first 2 to 3 years of life. In these children vis-a-vis young infants, it is simpler to make a diagnosis of a progressive disease, as obviously acquired skills are lost.

Disorders with the Hurler Phenotype

Many diseases presenting primarily with retardation or regression also have non-neurological manifestations. **Table 6** lists the many conditions that conform to the so-called Hurler phenotype. Hypothyroidism should always be excluded.

Table 6: Conditions Conforming to Hurler Phenotype

Hurler Phenotype	'Hurler Phenotype' Diseases
Coarse facial features	Mucopolysaccharidosis
Abdominal hernia	Mannosidosis
Corneal opacity	Fucosidosis
Deafness	Sialidosis
Dysostosis multiplex	GM1
Mental retardation	Gangliosidosis
Stiff joints	Mucolipidosis
Visceromegaly	Multiple sulphatase deficiency

Mucopolysaccharidosis (MPS)

Currently, there are seven types described. These are the most common metabolic disease in India with a 23% incidence in one large series. Hurler (Type 1) is the commonest MPS in North and South India while Hunter (Type 2), Sanfillipo (Type 3) and Morquio (Type 4) predominate in West India. Deficiency of either a lysosomal glucosidase or sulphatase leads to storage of glycosaminoglycans in the brain, reticuloendothelial system and the connective tissue leading to the varied manifestations. **Table 7** lists the important features of the different MPS.

Table 7: Main Characteristics of the MPS

Type	Systemic Manifestations	Neurological Features	Urine Excretion	Mode of Inheritance
Hurler (IH)	Marked severe dwarfism	Severe	DS+HS	AR
Schie (IS)	Very mild	Mild	DS+HS	AR
Hunter (II)	Marked severe dwarfism	Mild-Moderate	HS	XLR
Sanfillipo (III)	Mild/Absent	Severe and Progressive	HS	AR
Morquio (IV)	Marked osseous	Absent	KS	AR
Maroteaux-Lamy (VI)	Marked osseous Severe dwarfism	Absent	DS	AR
Sly (VII)	Mild to severe	Absent to Severe	DS+HS	AR

DS = Dermatan sulphate; HS = Heparan sulphate; KS = Keratan sulphate, Different enzyme deficiencies in different subtype.

Enzyme replacement by a bone marrow transplant is encouraging and is being tried in all the MPS with maximum success in those with little or no neurological manifestations.

Disorders Presenting as Gait Difficulty

Metachromatic leucodystrophy

This AR disorder is the commonest single metabolic disorder reported from India. There is a total or partial deficiency of arylsulphatase A and this is mapped to chromosome 22. There are three forms—late infantile, juvenile and adult. Severity differences are accounted by different mutations causing the disease. Onset is with gait difficulty at a mean of 17 months. Initially ataxia or spasticity is seen with depression of tendon reflexes. Blindness and mental regression occur later. Sometimes a floppy infant presentation may be mistaken for an acquired peripheral neuropathy. Cherry red spots are seen in a few. Raised CSF protein, reduced nerve conduction velocities consistent with demyelination and diffuse white matter changes on MRI (sparing the subcortical 'U' fibres) are characteristic. Enzyme diagnosis is readily available. Bone marrow transplant in early disease sometimes helps to stabilise it.

The juvenile variety comes in school age with progressive spastic ataxia without neuropathy while the adult disorder presents as an organic psychosis.

Neuroaxonal dystrophy

This AR as yet unclassified disorder may be a disorder of retrograde axonal transport. Onset is around 14 to 18 months. Arrest in motor and later regression of motor milestones occurs. Severe hypotonia and areflexia suggest a neuromuscular disorder. Later spasticity, dementia and blindness due to optic atrophy are seen.

Ataxia telangiectasia

This AR condition is also a neurocutaneous disorder.

A slow saccadic eye movement disorder results in sudden head thrusting movements—oculomotor apraxia. Choreoathetosis and dystonia are prominent in some. Ocular telangiectasia occurs after age two. Immune deficiency and lymphoreticular malignancies are common. Ataxia progresses and patients become nonambulant by 10 to 15 years. Diagnosis rests on a high alpha-foetoprotein, low IgA and IgE. MRI shows cerebellar atrophy and chromosomal analysis reveals spontaneous and radiation induced breakages. Truncating mutations in the ATM gene located on 11q22 to 23 account for the disorder.

Avoidance of X-rays and chemotherapies and prompt treatment of infections prolongs life.

Disorders Presenting with Movement Disorder

Glutaric aciduria type 1

This AR organic acidaemia is due to a deficiency of glutaryl CoA-dehydrogenase. Initial macrocephaly and mild developmental delay are seen. An acute 'encephalitis' presentation with seizures and altered sensorium is followed by sudden regression, severe dystonia and hypotonia.

Lesch-Nyhan syndrome

This X-linked disorder is due to deficiency of hypoxanthine guanine phosphoribosyl transferase and has been mapped to Xq26-27. The excess hypoxanthine results in hyperuricaemia. Initial developmental delay and hypotonia is followed by dystonia and choreoathetosis. Later spasticity and self mutilation becomes prominent. Moderate retardation with behavioural problems is common. Death occurs as renal failure secondary to uric acid nephropathy supervenes. Gouty arthritis also develops. Allopurinol prevents the joint problems but is ineffective for the neurological manifestations.

Disorders with Intermittent Neurological Worsening

Partial enzyme defects in the urea cycle disorders, organic acidaemias and certain aminoacidurias maple symptoms urine disease, Hartnup disease come with intermittent neurologic dysfunction as either ataxia or altered sensorium. Most have been discussed previously.

Fatty acid oxidation defects

This group of disorders are due to multiple enzyme deficiencies like the medium, short and long chain acyl CoA-dehydrogenases. There is a carnitine deficiency resulting in impaired lipid transport and beta oxidation.

Leigh's syndrome

This is a common mitochondrial disorder in India. It is seen from infancy to adult life with a characteristic spongiform changes secondary to hypervascularity due to capillary proliferation in the brainstem, cerebellum, and basal ganglia. In the majority of cases, dysfunction of the respiratory chain (particularly complexes I, II, IV, or V), of coenzyme Q, or of the pyruvate dehydrogenase complex are responsible for the disease. Hypotonia, ophthalmoplegias, respiratory irregularities, and bulbar symptoms point to the predominant brainstem pathology. Choreoathetosis, dystonia, seizures, episodic stupor, optic neuropathy, and peripheral neuropathy are other manifestations. High plasma and CSF lactate and pyruvate is very suggestive but not universal.

Treatment with low carbohydrate diet, high dose vitamins (B1, riboflavin, C, K), carnitine, and coenzyme Q is occasionally helpful. Acetazolamide may help in a few cases.

CHILDHOOD AND ADOLESCENT ONSET DISORDERS PRESENTING AS SEIZURES/DEMENTIA

Progressive myoclonic epilepsy (PME) is a symptom complex with a triad of epilepsy, myoclonus, and dementia. Visual disturbances and cerebellar ataxia are other manifestations. In South India of 30 cases analysed, Lafora Body disease (21 cases) was the most common; the others include NCL, Unverricht Lundborg disease and MERRF.

Neuronal ceroid lipofuscinosis

This AR disorder is associated with neuronal storage of lipopigments. Infantile, late infantile, juvenile, and adult onset varieties are described.

Lafora body disease

This AR disease has now been associated with mutations in the EPM2A and EPM2B genes. Periodic acid-Schiff (PAS) positive polyglucosan storage Lafora bodies are seen in several tissues including the brain, liver, and sweat glands. Mean onset age is around 13 years. Generalised tonic clonic seizures, fragmentary distal intention and action myoclonus and dementia occur finally in all patients. Cerebellar signs and visual failure occur in some. Skin and liver biopsies are diagnostic. Deterioration is rapid with death within 5 to 6 years of onset.

Unverricht lundborg disease

This is a milder disorder with relatively preserved intelligence and incapacitating intention myoclonus. A triplet repeat expansion in the cystatin B gene is localised to chromosome 21. Prognosis has been improved by the use of myoclonus-reducing drugs like piracetam, N-acetyl cysteine, 5-hydroxytryptophan and anti-epileptics like zonisamide, levetiracetam, valproate, clonazepam, and primidone.

Myoclonic epilepsy with ragged red fibres (MERRF)

This maternally inherited mitochondrial disorder has a point mutation in the mitochondrial gene for transfer RNA, the most common being A8344G. There is a combined deficiency of complexes I, IV and III of the respiratory chain. Intention and action myoclonias are the main manifestations with seizures. Cerebellar ataxia, impaired position sense, deafness, mild dementia, optic atrophy, and myopathy are also seen. CSF and plasma lactate are often raised. Muscle biopsy showing ragged red fibres is diagnostic.

Disorders Presenting as Stroke

Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS)

This mitochondrial disorder has mutations in the mitochondrial genome. The onset is between 3 and 35 years (though usually in teenage years) with an abrupt onset of hemiparesis, hemianopia or aphasia, encephalopathy and seizures preceded by migraine-like headaches and vomiting. Epilepsia partialis continua, progressive deafness, short stature, progressive ophthalmoplegia, GI complaints, intellectual and behavioural regression, retinal and cardiac dysfunction are other manifestations. Plasma and CSF lactate is increased. Muscle biopsies show the diagnostic ragged red fibres. Mutation analysis identifies more than 80% of cases and is most commonly A3243G in the mitochondrial genome.

Homocystinuria

This AR disorder is due to a deficiency of cystathione beta synthase localised to chromosome 21. There is an accumulation of homocysteine and methionine and a depletion of cysteine. Onset is in infancy with non-specific developmental delay. The characteristic ectopia lentis and thromboembolic manifestations occur later. High plasma and urine homocysteine levels confirm the diagnosis. Pyridoxine is useful in a third. Other treatments include a low methionine, high cysteine diet with folate and B12 supplementation. Aspirin is used as an antiplatelet agent.

Presenting as Movement Disorder

Wilson's disease

This AR disorder of copper metabolism is associated with mutations in the ATP7B gene. There is an absence of a copper transport protein leading to reduced biliary excretion and accumulation in the liver and tissues like the CNS and cornea.

This is a very common metabolic disorder reported from India (**Table 5**). Onset of hepatic disease is between 3 and 5 years of age though neurologic manifestations come after eight years. It is earlier in the Indian population as the daily intake of copper is high. Acute hepatitis, fulminant hepatic failure, recurrent jaundice, chronic hepatitis and cirrhosis are all manifestations. Neurologic manifestations include a dystonic form with drooling and dysarthria, an akinetic rigid syndrome, a pseudosclerotic form with intention tremor and a choreic form. Resistant rickets, renal tubular dysfunction, acute/recurrent haemolysis, acute psychosis and cataracts are other

manifestations. Presence of the Kayser-Fleischer ring at the corneal limbus, low caeruloplasmin and high urinary copper are suggestive. Treatment with chelating agents like penicillamine, trimethyl tetramine may in many cases cause worsening in neurological presentation of Wilson's disease. Although ammonium tetrahydromolybdate, a new chelating agent is effective and better tolerated it is not yet available for commercial use. Use of zinc acetate has been useful in stabilising neurological manifestations of Wilson's disease. The dosage varies between 50 and 150 mg per day in divided doses depending on the age of the patient. Urinary copper and zinc should be done at least annually for monitoring. Recently free copper estimation in the serum helps in monitoring the copper status during treatment.

Huntington's disease

This autosomal dominant CAG triplet repeat disorder is localised to chromosome 4. The abnormal protein is identified and is named Huntingtin. There is anticipation and the transmitting parent is usually the father. Only 5% to 19% of Huntington's present before 20 years of age. Among them, onset is between 3 and 9 years with a progressive dementia, akinetic-rigid syndrome, dysarthria, and chorea. Occasionally it can present as a progressive myoclonus epilepsy (PME). Slow saccades are characteristic. MRI shows caudate atrophy; positron emission tomography (PET) identifies presymptomatic individuals. Genetic testing (number of CAG repeats) confirm the disease in patients and presymptomatic relatives.

Neurodegeneration with brain iron accumulation (previously called Hallervorden-Spatz disease)

This AR disorder has axonal spheroids similar to neuroaxonal dystrophy (see above). There is destruction of the globus pallidi and substantia nigra with deposition of iron and calcium. Initially they present in late infancy as clumsy ataxic gait. Slowly progressive dystonia and rigidity presents later between 5 and 10 years and the oromotor muscles are maximally involved leading to significant feeding and hence nutritional problems. Mental deterioration and bilateral pyramidal signs come later. Night blindness is due to retinitis pigmentosa and is often early. Calcification in the pallidum and the characteristic 'eye of the tiger' appearance in the pallidum on MRI are diagnostic. Outcome is uniformly poor. Recently trials of treatment with deferiprone, an iron chelator are underway.

Presenting with Dementia and Visual Failure

Juvenile neuronal ceroid-lipofuscinosis (NCL) (see above) and X-linked adrenoleucodystrophy are the two common disorders.

Adrenoleucodystrophy

In this peroxisomal disorder there is impaired ability to oxidise VLCFA due to a deficiency of lignoceroyl CoA ligase. It has been mapped to Xq28. Other types are the adult onset adreno-myeloneuropathy and only adrenal insufficiency without CNS involvement. Onset is between 4 to 8 years with behaviour changes, aggression and scholastic deterioration. Cortical blindness and auditory inattention follow. There may be a skin hyperpigmentation due to the adrenal insufficiency. MRI shows demyelination in the posterior white matter, which enhances with contrast. Low cortisol and a high adrenocorticotrophic hormone (ACTH) are characteristic though not universal. High VLCFA is diagnostic. Prenatal and carrier diagnosis is possible. Lorenzo's oil (erucic and oleic acid) helps normalise the high VLCFA but has little effect on the neurologic deterioration. Mustard oil may be used to replace edible oil in the diet. Carefully selected candidates for HSCT (haematopoietic stem cell transplant) have a good prognosis especially in the pre-symptomatic period of the disease (male relatives of affected boys).

Presenting with Gait Disturbances

The juvenile onset leucodystrophies and the spinocerebellar degenerations are the two major groups of diseases. The former has been touched upon earlier.

Friedreich's ataxia

This disease has been covered extensively in the chapter on cerebellar disorders.

Abetalipoproteinaemia

This AR disorder is confused with Friedreich's ataxia. It is due to reduced apolipoprotein B leading to defective fat absorption and secondary deficiency of fat soluble vitamins. Initially there are features of malabsorption with failure to thrive and bulky stools. Later the vitamin E deficiency leads to ataxia, proprioceptive sensory loss, areflexia and ocular movement abnormalities. There is retinitis pigmentosa with night blindness. Acanthocytes on smear are characteristic. Cholesterol, triglycerides, vitamin A and E levels are reduced. Absent or reduced apolipoprotein B is diagnostic. Vitamin A and E supplementation along with a long chain fatty acid restricted diet halts progression.

Refsum's disease

This AR disorder is due to phytanic oxidase deficiency leading to accumulation of phytanic acid. It presents like an intermittent or progressive peripheral neuropathy, ataxia, retinitis pigmentosa, anosmia and progressive hearing loss. Ichthyosis is common and sometimes a cardiomyopathy is seen. Diagnosis is confirmed with a high phytanic acid. Phytol-free diet reverses the changes. Plasma exchange is used initially in reducing the phytanate load especially during crises.

Kearns-Sayre syndrome

This mitochondrial disorder is associated with mitochondrial DNA deletions. Initially episodes of stupor are seen. A prominent progressive ataxia, external ophthalmoplegia, ptosis and retinitis pigmentosa are characteristic. High CSF protein and sometimes symptomatic heart block are characteristic. High dose vitamins and coenzyme Q are tried but are rarely effective.

Niemann-Pick type C

This AR disorder is due to defective intra-cellular cholesterol esterification and is mapped to 18pll. The less severe, more common form presents at 4 to 5 years with scholastic failure and gait difficulty. Bone marrow shows storage cells e.g. the sea blue histiocyte.

Cerebrotendinous xanthomatosis

This rare disorder is caused by a deficiency of a liver mitochondrial enzyme 27 hydroxylase leading to increased cholestanol and bile alcohols. It is mapped to chromosome 2. There is a slow dementia, juvenile onset cataracts and tendinous xanthomas. A progressive spastic ataxia with a neuropathy occurs in teenage years and early atherosclerosis may lead to vascular events.

DIFFERENTIAL DIAGNOSIS

Developmental disabilities: Includes autism and disintegrative disorders.

Infections: Includes subacute sclerosing panencephalitis (SSPE)

Epileptic encephalopathies: Includes infantile spasms, Lennox-Gastaut syndromes, etc.

Immune mediated encephalitis: Includes NMDA receptor antibody, and voltagegated potassium channel antibody related encephalitis, etc.

PREVENTION

Prevention of these disorders are obviously far more rewarding than treatment strategies in neurometabolic disorders.

Neonatal Screening

TMS done routinely for all neonates may be useful in screening for more than 100 inborn errors of metabolism. Many countries have made it mandatory through government funded programmes. For it to be cost effective large numbers need to be screened. Also treatable disorders are given priority. In our setting screening all high risk newborns, e.g. h/o previous neonatal death, consanguinity, etc. may be a fruitful exercise.

GENETIC COUNSELLING AND PRENATAL DIAGNOSIS

Prenatal diagnosis of a disorder needs: a definitive diagnosis in the previous sibling; and genetic metabolic tests which have a high sensitivity and specificity in the diagnosis of that particular disorder in the Indian population. Chorionic villus sampling (CVS) at ~ 10 to 12 weeks is the preferred option while amniotic fluid sampling is done after 16 weeks if the patient presents later.

20.26 Intra-Cranial Space Occupying Lesions

P Sarat Chandra, PN Tandon

INTRODUCTION

The term space-occupying lesions clinically include neoplastic and non-neoplastic lesions like developmental and parasitic cysts, inflammatory granulomas, chronic abscesses etc, which by their growth produce symptoms and signs (either focal neurological deficits or features of raised intra-cranial pressure). In the following chapter, only the neoplastic lesions will be discussed.

EPIDEMIOLOGY

The incidence of brain tumours is estimated to be about 5–20 per 100,000 population. These affect all ages but with two distinct peaks, one in childhood (3 to 12 years) and another in adults (55 to 65 years). They constitute the second most common malignancy (after leukaemia) in children. Secondaries from systemic, specially breast, lung kidneys, thyroid, are common amongst the elderly, constituting nearly 25% of all systemic cancers. The incidence of primary central nervous system (CNS) lymphoma is on a rise with increasing HIV infection. **Table 1** shows a simplified classification of intra-cranial tumours.

AETIOLOGY AND PATHOGENESIS

Aetiology of neoplastic lesions of the brain is ill understood. Most CNS neoplasms are thought to arise from individual cell mutations. However, a few factors have been shown to be of significance.

- A prior history of irradiation to the head for reasons other than treatment of the diagnosed tumour increases chance of primary brain tumour.
- A few inherited diseases, such as neurofibromatosis, tuberous sclerosis, multiple endocrine neoplasia (type 1), retinoblastoma, and haemangioblastomas as part of Von Hippel Landau syndrome increase the chances to develop CNS tumours.
- Primary CNS lymphoma is a relatively frequent occurrence in HIV patients.
- Metastatic tumours reach the brain via haematogenous dissemination through the arterial system.
  - Lung cancer is the commonest solid tumour metastasising to brain, followed by breast, melanoma and colon cancer,
  - Prostate, uterine, and ovarian cancers are rare sources of brain metastasis.

Recent molecular studies have indicated the role of oncogenes, a variety of growth factors and chromosomal aberrations in the pathogenesis of some of the tumours.

Tissue culture, *in vitro* and *in vivo* labelling studies for cell kinetics, invasive index, chromosomal analysis in tumour tissue, evaluation of specific tumour markers have provided new insights regarding the pathogenesis of some of these tumours. Nevertheless, it must be acknowledged that we are still a long way from understanding the biology of most of the tumours.

Still, molecular diagnosis has become a standard for accurate characterisation of many brain tumours. The neurofibromatosis 2 tumour suppressor gene on chromosome 22q is inactivated in 40% of sporadic meningiomas. A homologous gene, DAL-1 (differentially expressed in adenocarcinoma of the lung), located on chromosome18p11.3 is lost in 60% of sporadic meningiomas. In malignant astrocytomas, there are losses of alleles at loci on chromosomes 1, 9, 10, 13, 17, 19, and 22 along with losses of p53 tumour suppressor genes and deletion of p15, and p16.

Pathophysiology

Tumours of the brain produce neurologic manifestations through a number of mechanisms.

1. By damaging specific neural pathways traversing the brain. Tumours can invade, infiltrate, and supplant normal parenchymal tissue, disrupting normal function.
2. The growth of intra-cranial tumours with accompanying oedema leads to raised intra-cranial pressure.
3. Tumours proximal and/or close to the third, lateral and fourth ventricles may obstruct the flow of cerebrospinal fluid, leading to hydrocephalus.
4. In addition, tumours generate new blood vessels (i.e., angiogenesis), disrupting the normal blood-brain barrier and promoting oedema.

The cumulative effects of tumour invasion, oedema, and hydrocephalus elevates the intra-cranial pressure (ICP) and impairs cerebral perfusion. Intra-cranial compartmental rise in ICP may provoke shifting or herniation of tissue under the *falx cerebri*, through the *tentorium cerebelli*, or through the foramen magnum.

Slow-growing tumours, particularly tumours expanding in the so-called silent areas of the brain, such as the frontal lobe, may be associated with a more insidious course. These tumours tend to be larger at detection.

Some tumours may predominantly present with epilepsy without any features of neurological deficits and raised intra-cranial pressure (ganglioglioma, dysembryonic neuro-epithelial tumours, cavernous malformations).

Most primary brain tumours do not metastasise. Rarely, when neural element tumours metastasise, intraparenchymal metastasis occurs much earlier than distant haematogenous dissemination via the arterial system.

Metastatic brain tumours from non-CNS primary tumours may be the first sign of malignancy, or they may herald a relapse. Nonetheless, the signs and symptoms of brain metastases simulate those of primary brain tumours.

Table 1: Classification of Intra-Cranial Tumours Neoplastic Lesions (modified from WHO Classification, 2000)

Neuroepithelial (Neuroectodermal)	Tumours arising from the structures of the brain, e.g. glial, neurons, etc.
Astrocytoma	
Oligodendroglioma	
Ependymoma	
Mixed Gliomas	
Choroid Plexus tumours	
Uncertain origin	
Neuronal and mixed Neuronal/Glial	
Pineal Parenchymal	
Embryonal	
Tumours of nerve sheath	Tumours arising from the covering of the nerves
Schwannoma	
Neurofibroma	
Malignant (peripheral) nerve sheath tumour	
Tumours of the meninges	Tumours arising from the covering of the brain
Meningioma	
Mesenchymal (not meningothelial)	
Benign	
Malignant	
Haemangiopericytoma	
Primary melanocytic lesions	
Lymphoma	Tumours arising from lymphocytes, usually of B cell lineage
Germ cell tumours	Tumours arising from germcells of CNS (similar to dysgerminoma of testis)
	germinoma
Cysts and tumour-like lesions	
Rathke cleft cyst	
Epidermoid cyst	
Dermoid cyst	
Colloid cyst	
Tumours of the sellar region	
Pituitary adenoma	
Craniopharyngioma	
Local extension of regional tumours	
Metastatic	
Unclassified	

CLINICAL FEATURES

Brain tumours as a rule, present with an insidious onset and progressive course. Infrequently, a tumour may manifest like a stroke, generally secondary to haemorrhage in the tumour. Rarely, there may be spontaneous remissions and exacerbations. The clinical features depend upon the age of patient, location of the tumour, its nature and rate of growth, and its effect on the cerebrospinal fluid (CSF) pathways. Brain tumours cause symptoms and signs by raising the ICP, interfering with the function of the region of brain involved. This may be either irritative or paralytic. As neuronal function is organised in a hierarchical manner, damage to one region may result in the manifestation of release symptoms and signs from a lower region. Clinical features may arise due to disturbance of function of neighbouring structures on account of oedema and vascular disturbances, or by displacement and distortion of remote structures due to foraminal herniations.

Raised Intra-Cranial Pressure

The bulk of neoplasm, oedema provoked by it and the extent of disturbance of CSF dynamics, singly or jointly, raise the ICP.

Headache

It is by far the most common symptom.

- Headache is the worst symptom in nearly 50% of patients.
- Most headaches in patients with brain tumours are non-specific and resemble tension-type headaches.
- A change in any patient's headache pattern should be cause for concern.
- New onset of headache in middle-aged or older patients should be investigated.
- The location of headache may indicate the side of the brain affected, but it does not indicate the precise site of tumour.
- Pituitary tumours confined to the sella cause midline vertex headaches.
- Typically headache is intermittent initially and becomes progressively more severe and persistent. It is only in very severe cases that it assumes the characteristic 'brain tumour' headache: often worse on waking up in the morning, interferes with sleep, throbbing in character, becomes worse on straining or exertion, usually diffuse, and relieved on vomiting.
- Tumours situated anteriorly tend to produce frontal and retro-orbital pain in the territory of trigeminal nerve. Tumours situated posteriorly or in the posterior fossa produce occipital pain in the distribution of the second cervical nerve.
- Suboccipital and nuchal pain, with or without associated neck stiffness, is of grave omen, being a manifestation of foraminal herniation.
- Vomiting is a frequent symptoms of raised ICP, but it may or may not be associated with nausea and often occurs at the peak of headache. It may be the initial or only symptom of a brain tumour in children, especially those with midline tumours in the posterior fossa, i.e. medulloblastoma or ependymoma.

Papilloedema

It is the swelling of the optic disc and, is clinically an unequivocal sign of raised intra-cranial pressure. It appears late in children in whom the skull can expand. It is also delayed in cases of slow growing tumours like meningiomas and neurofibromas. It appears early in rapidly growing tumours like gliobastomas and midline cerebellar tumours like medullo-blastomas. It may not manifest any symptom, in early stages but could progress rapidly to produce blindness with or without episodes of transitory visual obscurations. Its early detection is of paramount importance, to prevent irreversible visual loss. Hence the golden clinical rule of examining the fundus of each and every patient presenting with a neurological illness.

Optic atrophy

Persistent papilloedema leads to secondary optic atrophy even after the raised pressure is relieved by removal of the tumour. The visual loss may be irreversible.

Abducens palsy

Unilateral or bilateral abducens nerve palsy resulting in diplopia and paralytic squint is one of the most common false-localising signs of raised ICP and occurs due to stretching of both the nerves over the petrous bones ('pulled like the reigns of the horse') due to the descent of the brainstem, due to raised ICP.

Disturbance of higher mental functions like concentration, memory judgment and behaviour may result from raised ICP. With increasing ICP sensorial disturbances result, such as apathy, drowsiness, stupor and coma.

A tumour can produce focal symptoms and signs directly by destroying the neural tissue, by compressing it , by displacing or distorting it, or indirectly by involving a functionally eloquent area in secondary changes like oedema and vascular changes. These may result in irritative (epileptic) or paralytic manifestations.

Epilepsy

Seizures, focal or generalised, may be the earliest expression of a brain tumour.

- A 'Jacksonian pattern' (originally described by Hughlings Jackson), though uncommon yet strongly diagnostic of a focal structural lesion of the cortex. Here a focal seizure begins in one extremity and then progresses until it becomes generalised.
- Depending on the rate of growth of the tumour, seizures may be present for months to years before a brain tumour is diagnosed.
- Any middle-aged or elderly patient presenting with a first seizure should have CNS tumour high in the differential diagnosis.
- Patients with a brain tumour may present with acute neurologic changes mimicking those associated with stroke.

Mental status changes

Especially memory loss and decreased alertness, may be subtle clues of a frontal lobe tumour. Complaints may be as mundane as sleeping longer, appearing preoccupied while awake, and apathy.

Focal Neurological Deficits

- Tumours arising close to the motor and/or sensory strip present with progressive hemiparesis and sensory disturbances. Likewise tumours arising from language areas present with expressive aphasia (from left frontal opercular 'Broca's area') or with difficulty of comprehension (from left posterior temporal 'Wernicke's area').
- Temporal lobe neoplasms may lead to depersonalisation, emotional changes, and behavioural disturbances.
- Loss of smell strongly suggests a olfactory groove meningioma or basifrontal glioma (Foster Kennedy syndrome: optic atrophy with loss of smell).
- An acoustic neuroma may present as intermittent (then progressive) hearing loss, disequilibrium, and tinnitus.
- Symptoms of paediatric posterior fossa tumours include increased irritability, unsteadiness, ataxia, headache, vomiting, and progressive obtundation.
- Supratentorial tumours in children are more commonly associated with seizures, hemiparesis, visual field cuts, speech difficulties, and intellectual disturbance.
- Pituitary adenomas may be divided into two broad categories: nonfunctional and hypersecretory. Nonfunctional pituitary adenomas remain asymptomatic until they are large enough to encroach upon the optic chiasm and disturb normal vision. Most hypersecretory pituitary adenomas secrete prolactin, with affected women noting an amenorrhoea-galactorrhoea syndrome. Men with prolactin pituitary adenomas more commonly complain of headache, visual problems, and impotence.

Deformity of the skull, seen as generalised enlargement due to hydrocephalus or localised bulge in association with an arachnoid cyst in children, may occasionally be a presenting feature. Hyperostosis of the skull overlying a meningioma can at times produce a visible swelling. Lytic lesion of the skull with extra-cranial extension of the tumour is occasionally seen in cases of meningioma and rarely gliomas. Extension of a tumour along the optic nerve or through the superior orbital fissure may produce proptosis.

INVESTIGATIONS

Before ordering any investigation, it is essential to ascertain the site of the tumour on the basis of a careful neurological examination. This helps to plan appropriate investigations.

X-ray skull, even though hardly used nowadays can often provide useful information regarding the presence of a tumour and its site and nature, particularly in areas which have inaccessibility to a computerised axial scans (CT) or Magnetic Resonance Imaging (MRI) scans. Evidence of raised ICP should arouse suspicion of a tumour, e.g. bony changes, hyperostosis associated with meningiomas, ballooning of sella in cases of pituitary tumours, enlargement of internal acoustic meatus caused by acoustic neuromas or of optic foramen by an optic nerve glioma are a direct evidence of a specific tumour.

Plain X-ray may reveal calcification, which may be a tell-tale evidence of tumour.

Displacement of physiological calcification in midline structures like the pineal could suggest the side of a tumour.

With the availability of more sensitive and specific investigations like CT and MRI scans, the routine use of skull X-rays has become redundant, for all practical purposes. CT scan with contrast enhancement and MR imaging not only reveal the tumour, but also its precise site, size and often the nature, the extent of associated oedema, cystic degeneration, and the status of CSF pathways. MRI is preferred when a neoplasm is suspected to be near a dense bone, e.g. acoustic neuroma, tumours in the region of the foramen magnum, microadenomas of the pituitary. Similarly, small tumours in the brainstem or spinomedullary junction are better delineated in an MR study. Use of MR spectroscopy may help to determine the nature of the tumour.

Functional MR (fMRI) imaging would provide a precise relationship of the tumour to important functional regions of the brain like speech area or sensorimotor strip which help in better planning of surgery.

More recent MR imaging techniques have vastly enhanced the accuracy for diagnosis of tumours, cystic lesions and the associated brain involvement, e.g. Fluid attenuation inversion recovery sequence (FLAIR) shows the effect of fluid on the lesions. Diffuse tensor imaging (DTI) enables visualising white matter fibres in the brain and can map (tractography) subtle changes in white matter and provide its relationship to the tumour.

Cerebral angiography which was once a sheet anchor of diagnosis is now used to assess the anatomical relationship to the major vessels or to assess the vascularity of a tumour in case pre-operative embolisation is planned. MR angiography can provide a lot of this information.

A detailed neuro-ophthalmic examination and estimation of serum levels of appropriate hormones is essential for all patients with pituitary adenomas or craniopharyngiomas.

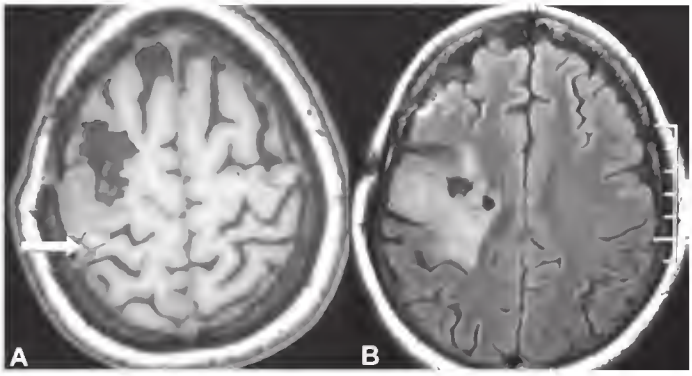
Neuro-otological investigations, including brainstem-evoked potentials (BAER), help to determine the damage in cases of acoustic neuromas. Pneumoencephalography and ventriculography are now only of historical interest.

MANAGEMENT

Early diagnosis is a prerequisite for good results. Once an important function like vision, hearing or speech is impaired or lost, even successful removal of the tumour would not resolve these functions. In our country where inflammatory lesions constitute a significant, percentage of all intra-cranial space occupying lesions, it is necessary to be alert, to this possibility since many of these; especially tuberculomas can be satisfactorily treated medically. Whenever in doubt, it is necessary to establish a histological diagnosis. Surgery, with or without radiotherapy, is the treatment of choice for a majority of neoplastic lesions. Wherever possible, total removal or maximal possible cytoreduction (especially in case of gliomas) is desirable.

Most tumours are associated with raised ICP due to brain oedema or hydrocephalus. Pre-operative use of diuretics and corticosteroids help to relieve oedema. In the event of severe rise of ICP due to hydrocephalus, especially associated with midline tumours in patient in poor general condition, external ventricular drainage or ventriculo-peritoneal shunt can be life-saving and reduce the risks of surgery. Microsurgical techniques with ultrasonic suction have markedly improved the results of surgery. The role of radiation, chemotherapy and immunotherapy is decided on individual basis. Surgery on very vascular meningiomas can be made safer by pre-operative vascular embolisation using interventional neuroradiological techniques. The residual tumour following incomplete surgical removal can now be treated with radio-surgery.

Many brain tumours may be safely operated with morbidity and mortality being same as surgery for any other part of the brain. Advances in imaging, neuroanaesthesia, operating techniques (operating microscopes, ultrasonic aspirators, brain mapping techniques, neuronavigation and stereotaxy) has now allowed surgery of tumours located in most difficult areas (mortality of 1% to 2%). However, malignant astrocytomas and glioblastoma multiforme (GBM) still carry a grim outlook. Surgery is the first consideration for supratentorial tumours (gliomas, meningiomas, ependymomas), posterior fossa tumours (medulloblastomas, ependymomas), para/intra-ventricular tumours (ependymomas, choroid plexes papillomas, pineal regions tumours) and pituitary region tumours (pituitary adenomas, craniopharyngiomas). However, the approach depends on the size and location of the tumours, e.g. pituitary tumours may be removed both through a trans-sphenoidal and a trans-cranial route.



For benign tumours removed completely, e.g. meningiomas and low grade gliomas there is no need for adjuvant treatment. However, tumours like GBM require full adjuvant treatment like radiotherapy and chemotherapy.

Contrary to earlier beliefs, even tumours in the neighbourhood of eloquent areas of the brain and those already causing neurological deficit like dysphasia or motor paralysis can be successfully treated with improved and not worsened deficit. Thus, maximal tumour removal, i.e. cytoreduction, remains the most important part of the therapeutic strategy. However, deep seated tumours and those involving optic pathways, basal ganglia and brainstem continue to pose a therapeutic challenge. Stereotactic biopsy followed by radiotherapy remains the mainstay of their management.

COMMON TUMOURS

Gliomas

Gliomas are the most common intra-cranial neoplasms, constituting 35% to 50% of all brain tumours. They may arise in any part of the brain, the supratentorial ones being the most frequent. They are a heterogeneous variety of tumours with varying grades of malignancy, the juvenile cystic astrocytoma being the most benign and glioblastoma the most malignant. The majority of cerebral gliomas are located in the frontal, temporal and parietal lobes. These spread by contiguity, often crossing the midline, but rarely metastasise outside the cranial cavity. Astrocytomas (**Figures 1A and B**), mixed gliomas and oligodendrogliomas are slow-growing tumours but may suddenly begin to grow rapidly and exhibit all the characteristics of a GBM.

Figures 1A and B: (A) Shows a low grade glioma (grade II) which is hypointense on T1 weighted MRI and not enhancing on contrast. The functional MRI study showed the leg activity much behind the tumour (arrow) which gave useful information to the neurosurgeon to allow complete resection. The patient was doing well at 4 years of follow-up and did not require radiotherapy, (B) shows the FLAIR (fluid attenuation inversion recovery sequence) which shows an accurate extent of tumour.

Glioblastoma is a very rapid growing tumour with an average life expectancy of 3 to 4 months without treatment and less than a year in spite of all therapy. CT scan with contrast enhancement and MR scan with gadolinium enhancement delineate these tumours well showing areas of necrosis, with severe oedema.

One of the greatest challenges of glioma therapy is the virtual inevitability of their recurrence. A variety of radiotherapy schedules, a number of chemotherapeutic protocols and experimental trials of immunotherapy, gene therapy and even stem cell therapy are being evaluated currently.

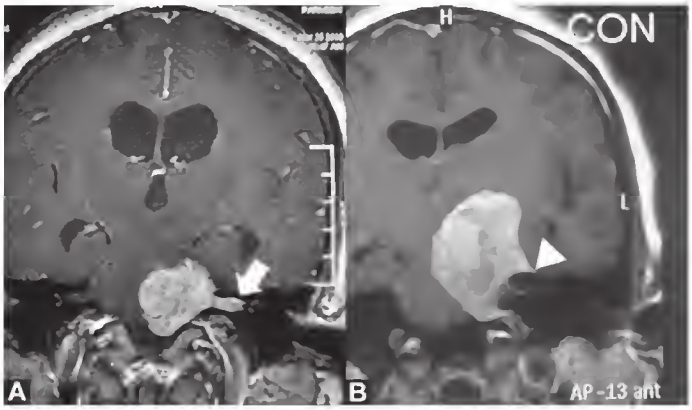
Medulloblastoma

It is a tumour of childhood, constituting 20% to 25% of all paediatric brain tumours. It commonly affects the cerebellar vermis, and is a highly cellular tumour. It usually presents with a short history of headache, vomiting and truncal ataxia. CT scan reveals a well-circumscribed enhancing tumour in the vermis, involving the fourth ventricle and producing hydrocephalus. Treatment consists of surgery followed by chemotherapy; 40% to 70% of patients survive for 5 years and 25% to 40% for 10 years.

Cerebellar Astrocytoma

It is a distinct clinical entity mostly occurring in children. It is often possible to completely excise these tumours, resulting in virtual cure. Recurrence may, however, occur after many years following subtotal removal. Radiotherapy and chemotherapy are not indicated.

Ependymomas



They arise from, ependymal cells lining the primitive central canal and hence occur in close proximity to the ventricular system. These constitute 5 per cent of all gliomas and two-thirds are situated infratentorially, the fourth ventricle being the commonest location. They have a tendency to disseminate along the CSF pathways to the spinal cord. Treatment consists of maximal tumour removal followed by radiotherapy.

Oligodendroglioma

Oligodendroglioma constitute approximately 5% to 7% of all primary brain tumours. Majority of these tumours are supratentorial predominantly affecting the frontal lobes. These tumours grow relatively slowly. A quarter to one-third of them show calcification on plain X-ray of the skull. The treatment consists of radical surgical excision as possible followed by radiotherapy.

Acoustic Schwannoma

It is also called acoustic neuroma or neurinoma, arises from the vestibular nerve. They constitute approximately 8% of all intra-cranial tumours. They commonly occur between the fourth and sixth decade of life, with a slight female preponderance. A majority of these tumours are sporadic and unilateral, but 5% to 10% may be bilateral as a manifestation of von Reckling hausen's neurofibromatosis. The tumour arises in the internal auditory meatus and extends into the cerebellopontine angle. The signs and symptoms are initially those referable to the eighth nerve, i.e. tinnitus, hearing impairment and vestibular dysfunction. As the tumour enlarges, it involves the facial, trigeminal and much later glossopharyngeal and vagus nerve. Large tumours also manifest signs and symptoms of cerebellar and brainstem involvement. Raised ICP is a late feature seen only with large tumours. It is possible to diagnose these tumours when they are small and still restricted to the acoustic meatus by brainstem auditory-evoked potential (BAER), CT and MR scan with gadolinium enhancement (**Figures 2A and B**). The aim of surgery is to achieve total excision with preservation of the facial and as far as possible the eighth nerve using microsurgical techniques; this is possible only in case of small tumours. One of the most gratifying advances in brain tumour surgery is in acoustic neurinomas. Utilising micro-surgical techniques it is now possible to save the facial nerve in 80% to 90% of tumours less than 3 cm in diameter and 60% to 70% of even larger tumours. Hearing preservation is also being increasingly achieved. With the advances in neuroimaging it is now possible to diagnose small tumours (<3 cm), which can be successfully treated with stereotactic radio-surgery using gamma-knife or Linnac. With advances in micro-surgery and skull base surgery it is now possible to completely excise even large tumour with a mortality of <5%, preservation of facial nerve in 60% to 70% and even the eighth nerve function in some.

Figures 2A and B: MRI (with gadolinium contrast) shows an acoustic tumour (A) Note that this tumour is well demarcated from the surrounding brainstem enhancing homogenously and well with contrast with an extension into the internal acoustic meatus (arrow). This is to be differentiated from a meningioma, (B) which too enhances well with contrast but has a wide attachment to the meninges 'dural tail' (arrow head) and has no extension into the internal acoustic meatus.

Meningiomas

These are the most common benign tumours of the brain, constituting about 10% to 15% of all intra-cranial neoplasms. They are generally located in the neighbourhood of major dural venous sinuses. They mostly occur in the middle decades of life, more often in females. This may not be possible (due to the very large size of tumour or its close relationship to vital structures, such as the optic nerve, the brainstem, a major venous sinus or the Circle of Willis. Small tumours (<3 cms in size) on residual tumour after subtotal resection can be successfully treated with stereotactic radio-surgery. These tumours are generally very vascular. The clinical picture depends upon the site and size of the tumour. Focal epilepsy and slowly progressive neurological deficits often precede symptoms and signs of raised ICP. A tumour may remain asymptomatic till it attains a large size. Occasionally these may be multiple and rarely malignant. Plain X-ray skull may reveal hyperostosis, lytic lesions, enhanced vascular markings and tumour calcification. CT scan reveals a well circumscribed hyperdense or isodense tumour with significant contrast enhancement. MR angiography may be utilised to determine the vascular anatomy in relation to the tumour. Cerebral angiography may be useful for selected

patients. Total surgical excision is the ideal treatment. This may not always be possible in which case the residual tumour may be treated with radiotherapy.

Pituitary Tumours

These constitute 8% to 12% of all intra-cranial neoplasms. The most common pituitary tumour is an adenoma arising from the anterior pituitary.

The functional tumours often produce clinical symptoms of endocrinopathies while they are still small (microadenomas) and restricted within the sella. Only when a tumour grows outside the sella can it compress the optic chiasm and nerves; the optic chiasm is situated 8 to 13 mm above the diaphragma sellae. A variety of visual field defects have been observed, the most common being bitemporal hemianopia, either incomplete or complete. As the tumour progresses it may result in primary optic atrophy and blindness. If the tumour invades the cavernous sinus it may produce oculomotor nerve palsies. A very large tumour may press on the hypothalamus, further aggravating the endocrinal dysfunction and producing behavioural and sensory disturbances. Management of these tumours requires careful evaluation of endocrinal and visual status. Medical therapy using bromocriptine or other dopamine agonists is the first-line of treatment for prolactinomas. Trans-sphenoidal surgery is indicated if the tumour is unresponsive to dopamine agonists, or the patient cannot tolerate these, as also for patients with rapid progression of visual loss. Octreotide, a cyclic octapeptide analogue of somatostatin, has been extensively used for the treatment of acromegaly or as an adjuvant to surgery if the growth hormone levels remain high post-operatively. For most other tumours trans-sphenoidal surgery is the treatment of choice, unless the tumour is very large or has atypical extension (temporal or retroclival) when transcranial surgery is preferable.

Radiotherapy is reserved for patients with incomplete tumour removal. Instead of conventional radiotherapy stereotactic radiosurgery is being used to treat residual tumours, selected tumours in place of surgery, or recurrent tumours). Hormone replacement is required post-operatively for patients with hypopituitarism.

Craniopharyngiomas

They are the commonest intra-cranial tumours of childhood. They constitute 3% to 5% of ICSOL at all ages and 12% to 15% of tumours in childhood. They can occur in adults as well. These tumours are located mainly in the suprasellar region, though they can occur anywhere along the infundibulum. They are predominantly cystic in nature with a high incidence of calcification. Clinically they manifest with features of raised ICP, endocrinological deficits and visual symptoms. Short stature, obesity and hypogonadism with delayed sexual development characterise the patients in the paediatric age group. In adults gonadal failure leads to loss of libido and secondary amenorrhoea. Visual impairment, papilloedema, primary or secondary optic atrophy and visual field defects are observed. Plain X-ray skull, by revealing characteristic changes in the sella and tumour calcification, is diagnostic in 70% to 80% of paediatric patients. CT or MR scan confirm the diagnosis. Complete endocrinal evaluation is necessary. Large tumours need surgical excision. Alternative treatment modalities like stereotactic aspiration of predominantly cystic tumours, followed by instillation of radioactive agents, or radio-surgery for small, solid tumours have provided gratifying results in selected cases. Hormone replacement, both pre and post-operatively, is necessary.

Pineal Region Tumours

Tumours in the pineal region constitute a distinct clinico-pathological entity. They account for only 1% of all intra-cranial neoplasm and often present with a characteristic clinical syndrome - 'the pretectal' or 'Parinaud's syndrome.' By pressure on the tectum, they produce vertical gaze palsy (restriction of upward gaze), binocular impairment of papillary light reflex and convergence retraction nystagmus. Some of these manifest endocrinal syndromes like precocious puberty, diabetes insipidus, hypogonadism or panhypopituitarism. Raised ICP due to hydrocephalus is present in a majority of these patients. Owing to their strategic location they present a challenge for surgical excision. Stereotactic biopsy and radiotherapy provide alternative strategy.

RECENT ADVANCES

Recent advances in neuroimaging, improved anaesthetic and intensive care management, use of new technologies, such as micro-surgery, image guided or frameless stereotactic surgery, interactive image-guided surgery using pre-operative CT/MR, use of endoscopes have dramatically improved the management of brain tumours, even those strategically located. Tumours located in eloquent areas (e.g. motor/sensory or language areas) now undergo accurate localisation of these areas using modalities like functional MRI, intra-operative brain mapping and be operated under awake conditions. Intra-operative MRI is another recent tool that allows the surgeon to visualise residual tumour in the operating room itself by performing an MRI on table and is useful particularly for performing total resection in low grade gliomas. The overall post-operative mortality has come down to negligible levels. The post-operative morbidity has been minimised.

Gene therapy for gliomas is showing a promising future. Herpes simplex virus-thymidine kinase gene therapy reached the most advanced (phase 3) of all gene therapy methods in clinical trials for glioblastoma multiforme. There was reduction in the size of the tumour with prolongation of life, but the tumours still grew and the patients died. The development of this therapy was discontinued because of lack of significant efficacy. Several modifications of viral-vector mediated gene therapy are still in clinical trials. Unfortunately a cure for gliomas is not in sight. While there is a place for technological advances, there is even greater need for research on biology of these tumours.

20.27 Head Injury

AK Singh

DEFINITION

There is no agreed definition of head injury for epidemiological purposes. Anatomically, head refers to the scalp, skull, meninges, blood vessels and brain, i.e. all the structures above lower jaw. Trauma to any of these structures, technically, should be called head injuries, but traditionally, maxillofacial trauma is considered separately from head trauma. The term 'craniocerebral trauma' is the closest to clinical usage.

EPIDEMIOLOGY

Deaths from Trauma

Injuries are a leading cause of deaths. In 1998, about 5.8 million people died of injuries worldwide and they constituted 16% of global disease burden. India with 1% of world vehicles accounts for 6% of global road accidents. India also has a disproportionately high death rate from road accidents – at 29 per 100,000 people it is double to that of developed nations. India records 35 incidents per 1,000 vehicles, amongst the highest in the world. Head trauma is present in majority (76% according to a Mumbai study of 2004) of polytrauma victims with severe Traumatic Brain Injury (TBI) present in 47%.

Causation

Road traffic accidents are the leading causes (60%), followed by falls (20% to 25%) and violence (10%). According to Delhi police records, in road accidents, 41% of victims are pedestrians, 27% two wheeler drivers/riders and 14% pedal cyclists. Alcohol intake is reported in 15% to 20% at the time of injury.

Cost

The estimated cost of road accidents in India is 3% of gross domestic product (GDP). Costs are direct and indirect. Direct cost is the monetary value of real goods and services that were provided for health care and indirect costs are the monetary loss incurred by society because of interruption of productivity by the injured person. The family which provides the support in the recovery phase also suffers significant monetary loss besides the emotional trauma and the physical effort required for providing such care.

PATHOMECHANICS

A traumatic impact on head is a physical event that disrupts tissues, which either injures the tissue directly or starts a biochemical cascade leading to brain injury. Traditionally, we divide brain injury into primary (e.g. skull fractures, mass lesions and tissue tears) and secondary brain injuries [raised ICP and its effect and hypoxia-ischaemia, but in injuries such as diffuse axonal injuries the cascade of molecular events is common and in secondary white matter changes; only our current imaging methods are unable to show them. Some basic physical terms that are needed and used for understanding the pathomechanics are described as follows.

Mechanical Concepts

Impact, impulse and force

Impact is a type of impulsive loading. The two can accelerate a stationary head or decelerate a moving head. Mostly an impact on the head will lead to skull deformation or fracture and associated brain injuries. The magnitude of force applied to the head in an impact is a function of the mass and velocity of the striking object.

Mass

Other things (stiffness and impact velocity) being equal to the ratio of the mass of the object striking, or struck by, the head to the mass of the head itself determines the head acceleration produced by the impact.

Impact velocity

The mass and the impact velocity of the head determine the energy that must be managed to prevent head injury in an impact. There is no physical difference between the forces involved in a stationary head being hit or a moving head striking a fixed object, the other parameters being the same.

Stiffness

Stiffness is different from hardness. The less a spring deflects under a load, the stiffer it is said to be. On the other hand, a pane of glass is very hard on the surface, but will bend easily when loaded. It has low stiffness.

Moving head

Mechanism and extent of head injury depend on whether the head is free to move when stuck. If head is not free to move the entire crushing force is spent in site of impact leading to greater crush injury.

Acceleration of head

If the line of action (the vector) of the impacting force passes through the centre of gravity of the head, the head will accelerate without rotation. But if the vector passes eccentrically, the head will rotate in addition to being accelerated.

Stress

Stress is force per unit area. Mechanical stress is produced in skull and brain by an impact and the consequent head acceleration.

Strain

It is the response of the material being stressed. It is measured in terms of the proportional change in length in the direction of the tensile or compressive stress.

Shearing force

Shearing stress is force per unit area with the area measured in plane of the force. Shearing strain is proportional displacement measured in terms of the material's thickness.

Injuries to Head on Impact

Skull fractures

They can be grouped into three types: penetration fractures at impact site; comminuted fractures at site of impact; and linear fractures remote from impact site (Melvin and Evans, 1971). If the surface area of impacting object is less than one square inch, depressed fractures result with fracture starting at the external table and the diploe failing under the compressive load of the impact. If the loading of skull exceeds the minimum failure level of the diploe (approximately 1500 psi), a penetrating fracture results. Remote linear fractures usually result when the blunt trauma occurs to head. Base of skull fractures are such fractures. These are probably due to local outbending of the skull, remote from the site of impact. Once initiated, the fracture progresses bilaterally towards and away from the site of impact. For this to happen, however, the skull had to withstand local bending at impact site otherwise a depressed fracture will result.

Focal brain Injuries at the site of impact

Local skull deformation at the site of impact often causes direct damage to underlying brain. This occurs almost always with depressed fractures but even the minor indentation of skull in the first few milliseconds of the impact can compress the underlying brain even though the skull may return to its original position with no external evidence of bony deformation. These injuries are called coup injuries.

Remote focal brain injury

Contrecoup is an injury to brain on the far side of the impact site on the head. Possibly these are the results of rapid and localised pressure changes near the brain surface due to cavitation effects due to movement of brain relative to cranial cavity; brain and skull have different physical characteristics of deformation. In case of occipital impacts, however, it is possible that the remote injuries to basal frontal and temporal regions are the result of movement of brain against the irregular bony anatomy of those areas.

Multifocal and diffuse injuries

Holbourn in 1943 hypothesised that the brain is effectively incompressible. Thus pure linear acceleration could not deform brain, but angular acceleration, however, will setup shear strains within brain, thus causing injuries. These are diffuse axonal injuries and injuries to neurovascular structures. Holbourn's hypothesis has been validated by many researchers.

PATHOLOGY

Traumatic brain injuries are classified as primary, due to mechanical deformation of tissues, or secondary, due to various complications of primary mechanical injuries like brain damage.

Primary Traumatic Brain Injuries

- Diffuse/multifocal
  - Diffuse axonal injury (DAI)
  - Diffuse vascular injury (DVI)
- Focal
- Vascular injury resulting in
  - Intra-cerebral haemorrhage
  - Subdural haemorrhage
  - Extradural (epidural) haemorrhage
  - Subarachnoid haemorrhage
- Axonal injury
- Contusion: A complex dynamic evolving time dependent neural tissue injury involving vascular, glial, neuronal injury along with secondary oedema and ischaemia
- Laceration

Secondary Brain Damage/Injuries

- Diffuse
  - Diffuse hypoxic-ischaemic damage
  - Diffuse brain swelling
- Focal
  - Focal hypoxic-ischaemic injury
  - Focal brain swelling

PATHOPHYSIOLOGY OF TRAUMATIC BRAIN INJURIES

Brain is contained within the skull, a rigid and inelastic container. Only small increase in volume within the intra-cranial compartment can be tolerated before pressure within rises dramatically. This concept was defined by the Monro-Kellie doctrine, which states that the total intra-cranial volume is fixed because of the inelastic nature of the skull. In an adult, the intra-cranial volume is approximately 1,500 ml, of which the brain accounts for 85% to 90%; intravascular cerebral blood volume accounts for 10%; and cerebrospinal fluid (CSF) accounts for the remainder (<3%). When a significant head injury occurs, cerebral oedema often develops, which increases the relative volume of the brain. As the intra-cranial volume is fixed, the pressure within this compartment rises unless some compensatory action occurs, such as a decrease in the volume of one of the other intra-cranial components. This is intimately related to the concept of intra-cranial compliance, which is defined as the change in pressure due to changes in volume.

Simply stated, the brain has very limited compliance and cannot tolerate significant increases in volume that can result from diffuse cerebral oedema or from significant mass lesions, such as a haematoma. The rationale for each treatment of head injury is based on the concept of the Monro-Kellie doctrine and how a particular intervention affects the intra-cranial compliance. When the volume of any of the components of the total intra-cranial volume is decreased, the ICP is reduced.

A second crucial concept in TBI pathophysiology is the concept of cerebral perfusion pressure (CPP). The CPP is defined as the difference between the mean arterial pressure (MAP) and the ICP. In practical terms, CPP is the net pressure of blood delivery to the brain. In the noninjured brain in individuals without longstanding hypertension, cerebral blood flow (CBF) is constant in the range of MAPs of 50 to 150 mm Hg. This is due to autoregulation by the arterioles, which will constrict or dilate within a specific range of blood pressure to maintain a constant amount of blood flow to the brain. When the MAP is less than 50 mm Hg or greater than 150 mm Hg, the arterioles are unable to autoregulate and blood flow becomes entirely dependent on the blood pressure, a situation is defined as 'pressure-passive flow'. The CBF is no longer constant but is dependent on and proportional to the CPP. Thus, when the MAP falls below 50 mm Hg, the brain is at risk of ischaemia due to insufficient blood flow, while a MAP greater than 160 mm Hg causes excess CBF that may result in increased ICP. While autoregulation works well in the noninjured brain, it is impaired in the injured brain. As a

result, pressure-passive flow occurs within and around injured areas and, perhaps, globally in the injured brain. While passive damage is instantaneous, secondary brain insults occur from hours to several days after TBI and significantly alter the prognosis.

BIOCHEMICAL CHANGES

Transient mechanical microporation, cell rupture, activation of voltage and ligand gated NMDA channels and ischaemia result in entry of Ca^{++} and Na^{+} inside cells and egress of potassium ions from cells and altered state of consciousness. Even in concussive states without significant parenchymal damage, the concentration of extracellular K^{+} is increased by 50 fold. There is a direct relationship between extracellular potassium and mortality. Excess potassium in extracellular fluid (ECF) is sequestered by the glial cells, leading to swelling of the astrocytic footplates, cytotoxic oedema, increased ICP and secondary ischaemia. Disturbance of calcium homeostasis through inward movement of Ca^{++} results in metabolic cascades with dire consequences. Elevated levels of calcium in cytosol results in multimeric transformation of proteins in mitochondrial outer membrane and formation of mitochondrial permeability transition pore (MPTP). The MPTP allows abnormal concentrations of calcium in the mitochondrial matrix, disturbance of electron transport, formation of reactive oxygen species and activation of lipases, proteases and endonucleases, hence enhanced cell necrosis. Release of apoptogenic protein from mitochondria, along with intrinsic pathways, signal activation of apoptotic processes result in programmed cell death. Abnormal concentrations of Ca^{++} into the axons activate calpain-mediated cytoskeletal damage and axonal transport. The long-term effect of cytoskeletal damage is axotomy and Wallerian degeneration.

CLINICAL EXAMINATION AND GRADING

Severe closed head injuries are nowadays routinely investigated by an early CT scan, which visualises most pathological lesions of immediate surgical importance. In neuro ICUs, it is also a routine to monitor ICP and other neurophysiological parameters to better calibrate medical and surgical management. So is there any role, nowadays, for clinical neurology in traumatic brain injuries? The initial clinical assessment is still very crucial for triage and as a baseline for assessing progress for often the development of clinical symptomatology is more helpful in deciding what line of treatment to follow. Prognosis depends, to a large extent, on initial examination findings. Further, neuroradiological findings must be interpreted in light of clinical findings. Thus, neurological examination of head injury patients remains indispensable. However, modern strategies of severe head injury management have enforced a very basic change in the nature of this examination; early endotracheal intubation is established as an independent prognosticator for recovery from TBI. Therefore, the first neurological examination is now usually performed at the accident site or in the emergency room by someone with no special training in neurology, i.e. the paramedic, the intensivist or the emergency physician who must be, therefore, competent in performing an appropriate neurological examination before intubation and respiratory paralysis are started. This means that such people must be skilled in making a few basic neurological observations and recording them faithfully. These observations are done in two stages. The primary survey records, amongst other things, the consciousness level and the pupillary response (**Table 1**). If intubation is needed, a quick assessment of limb movements must be done.

Table 1: The Primary Survey—the ABCDE

	Survey	Check	Note and Record
A	Airway	Patent Noisy	Obstruction
B	Breathing	Effective	Rate and depth Chest movements Air entry Cyanosis
C	Circulation	Adequate	Pulse rate and volume Skin colour Capillary return Haemorrhage Blood pressure
D	Disability (= neurological status)	Normal	Conscious level: AVPU or preferably Glasgow coma scale (GCS) pupillary light reactions
E	Exposure (= undress)	Other injuries	Limb movements on command or on painful stimuli

In secondary survey, after resuscitation, the findings of the initial survey are checked and an assessment is made of limb movements, vision and cutaneous sensations (**Table 2**).

Table 2: The Secondary Survey—Conscious Level

History	From patient and observers
Reassessment of vital signs	As in primary survey
External signs of injury	Inspection and palpation of scalp, face, eyes and neck
Conscious level	GCS is repeated; this entails evaluation of speech and record of airway
Vision	Pupils: evaluation of size, symmetry and light reactions. Acuities and fields: assessed bedside
Limb weakness: lateralised or localised?	Detected from observation of spontaneous movement, movement on commands and on pain

GLASGOW COMA SCALE

Glasgow coma scale (**Table 3**), published by Graham and Teasdale, 1976, is the most prominent of the scores used for performing a quick assessment of neurological status, for assessing the progress and for prognosticating.

Table 3: Glasgow Coma Scale

Category	Response	Score
Eye opening	Spontaneous	4
	To sound	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Best motor response	Obeys commands	6
	Localises pain	5
	Flexion: withdrawal	4
	Flexion: abnormal	3
	Extension	2
	None	1
Maximum score	—	14
Number of levels	—	13

Paediatric Scoring Systems

Infants or children cannot perform some of the functions tested in GCS. It is not easy to assess the conscious level in a child. A slightly modified scale is thus used for assessing infants and children (Table 4).

Table 4: Paediatric Coma Scale

Category	Response	Score
Eye opening	Spontaneous	4
	To sound	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Words	4
	Vocal sounds	3
	Cries	2
	None	1
Best motor response	Obeying	5
	Localising	4
	Flexing	3
	Extending	2
	None	1
Maximum score	—	9 to 14 depending on age of infant/child

The Pupils

Pupillary size, shape and reactivity should be recorded and then periodically reassessed to monitor the progression of disease. It is necessary to use a strong focused beam and to shield the opposite eye when performing this examination. Differential pupillary size and reactivity is often the first sign of impending brain herniation.

Eye Movements

In routine neurological examination of an unconscious patient, spontaneous eye movements should be looked for. If none is present, one should look for the Doll's eye reflex—the oculocephalic reflex—by turning the head laterally and vertically, but only after excluding cervical spinal injury. Eye movements along with the respiratory rate and rhythm are the best guides to state brainstem functions. The brainstem score made by Jennett *et al* has not found wide usage. Bonn *et al* from Liege have devised a brainstem reflex score, which when combined with GCS, in the form of Glasgow-Liege Scale (GLS), provides a more complete picture of status of an unconscious patient (Table 5).

Table 5: Liege Reflex Scale (Bonn *et al* 1982)

Brainstem Reflex	Method of Eliciting	Score
Fronto-orbicular	Light tap on glabella	5
Vertical oculocephalic	Rapidly moving head up and down	4
Pupillary light	Shining bright light in eye	3
Horizontal oculocephalic	Rapidly turning head sideways	2
Oculocardiac	Pressure on eye globe	1
No response	—	0

Fundus Examination

In acute phase, it is difficult to conduct the examination, which must be done without atrophine instillation since pupillary examination is far more informative. Retinal haemorrhages may indicate a phase of sudden rise in ICP. Massive intraocular haemorrhage may endanger vision. Papilloedema is usually not present initially but the baseline examination is useful in assessing, if it develops later on.

Limb Movements and Reflexes

The GCS examines motor functions but only the best response. It is necessary to note if either side or a limb has decreased response, the extent of its temporal course and presence of changes in tone; decreased tone indicating lower motor neuron (LMN) lesions, i.e. peripheral lesions, and increased tone suggesting upper motor neuron (UMN) lesions. Plantar reflex must be noted and monitored.

Cardiorespiratory Parameters

Raised ICP leads to slowing of pulse rate, rise in systolic BP (begins with rising pulse pressure) and irregularity and slowing of respiration (Cushing's triad). In children, a losing of pulse often happens before a fall in conscious level. Tachycardia and hypotension point to an extra-cranial source of blood loss.

Extra-cranial and external findings

Scalp and face should be carefully examined, carefully recording wounds, abrasions and swellings on a diagram. Photographs are very useful for medicolegal purposes. Impact site can be very useful, if a CT is not available and an emergency craniotomy is needed. Impact sites also have medicolegal and litigation implications. Orbital swelling may indicate anterior fossa fractures. Bruising behind ear (Battle's sign) may indicate a fracture of petrous bone, often a sign of temporal extradural haematoma.

RADIOLOGICAL ASSESSMENT

The CT scan, since its inception, has remained the investigation of choice for first and subsequent examinations for deciding the course of management (Figure 1). In an emergency room, a CT examination must include the cervical spine as well since in road traffic accidents, the cervical spine is injured in a significant number of victims. The MRI can show injuries not seen on CT and is useful in subacute and chronic phases especially for prognostication, grading of DAI and for assessing vascular injuries. In acute phase, its major role is in assessing cervical spinal cord trauma in an unconscious and intubated patient. Positron emission tomography (PET) and single photon emission computed tomography (SPECT) imaging are useful for cerebral protection strategies and for research into changed metabolism of injured brain. Plain X-rays of skull are nowadays used, either in centres unequipped with a CT scan or in patients with minor head injuries for identifying those with a fracture so that those can be electively scanned within the next 24 hours. At least two views at right angle to each other must be taken for a plain X-ray examination.

MANAGEMENT

Emergency

- Initial resuscitation and management: Hypotension (SBP <90 mm Hg) or hypoxia (apnoea, cyanosis, or O_2 saturation <90% or PaO_2 <60 mm Hg) must be monitored and avoided/corrected as soon as possible
- Maintain SBP >90 mm Hg
- Admit all head injury patients for observation at least for 24 hours

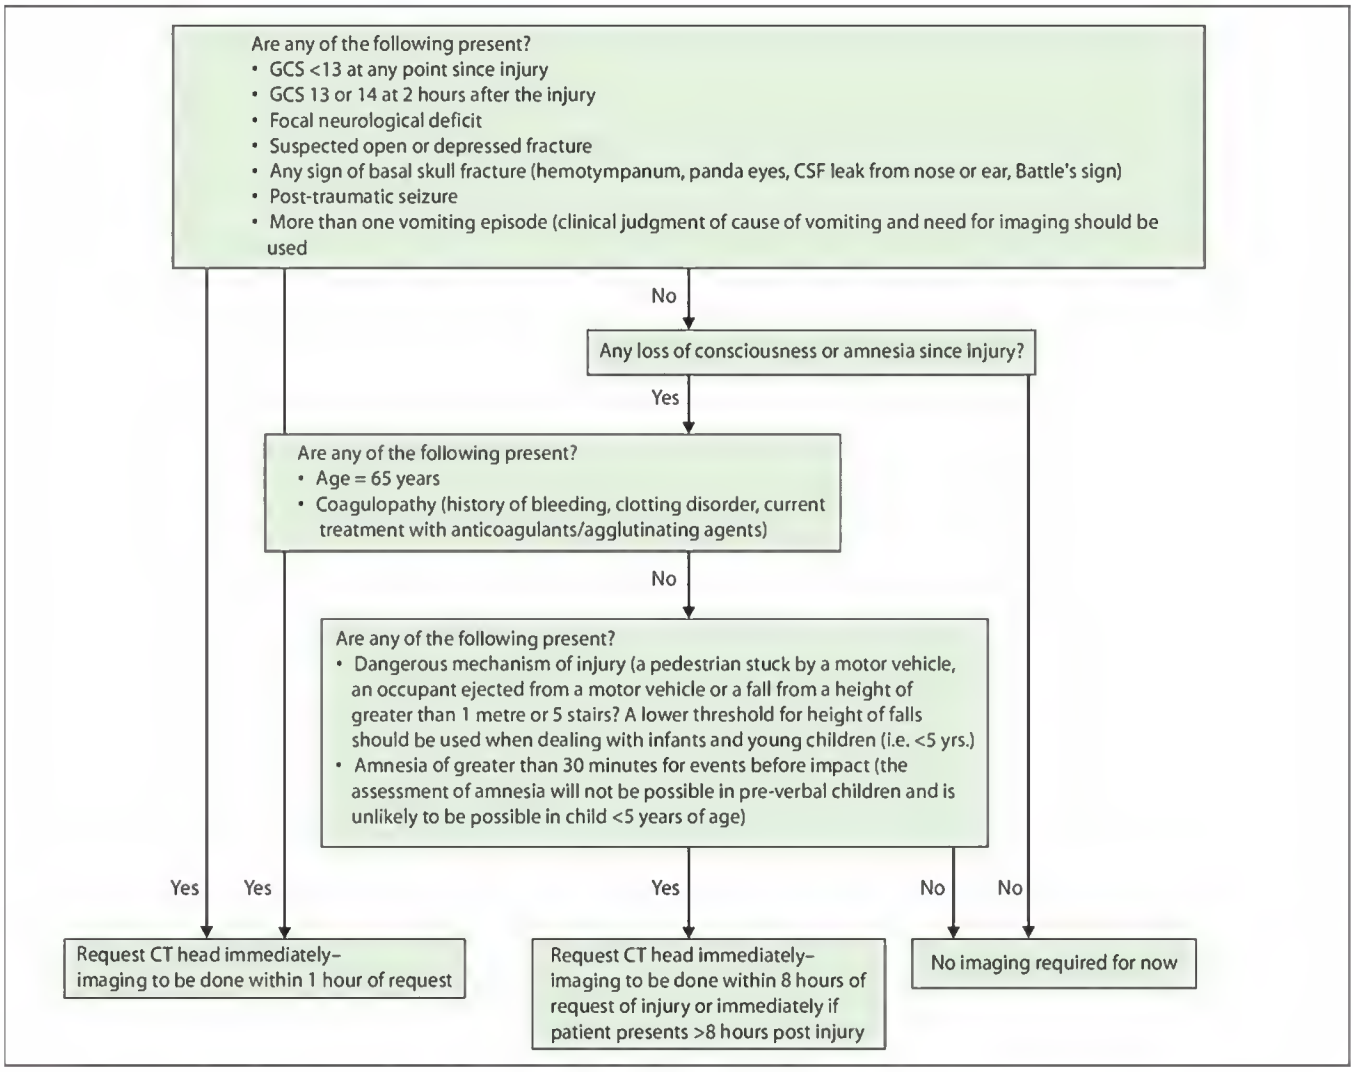

Figure 1: NICE guidelines for CT after head injury (2003).

- Nursing
  - Elevate head end 30° to 45°
  - Neuro check every 1 hour
  - Nil per orally (NPO) till alert; begin with clear fluids and advance as tolerated
  - Isotonic IV fluids: NS + 20 mEq KCl/L run at maintenance dose of approximately 100 mL/hour for adults; for children–2,000 mL/m^2/day
  - Mild analgesic
  - Antiemetics infrequently to avoid oversedation; avoid phenothiazines; use trimethobenzamide
- Patients with GCS <13 or with CT abnormalities
  Admit in ICU, preferably neuro ICU for further observation and management of ICP
- Use of paralytics and sedatives
  - Sedation and neuromuscular blockade can be useful for transporting head injury patients, but they interfere with neurological examination.
  - Paralytics should be used if sedation is inadequate, routine use of these can lead to higher pneumonia and longer ICU stay. Therefore, these should be used when absolutely essential for controlling ICP or shifting patients.
- Intubation and hyperventilation
  - Secure the airway with intubation, if needed – GCS <8; hypoxic despite supplemental O_2; maxillofacial injuries; need for pharmacological paralysis for evaluation or management.
  - If skull base fracture is suspected, avoid nasotracheal intubation and nasogastric tube placement.
  - Hyperventilation should be used in conjunction with ICP monitoring. Only if there is evidence of tentorial herniation or progressive neurological deterioration should one consider hyperventilation and that too for brief periods only. Aim at pCO_2 = 30 to 35 mm Hg. Below pCO_2 of 30 mm Hg HPV reduces CBF without reduction in ICP.
- Mannitol in emergency room
  - Mannitol to be given as a bolus approximately 0.25 to 1 gm/kg over <20 minutes. Peak effect occurs in approximately 20 minutes.
  - It is to be administered in the following cases:
    a. Evidence of raised ICP.
    b. Evidence of mass effect (focal deficit like hemiparesis).
    c. Sudden deterioration (including pupillary dilatation) prior to CT.

d. After CT, if a lesion associated with raised ICP is identified.
e. After CT, if patient is going for operation—to 'buy' time.
f. To assess 'salvageability' – in patients with no brainstem functions, look for return of brainstem reflexes.

- Anti-epileptic medication:
  As of now there is no evidence to recommend routine prophylactic use of phenytoin or carbamazepine for preventing late onset seizures. However, AEDs should be used prophylactically in patients at high risk for developing early onset seizures after TBI.

Conditions with increased risk of post-traumatic seizures

- Acute subdural, epidural or intra-cerebral haematoma
- Open-depressed fracture with parenchymal injury
- Seizure within first 24 hours after injury
- GCS less than 10
- Penetrating brain injury
- History of significant alcohol abuse
- Cortical contusion on CT

SURGICAL

Timing of decompression and adequacy of decompression are the two most important factors in prognosis. Great surgical skills are not required for these very simple and basic neurosurgical procedures nor are very advanced equipment needed for performing these procedures.

Exploratory Burr Holes

In a trauma patient, the triad of altered consciousness, asymmetrical pupils and contralateral hemiparesis is due to midbrain compression due to an uncal herniation, which is mostly due to an extra-axial intra-cerebral haematoma. The prognosis of patients with transtentorial herniation is poor. Outcome is improved by the speed with which decompression is done. Burr holes are primarily diagnostic tools since adequate decompression can often not be done through them alone but they do permit a modest decompression while a definitive craniotomy is done. With widespread availability of CT scan exploratory burr holes are rarely used nowadays. Burr holes when indicated should be placed, preferably, in the operation room but if the patient is rapidly deteriorating they can be put in emergency room/intensive care unit. A few lives may be saved thus, even in centres within house CT and 24 x 7 operating rooms.

Decompression

The site and exact techniques vary according to the site of haematoma and the location, i.e. whether it is sub or epidural or intra-cerebral. For acute subdural haematomas, the prognosis is grave and very time-dependent. If the haematoma is significant, it must be removed by a large, often a hemispheric one, craniotomy. In this, as in malignant traumatic oedema, the bone flap is best stored in the subcutaneous plane of the patient. The bone flap should be replaced as soon as the patient is stable. In epidural haematomas which are causing clinical symptoms, the craniotomy is placed on the haematoma site. In intra-cerebral haematomas a smaller suitably placed craniotomy is adequate since damage to overlying brain must be kept to a minimum. In temporal lesions which have already caused transtentorial herniation, best results are obtained by infratemporal lobectomy and section of free edge of tentorium to release the uncus and equalise CSF pressures within supra- and infra-tentorial compartments.

Depressed Fractures

Pond fractures

These are found in infants and in very small children where the bones are still elastic and thus skull vault often bends inwards under an impact. Small indentations, especially those away from eloquent areas, require no elevation and the bone often gets remodelled as the child grows. But large depressions, especially those on the motor area, are best elevated using a small burr hole and a blunt Penfield dissector for elevating the depressed bone.

Large or comminuted fractures

These should be surgically debrided and converted into simple fractures as early as possible.

Penetrating Wounds

Missile

Gunshots are self sterilising due to the high heat. However, the gunshots also drive in many dirty particles, hair and dirt from outside. These wounds should be removed and the wound closed after debridement.

No missile penetrating wounds

They require debridement at the earliest.

CSF Otorrhoea

Mostly settles down with conservative treatment which includes prophylactic antibiotics and dehydrants.

CSF Rhinorrhoea

Majority of post-traumatic CSF rhinorrhoea settle down with conservative management within a week. Sometimes, if the defect is large or if there is significant basal contusion surgical repair with removal of contused brain may be required. Late CSF leaks are mostly sealed using the trans-nasal endoscopic route.

PREVENTION

Primary Event

Prevention is always better than cure and a lot less costly too. Public awareness and education are the cornerstone, since the victims are part of society and will influence laws that govern. One such public awareness programme is the 'Think First Prevention Programme'. Some of the important aspects are:

Road traffic safety

Obey traffic rules

Alcohol control

- Avoid driving after consuming alcohol
- Take a taxi

Better Roads and Speed Control

Pot-holed roads with poor lighting and unmanned crossings cause problems. Roundabouts seem to be better at reducing speed than cross roads.

Vehicle Design

- Non-shattered windscreens, airbags and seat belts must be provided for all commuters.

- Airbags should be for all occupants, not only front seat passengers.
- Children should be harnessed and on the rear seat. Seat belts, properly designed, save many lives.
- All occupants, including the ones on rear seats should fasten the belts in a moving vehicle.

Driver Behaviour

In India, it is still possible to obtain a driver licence without any training! Road rage is becoming common. Traffic rules are observed only when the constable is present.

Helmets

For motorcycle, scooter and bicycle drivers and riders have prevented more serious head injuries than any other single measure. Helmets, properly designed and constructed, act as second skull absorbing most of the shock of an impact thus deflecting the force from harming brain.

Secondary Insult

The entire management from the moment of impact is geared towards preventing or minimising secondary injuries that are set in motion from the moment of primary injury.

20.28 Myelopathies

S Venkataraman

Diseases of the central nervous system (CNS) can be confined to the spinal cord, sometimes resulting in extensive and varied clinical syndromes of quadriplegia, paraplegia with sensory deficits and bladder involvement because the spinal cord contains the entire motor/sensory output of the trunk and limbs in a small cross sectional area. Disorders of the spinal cord can be caused by hereditary, traumatic, vascular, inflammatory, neoplastic, demyelinating disorders and nutritional deficiency. Myelopathy, is a generic term to denote the involvement of the spinal cord, due to compressive or non-compressive causes. Many spinal cord diseases (compressive/non-compressive) may be treated efficiently if identified at an early stage. Neuroimaging techniques like CT/MRI have greatly improved the diagnostic accuracy in spinal cord disorders and have shifted the emphasis more in favour of compressive lesions. Though the conditions causing myelopathy (compressive/non-compressive) are dealt with in this chapter, certain diseases like motor neuron disease, fluorosis and myelopathy due to cervical/lumbar spondylosis have been dealt with in detail elsewhere.

A review of spinal anatomy and vascular supply of the spinal cord will ensure a better understanding of disorders causing myelopathy.

ANATOMY

The spinal cord is 42 to 45 cm long and occupies the vertebral column, extending from the foramen magnum above to the conus medullaris at its lower end at the level of the L1-L2 intervertebral space. The filum terminale, the remnant of the neuroectodermal bud, accompanies the arachnoidal sac to its termination at the second sacral segment. The spinal cord has two enlargements the cervical and lumbar from which originate the nerves of brachial and lumbar plexuses, respectively (**Figure 1**). Spinal cord is covered immediately by the pia mater which is continuous with the pia of the brain and is bathed in cerebrospinal fluid (CSF), with the arachnoid mater and the dura mater forming the outer meningeal sheaths. The dura mater is firmly attached to the edge of the foramen magnum at its upper end, but below, there is an epidural space containing veins and fatty tissue. The nerve roots and spinal nerves in the spinal canal up to the intervertebral foramina are covered by meningeal sheaths and are also bathed in CSF. The cord is kept in place in the spinal canal by two rows of transverse denticulate ligaments.

The spinal cord gives out paired nerve roots, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. Ventral or anterior roots are motor and dorsal or posterior roots are sensory. These two roots coalesce to form the mixed spinal nerve, and there are a total of 31 pairs. The first cervical segment lacks a dorsal root in human beings. The dorsal root has a dorsal root ganglion. The nerve roots exit from the vertebral column through the intervertebral foramina. As the growth of the cord lags behind that of the vertebral column, in the embryonic stage, the

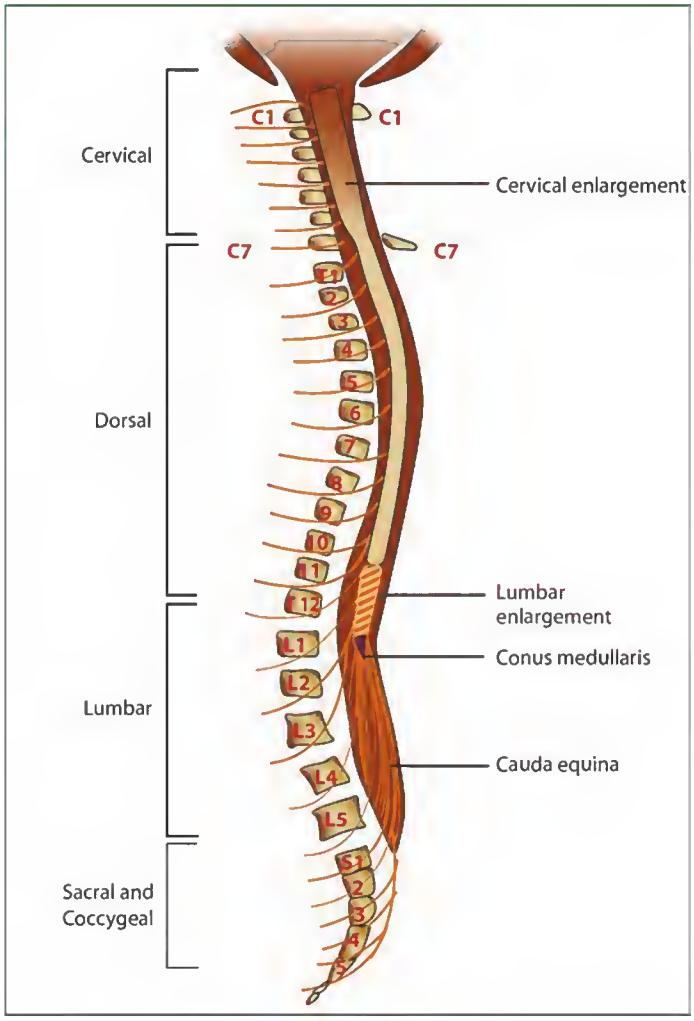

Figure 1: Spinal nerves.

downward direction of the spinal nerves is progressively greater as we approach the lower end of the cord, though at the cervical end, the 8th cervical spinal nerve exits between the C7 and T1 vertebrae. In the lumbosacral region, the nerve roots descend below the cord forming the cauda equina.

A cross section of the spinal cord shows an internal mass of grey matter shaped like a butterfly, with the anterior portion which is mainly motor and the posterior portion which is sensory.

The white matter is made up of columns and ascending and descending tracts. The dorsal columns (gracile and cuneate fasciculi), lying between the posterior horns of the spinal grey matter contain primary afferent fibres from cutaneous and articular mechanoreceptors. The dorsal columns and dorsal spinocerebellar tracts are ipsilateral with respect to their peripheral input while the ventral spinocerebellar and spinothalamic tracts are crossed. The spinoreticular pathways

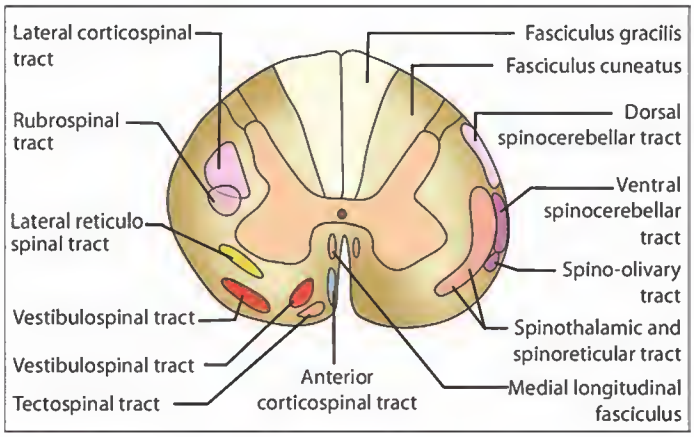

Figure 2: Cross-section of spinal cord.

are both crossed and uncrossed. The long descending tracts are found in the lateral and anterior funiculi (**Figure 2**). Of these the corticospinal tract from the sensorimotor cortex and the rubrospinal tract from the red nucleus are crossed, while the reticulospinal fibres from the reticular system are both crossed and uncrossed. The long descending tracts are found in the lateral and anterior funiculi. The vestibulospinal fibres from the vestibular nucleus of the medulla are uncrossed.

Arterial Supply

Arterial supply is divided into extraspinal system (extramedullary) and intraspinal system (intramedullary).

Extraspinal system

The extraspinal system is formed by the anterior and posterior spinal arteries. There is a single anterior spinal artery which supplies the anterior two thirds of the cord and paired posterior spinal arteries supplying posterior one-third of the cord on either side (dorsal columns and the dorsal horns).

These are in turn supplemented by radicular arteries arising from, vertebral, ascending and deep cervical arteries and the aorta. The most important radicular artery is the 'artery of Adamkiewicz' which supplies the cord below T9-T10 level. Another area of importance is the mid-thoracic region (T4) which is poorly vascularised and is considered as the vascular 'watershed area'.

Intraspinal system

The branches from anterior and posterior spinal arteries form a perimedullary circuit around the cord. Branches from this plexus supply the deeper parts of the cord.

Dermatome

A dermatome is a well defined segmental portion of the skin to which the sensory component of each spinal nerve is distributed (**Figure 3**). The cutaneous distribution usually coincides with the segmental distribution of underlying muscle innervation (myotome). Thus, a single nerve root lesion may be traced by detecting the dematomal distribution of the sensory deficit and the 'segment-pointer muscle' that is involved.

CLINICAL LOCALISATION OF SPINAL CORD DISEASES

The presence of a transversely defined level below which motor, sensory and autonomic functions are altered is the hallmark of spinal cord disease. At the level of the lesion weakness of the affected muscles supplied by the segment and loss/diminished tendon reflexes are elicitable. The level of sensory loss or impairment indicates the damage to the spinothalamic tracts one or two segments above perceived level of a unilateral spinal cord lesion and at the level of a bilateral lesion. Below the level of lesion there is upper motor neuron type of weakness—spasticity, brisk or exaggerated deep tendon reflexes and extensor plantar response—due to involvement of descending cortico-spinal tracts. Autonomic dysfunction below the level of lesion manifests as abnormality in sweating, bladder, bowel and sexual dysfunction.

The uppermost level of lesion in a spinal cord disorder can be assessed by observing 'segmental sign' which corresponds to the disturbed motor/sensory innervation of the affected segment – a band of hyperalgesia or hyperpathia at the upper end of sensory disturbance, atrophy/fasciculations in the muscles innervated by the affected segments and diminished/absent deep tendon reflexes involving the muscles supplied by the affected segment.

The main features of transverse level spinal cord lesion at various levels may be summarised as under:

Cervical cord lesions may produce quadriplegia and weakness of diaphragm. Weakness in upper limbs is of lower motor neuron type and upper motor neuron type in lower limbs. Quadriplegia occurs with C4/5 lesion; weakness of biceps with C5/6 and weakness of triceps and extensors of wrist and fingers with C7 lesions may be prominent.

Dorsal cord lesions may be localised with sensory level/back pain at – T4 for nipple level and T10 for umbilical level. With T9/T10 level lower abdominal muscles may be weak and on abdominal wall contraction umbilicus may move up (Beevor's sign).

Lumbar cord lesions between L2-L4 segments results in weakness of adduction/flexion of thigh and extension of knee with loss of knee jerk, whereas lesions between L5 and S1 cause weakness of foot and ankle movements, flexion of knee and extension of thigh with loss of ankle jerk.

Sacral cord/conus medullaris: Lower sacral and coccygeal segments are contained in the tapering Conus end of the spinal cord. Conus medullaris involvement results in bilateral saddle anaesthesia (S3-S5), bladder and bowel dysfunction and impotence. Bulbo-cavernosus and anal reflexes (S4/5) are absent, whereas muscle strength is by and large preserved.

Cauda equina lesions are characterised by low back and radicular pain, asymmetric weakness in legs, asymmetry in deep tendon reflexes with relative sparing of bladder and bowel function.

PATTERNS IN SPINAL CORD DISEASE

Spinal cord contains ascending and descending pathways which may be crossed or uncrossed. The posterior columns, spino-cerebellar and pyramidal tracts are uncrossed (ipsilateral to the side they supply) in spinal cord whereas afferent fibres mediating pain and temperature ascend contralateral to the side they supply.

Based on the anatomic configuration of the tracts, characteristic clinical syndromes are identifiable.

Foramen Magnum Syndrome

At this level decussating pyramidal fibres for the leg cross caudal to the fibres for the arms and results in weakness of legs—crural paresis. Compressive lesions cause weakness of ipsilateral shoulder and arm followed by weakness of ipsilateral/contralateral leg and lastly contralateral arm. There may be pain in suboccipital region radiating to neck and shoulders.

Central Cervical Cord Syndrome

The damage occurs to the grey matter and crossing spinothalamic tracts near the central canal. In the cervical cord it produces weakness of arm out of proportion to leg weakness with dissociated sensory loss—loss of pain and temperature in cape distribution in contrast to preservation of touch, joint and vibration sense. Usual causes are trauma, tumours, anterior spinal artery ischaemia and syringomyelia.

Anterior Spinal Artery Syndrome

Occlusion of anterior spinal artery results in extensive destruction of anterior two thirds of the cord bilaterally sparing posterior columns. Motor, sensory and autonomic functions are lost below the level of lesion with the exception of retained

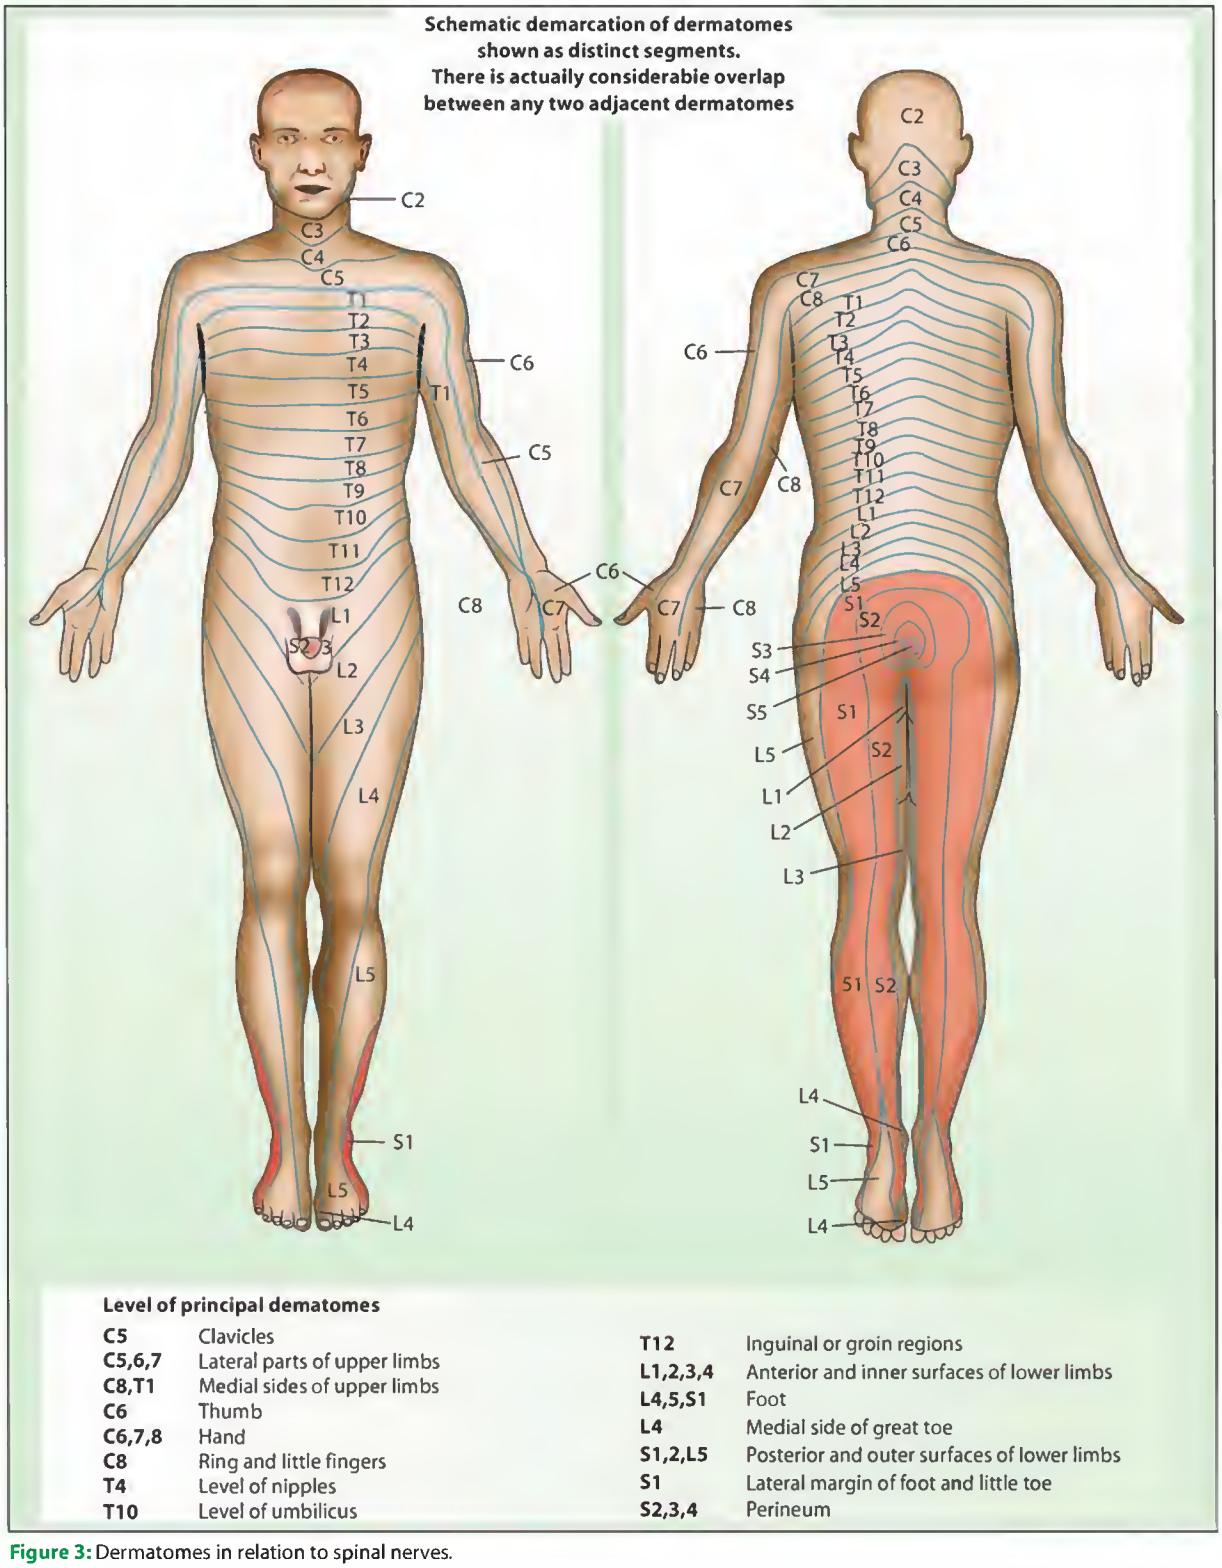

Figure 3: Dermatomes in relation to spinal nerves.

vibration and position sensations. Usual aetiology is embolic occlusion of anterior spinal artery.

Posterior Spinal Artery Syndrome

This is rare as posterior spinal arteries are paired. Clinically there is segmental paraesthesiae of burning nature. The cortico-spinal tracts are usually spared and the condition is usually reversible. Sensory and tendon reflexes levels are good indicators of levels of lesion. Other conditions where posterior columns are preferentially involved are vit B12 deficiency and tabes dorsalis.

Brown-Sequard Syndrome

This is a 'hemi cord' syndrome with ipsilateral paresis, cortico-spinal signs and impairment of vibration, joint and position sense and contralateral impairment of pain and temperature sensation usually with preserved touch sensation. There may be unilateral 'segmental sign,' such as radicular pain, muscle atrophy and loss of deep tendon reflexes. This is seen mainly from penetrating injuries to the cord though partial lesions are more common than classical pattern.

After identifying the spinal cord disease one should attempt to localise: (a) rostro-caudal level of the lesion - cervical, thoracic, lumbar or sacral; (b) extent of the lesion in all axes; and (c) whether compressive or non-compressive and if compressive whether extradural, intradural but extramedullary or intramedullary.

The principal structure outside the dura is the vertebral column, which surrounds the cord as a protective fortress. Most extradural diseases originate in or involve the bone or cartilage of the vertebral column and compress the dura and cord. Malignant tumours, infections, spondylitis, disc herniations, fractures (traumatic or spontaneous) and dislocations can compress the dura and compromise the cord. Most extradural diseases are classified as 'surgical' and 'urgent', since the longer the cord is compressed it is unlikely that the damage will be reversible after decompression. Occasionally epidural abscesses, tumours or haematomas compress the cord without involving the bone.

The majority of intradural extramedullary lesions are benign tumours either meningiomas or neurofibromas, that produce gradually evolving symptoms.

In sharp contrast most intramedullary diseases are medical and the differential diagnosis is much broader. Viral infections, transverse myelitis, infarction, haemorrhage, cysts, tumours and degenerative diseases lead the list.

NEUROGENIC BLADDER

Bladder Innervation

The normal anatomy and physiology of micturition and bladder innervation form a complex subject. The bladder is a hollow bag made of a syncytium of smooth muscle with stretch receptors. There is no true internal urethral sphincter, but the smooth muscle arrangement around the bladder neck produces a sphincteric action. The external urethral sphincter is made of striated muscle.

The parasympathetic fibres are derived from S2 to S4 segments and traverse the pelvic nerves. They fuse with the sympathetic fibres to form the vesical plexus. The sympathetic fibres emerge from the sympathetic trunk at L1-L4 and form the hypogastric plexus. The somatic efferent fibres to the external urethral sphincter are derived from S1, S2 segments and little below and form the pudendal nerve. The afferent fibres from the bladder proceed centrally along the routes taken by the efferent. The stretch receptors are stimulated by a rise in intravesical tension achieved in normal bladder function by filling with urine to a capacity of about 400 mL. This causes a parasympathetically induced contraction of the detrusors and simultaneous opening of the internal sphincter. The role of the sympathetic innervation in the function of micturition is not clear. It has been suggested that it plays a part in maintaining 'bladder tone' in conjunction with the parasympathetic innervation. Animal experiment in the cat suggests that sympathetic innervation has an inhibitory effect on bladder tone and raises the threshold for micturition. During ejaculation, backflow of seminal fluid into the bladder is prevented by mediation of the sympathetic fibres to the ductus deferens.

The regulation of bladder tone is essentially a spinal reflex function. However, like other spinal reflexes it comes under the control of higher centres. The two mutually exclusive activities of the bladder, i.e. the storage and voiding are controlled by neural processes that exist in pons and suprapontine influences act to switch it from one state to another. The pontine micturition centre (PMC) has a lateral part which controls storage (continence) and a medial part which is the site of activation for micturition. There are no direct afferent inputs from the bladder to PMC, but connections between periaqueductal grey are thought to provide information as to the state of fullness of the bladder.

In the neurological process that determine the switch from storage to voiding , in man, the extent of bladder fullness is the critical factor, as the urgency may not necessarily reflect the bladder volume. It is likely that frontal input is involved in the inhibition of micturition until it is socially appropriate. Thus, to effect both storage and voiding, higher control as well as connection between pons and the sacral spinal cord must be intact, as also the peripheral innervation that arise from the most caudal segments of the sacral cord.

Disturbances of Bladder Function

Lesions involving the sacral reflex arc cause retention of urine. In tabes dorsalis, the afferent fibres are involved, producing a painless distended bladder with overflow incontinence. Lesions of the *cauda equina* interrupt the afferent and efferent fibres causing incontinence of urine with loss of control over anal/urethral sphinctors. Involvement of the afferent fibres alone causes a painful distension of the bladder.

Lesion Above the Sacral Centre

Incomplete lesions of the spinal cord affect the inhibitory fibres for sympathetic outflow. This produces difficulty in holding urine and micturition is precipitate. Incomplete lesions can also interfere with the descending fibres concerned with voluntary initiation of micturition, causing retention of urine or hesitancy of micturition. With complete transection of the cord, there is initial retention of urine during the phase of spinal shock. Subsequently, reflex evacuation of the bladder occurs by means of the sacral reflex arc. This may be facilitated by stimulation of the sacral cutaneous areas.

Central Lesion

Diseases involving the superior frontal and anterior cingulated gyri cause loss of control of micturition. When the lesion is more

anterior, the patient is not worried or embarrassed by the incontinence due to a disinhibition state.

Investigation of Bladder Function

Normal micturition can be studied by a constant recording of intravesical and intraurethral pressure, and with perineal floor electromyography (EMG) with fluoroscopic monitoring. These urodynamic studies facilitate the diagnosis of neurogenic bladder dysfunction.

Treatment of Bladder Disturbance

When retention of urine occurs, bladder drainage by means of an indwelling catheter under strict aseptic conditions is necessary. Intermittent catheterisation may be resorted to, to prevent infection. Prophylactic antibiotics may be necessary. Parasympathomimetic drugs like carbachol and bethanecol cause contraction of the detrusor and are useful in flaccid paralysis of the bladder. In spastic paralysis, propantheline, which acts as a muscarinic antagonist causing relaxation of the detrusor may be tried.

SPINAL CORD DISEASES—DEPTH LOCALISATION

Extradural Pathology

Extradural lesions usually involve the bone first; so bone pain usually precedes neurological symptoms. Localised bone tenderness in response to fist percussion and radiologically demonstrable abnormalities of the vertebral column are often present at the level of the lesion. As the bony process expands, nerve roots that lie just out side the dura are distorted or compressed, root pain and paraesthesias result. Movement, straining or a cough or a sneeze often increases bone pain and root pains.

With further expansions or bone displacement the cord is compressed, causing relatively symmetric loss of pyramidal tract and posterior column function below the level of the lesion.

Intradural Pathology

With the intradural extramedullary lesions bone pain and tenderness are absent but root pain and cord compression otherwise mimic extradural disease; signs of cord compression are usually asymmetric.

Intramedullary Pathology

Osseous pain, tenderness and radiographic abnormalities are absent, and root pain is seldom prominent. Motor and sensory sign may be asymmetric, sensory loss can be dissociated (touch can be preserved in regions of loss of pain) and since centrally placed lesions may not affect outer fibres in the long tracts, sensation in the distal legs and perineum may be spared. Intramedullary disease is often painless or can have radicular type of pain. Bladder symptoms are more common and occur early.

Myelopathy is a generic term for specific disorders of the spinal cord caused by a heterogeneous group of conditions in which there is acute, subacute or chronic involvement of the spinal cord with or without the involvement of the nerve roots (myeloradiculopahy) or peripheral nerves (myeloneuropathy).

Clinically myelopathy is characterised by a definite sensory level below which there is a loss or diminution of sensation, a reflex level at the level of lesion indicated by the absence of corresponding deep tendon reflex and exaggerated deep tendon reflexes caudal to this level and a motor level with evidence of lower motor neuron dysfunction like wasting and fasciculations at the level of lesion and caudally features of upper motor neuron findings. Symmetric dysfunction involving the bladder and bowel confirm the lesion to be myelopathy.

Radiculopathy is characterised by segmental myotomal weakness; dermatomal sensory loss and corresponding reflex loss. A very sensitive clinical finding in root lesions is a depressed deep tendon reflex of the muscle that receives much of its innervation from the affected root. Radiculopathy is characterised by root pain, which is deep burning, and diffuse in ventral root affliction (myalgic) and a rapid electric-shock like sensation (neurologic) in dorsal root lesions. In myelo-radiculopathy features of both myelopathy and radiculopathy coexist.

INVESTIGATIONS IN DISEASES OF SPINAL CORD

Investigations in spinal cord disorders consist of examination of CSF, electrophysiological studies and neuroimaging. Plain radiographs of appropriate areas of spine has become less important with the advent of neuroimaging techniques. Conventional myelography was earlier the deciding line between compressive and non-compressive causes of myelopathy but has been superceded by CT scan, CT myelography and MRI. In many cases where conventional myelography is normal, CT scan or CT myelography may demonstrate structural lesion responsible for compression of the cord.

MRI has the advantage of being non-invasive mode of neuroimaging for diagnosis of structural lesions of spinal cord. Both sagittal and axial views can be obtained to confirm/exclude compression of the cord. Intramedullary lesions of spinal cord like tumours, AV malformations and syringomyelia can be visualised even before obstruction of subarachnoid space is evident. Thus, with the availability of MRI, there is a shift in favour of compressive lesions of myelopathy and the concept of compressive myelopathy has been extended to include CT scan, CT myelography and MRI findings for exclusion of compressive lesions-extradural,extra/intramedullary.

Electrophysiological studies like somato-sensory evoked potentials (SSEP) may help in confirming the cord involvement whereas nerve conduction (motor/sensory) studies/EMG may be of help to diagnose radiculopathy/neuropathy.

Role of CSF is mainly in the inflammatory/infective/demyelinating lesions of the spinal cord. It should be done only after ruling out compressive pathology by an appropriate imaging modality.

COMPRESSIVE MYELOPATHY

Spinal Cord Trauma

Fifty per cent of spinal cord injuries occur due to road traffic accidents. In direct injury to the cord with high velocity missile or a sharp instrument, often the vertebral column is also involved in the injury. In the presence of predisposing conditions like cervical or lumbar spondylosis, spinal canal stenosis, rheumatoid arthritis, the cord is prone to damage with even moderate force. Analysis of the mechanism of injury is of prime importance. The force of the violence may result in flexion, hyperextension, rotation or vertebral compression. The resultant cord injury may

be contusion, stretch, laceration or crush injury. Often the vertebral column is also involved in the injury.

Prognostication in spinal cord injuries depends on several factors. The higher the level of cord injury, the greater is the sensory, motor and autonomic involvement. Injury may be at a single level or involve multiple levels. The transection may be complete or a partial section, again determining the resultant disability. Whether the onset of the symptomatology is gradual or sudden is also of significance for prognostication.

Pathology

The spinal cord is soft and oedematous during acute phase and there may be haemorrhage. The destruction of white and grey matter is of varying extent. During the phase of repair, the oedema subsides, macrophage set to work and post-traumatic myelomalacia with thinning of the cord occurs. As a final step, cavitation and gliosis occur. Sometimes, the expansion of the cord (traumatic syringomyelia) may occur several months after partial recovery from spinal injury with reappearance of neurological symptoms and signs. Other late sequelae are cord atrophy and progressive myelopathy. Subarachnoid adhesions can form, resulting in cord tethering or multiple arachnoid cysts.

Clinical Features

Spinal cord trauma can cause a variety of syndromes depending on the extent of cord involvement. This syndromic classification of lesions is not confined to spinal cord injuries alone, but can be applied to various other types of spinal cord lesions as well.

Complete Transection

Transection of the cord is an acute event most often due to spinal injury, with accompanying fracture of vertebrae adjoining it. Below the level of the lesion, there is flaccid paralysis, as all function is lost due to spinal shock. Within one to six weeks minimum reflex activity appears. The bulbocavernosus reflex is the first reflex to recover, and when this is brisk in the presence of severe cord injury, it may indicate poor recovery. The tendon reflexes become exaggerated and plantar responses become bilaterally extensor. Reflex emptying of the bladder takes over. Muscle tone return with spasticity setting in. Other syndromes like Brown-Sequard syndrome, central cervical cord syndrome, anterior or posterior spinal artery syndrome as mentioned earlier can occur. Depending on the level of cord involvement, any of the cord syndrome described earlier may be encountered.

Treatment

Basic physiological parameters must be recorded on the spot and multiple injuries including head injury assessed. It must be kept in mind that due to autonomic failure, a sudden drop in the blood pressure may occur or paralytic ileus may set in. The patient requires to be carried onto the stretcher, in the horizontal position with the back well supported to avoid damage to the cord. Radiograph of spine, antero-posterior, lateral and oblique views, help in immediate assessment of the extent of injury, presence of vertebral fracture or dislocation with possible pressure on the spinal cord, or involvement of the nerve roots. CT scan, with close transverse images can be reformatted in the other planes to provide further information if required. But MRI, where available, is the imaging modality of choice in spinal cord disorders and trauma and may be resorted to subsequently where indicated. Of particular value is the sagittal view to pick up the lesion and also any soft tissue injury around the vertebrae, as bone does not yield an MR signal.

A complete general medical check up, and neurological assessment must be carried out initially in order to plan the treatment regimen. Treatment must be comprehensive and include management of pain, muscle spasms, prevention of bedsores, and bladder care in the presence of incontinence. Intermittent catheterisation of the bladder may be preferable and urinary infection must be prevented or checked early. In conservative management methylprednisolone is given during the acute phase. Neurosurgical opinion is sought and early decompression may be indicated in some cases of spinal injury.

Various splints may be used to immobilise, realign and stabilise the vertebral column and traction may be indicated. The halo ring and Gardner Wells tongs are useful devices here. The rehabilitation programme must include regular physiotherapy, prevention of contractures, occupational therapy, patient counselling, and family counselling to encourage maximum family participation in long term patient care. Lioresal may help to reduce spasticity. Gait training use of walking calipers, or use of hands to independently push the wheel-chair require to be taught to the patient, depending on the extent of disability. The recent concepts on regeneration of nervous tissue, comprehensive medicare, greater public awareness, availability of employment under the handicapped quota and even a possible participation in the para Olympics has encouraged a more positive attitude in the paraplegic.

INFECTIVE CAUSES OF THE CORD COMPRESSION

Tuberculosis

(See chapter on Neurotuberculosis in this section)

Spinal Arachnoiditis

Spinal arachnoiditis is an inflammatory process of the arachnoid mater, often chronic with adhesions to the dura and pia mater. The outstanding pathological feature of the condition is thickening and loss of translucency of the arachnoid membrane. In subacute arachnoiditis plenty of inflammatory cells per present.

In India, tuberculosis is the main cause of arachnoiditis. And usually involves the thoracic region. Tuberculous arachnoiditis may follow as a sequel to tuberculous meningitis or may be a direct spread from caries spine. Trauma and chemical inflammation following spinal anaesthesia, myelography and intrathecal medication, radiation and pyogenic infection are other aetiological factors. In 20% to 50% of cases, the primary cause remain unknown. Any level of the cord may be affected.

The clinical presentations may be radicular pain. Spastic paraplegia with progressive deterioration occurs sometimes with poor response to anti tuberculous treatment. The

differential of spinal arachnoiditis includes other causes of cord compression.

Myelography is important and shows a patchy hold up dye for several segments above and below the area of cord mainly involved. The prognosis is poor in thoracic arachnoiditis, but lumbar arachnoiditis (reported more often in developed countries recently) responds moderately well to surgery. The prognosis is best in a localised lesion. MRI spine with contrast has replaced the need for myelography.

Spinal Cysticercosis

(See chapter on Tapeworm and Roundworm Infections in section Infectious Diseases)

Spinal Epidural Abscess

The causative organism is usually *Staphylococcus aureus*, followed by streptococci, Gram-negative bacilli and anaerobes.

The disease is characterised by fever, backache, followed by radicular pain, within a few days. Headache and back stiffness, may be present. After a few days, progressive paraparesis, sphincteric involvement and sensory loss occur. This is a surgical emergency and if intervention is delayed, ischaemia of the cord occurs and the process becomes irreversible. The antibiotic of choice must be given. Spinal cord abscess is a rare condition with signs and symptoms indistinguishable from spinal epidural abscess. Occasionally, it may occur as a complication of spinal dysraphism.

Fungal and Parasitic Infection

A wide variety of fungi, namely actinomyces, blastomyces, coccidiodes and *Aspergillus* may cause cord involvement from an osteomyelitic focus or through haematogenous spread. *Echinococcus* and *Schistosoma* may also cause spinal cord pathology.

TUMOURS OF THE SPINAL CORD

Tumours of the spinal cord may be extradural, intradural, intradural-extramedullary or intramedullary. Neurofibromas, meningiomas, metastatic tumours, sarcomas, chordomas, and teratomas are extramedullary tumours which usually manifest clinical signs by pressure on the nerve roots with lancinating pain in the dermatome of the affected roots which increases on coughing. This may be followed by segmental distribution of muscle weakness and wasting. Intramedullary tumours of the spinal cord have the same cellular origin as tumours arising in the brain, namely ependymomas, astrocytomas, oligodendrogliomas and some non-gliomatous tumours. These tumours cause cord compression and also invade the white matter. Investigations of importance are CSF cytology and contrast myelography, but ideally CT scanning or MRI. All tumours causing compression require laminectomy, decompression and excision. If malignant, they will require radiotherapy. Epidural spinal cord compression by metastases is more common than compression by primary spinal tumours, 70% of the metastasis being to the thoracic spine. Bony lesions occur in the majority of patients with spinal metastasis. Ependymomas, unlike astrocytomas do not invade normal tissue and can be removed surgically with minimum morbidity. Differences between extra and intramedullary tumours are summarised in **Table 1**.

Table 1: Difference between Extramedullary Tumours and Intramedullary Tumours

Extramedullary Tumours	Intramedullary Tumours
Extramedullary tumours arise outside the spinal cord (extradural or intradural) and the symptom complex may be due to pressure of the tumour on nerve root, compression of the spinal cord or occlusion of spinal blood vessels	Intramedullary tumours arise within the substance of the spinal cord and interfere directly with structural pattern by invading and destroying nerve roots tracts and grey matter
The tumour usually occupies a few segments and produces focal signs	The tumour occupies multiple segments and may even stretch throughout the length of the cord
Root pain may be the presenting symptom. With cord compression, spastic paraplegia, sensory deficit level and poor bladder control occur. Total transection of the cord results in flaccid paralysis. Sacral involvement occurs rarely, and is based on lamination of the fibres	Following features are seen: a. Central pain with conus medullary tumours b. Root pains with cauda equina tumours c. Symptoms depend on location of the tumour. If high cervical or cervical they mimic syringomyelia
The commonest tumours are neurofibromas, and meningiomas	The commonest tumours are ependymomas and gliomas in the cervical region. Dermoids and teratomas occur only in children
CSF protein is markedly raised in extradural lesions and raised in intradural extramedullary lesions	CSF protein may be normal in cervical cord lesions or raised especially in ependymomas. In conus medullaris lesions, CSF protein is markedly raised
Visible, palpable or radiographic evidence of vertebral destruction points to an extradural extramedullary tumour, e.g. cold abscess or gibbus	Bony changes in adults in intramedullary presentations are unusual. MRI scan is more definitive
Radiological diagnosis Plain X-ray Erosion of the pedicle early sign of intradural extramedullary tumour (e.g. Neurofibroma) Reduction of intervertebral space is characteristic of Pott's disease. Preservation of intervertebral space suggests a diagnosis of secondaries	Bony changes may be is an completely absent
Myelogram The classic signs are 'meniscus sign', in intradural tumours and 'brush border sign' in extradural tumours. The block may be complete of incomplete	'Expansion sign' of the cord is diagnostic of syringomyelia
CT Scan The above radiological findings are seen with greater anatomical clarity	Usually no bony changes are seen unless there is associated syringomyelia
MRI Spinal cord definition is excellent. Craniovertebral junction anomalies are well brought out	Spinal cord definition is excellent. Expansion sign caused by Syringomyelia is cleared defined

NON-COMPRESSIVE MYELOPATHY

Non-compressive myelopathies (NCM) are a group of spinal cord diseases where compression has been ruled out by available neuroimaging techniques. They constitute about 46% to 62% of all myelopathies. Cord involvement may or may not be associated with affection of brain (encephalomyelitis), radicles (myeloradiculopathy) or nerves (myeloneuropathy). Cord structure may be thoroughly destroyed or the damage may only be limited to white matter (leucomyelitis) or anterior horn cells (poliomyelitis, motor neuron disease). The onset of NCM may be acute, subacute or insidious. The course of illness can be monophasic with complete remission or progression with or without remissions and relapses.

In Western countries non-compressive lesions of spinal cord may be due to demyelinating diseases or hereditary spastic paraplegia whereas infections and nutritional factors may be responsible in developing countries. Demyelinating diseases including multiple sclerosis are being increasingly recognised as a cause of non-compressive myelopathy. After detailed investigation in 4.4 % to 26.6% of cases of paraplegia in different series no cause could be attributed and these cases have been labelled as 'Myelopathy of unknown origin' or 'Obscure myelopathies'.

Disease of the spinal cord without evidence of compression on myelography, CT myelography or MRI can be classified according to aetiology. They can be (a) acute (viral, immuno-allergic, toxic, demyelinating disease), (b) subacute (neurolathyrism, tropical spastic paraparesis), and (c) chronic (infectious and radiation myelopathy). Viruses like that of poliomyelitis have predilection for anterior horn cells and are dealt elsewhere in this book. Some of the important conditions causing non-compressive myelopathy in India are highlighted (**Table 2**).

Inflammatory Disorders of the Spinal Cord

Acute transverse myelitis

Acute transverse myelitis is development of isolated spinal cord dysfunction over hours or days without any evidence of compressive lesion. One third of the patients have preceding febrile illness. Nearly 50% develop maximal deficit in one week. MRI of the spine will reveal abnormal signal changes involving long segments with or without contrast enhancement. Treatment includes short course of steroids along with other supportive and rehabilitation therapy. Nearly 20% of the patients have a favourable response.

CSF shows increased protein and mononuclear cells which may number from a few to several hundreds.

Non-compressive myelopathy due to infections

Most viruses, except HTLV-1 and AIDS, invade the spinal cord and affect grey matter nuclei predominantly sparing white matter long tracts (e.g. anterior horn cell damage due to the poliomyelitis virus and posterior horn cell due to Herpes Zoster). This is an important observation and helps in distinguishing viral myelitis from other causes of myelopathy. In cases of inflammation of the spinal cord where white matter tracts bear the brunt of involvement, aetiologies other than viral myelitides such as parainfectious myelitis, post vaccination myelitides, multiple sclerosis and paraneoplastic myelopathy are to be considered.

Table 2: Causes of Non-Compressive Myelopathy

Infections	
Viral	Poliomyelitis
	Rabies
	Herpes Zoster/Varicella
	Mumps
	Viral hepatitis
	EV 70 disease
	AIDS related myelopathies
Bacterial/ Spirochaetal	Bacterial meningitis
	Typhoid
	Tuberculosis
	Syphilis
Parasitic	Schistosomiasis
	Malaria (falciparum)
Immuno-allergic (Post-and parainfectious)	
	Influenza and other viral infections
	Post exanthematous (measles, varicella)
	Post vaccinal (smallpox, rabies, poliomyelitis)
Demyelinating diseases	
	Multiple sclerosis
	Neuromyelitis optica
	Eales' disease
	Acute disseminated encephalomyelitis (ADE)
Heredofamilial/Degenerative disease	
	Motor neuron disease
	Heredofamilial spastic paraplegia
	Spinocerebellar ataxia
Toxic myelopathy	
	Neurolathyrism
	Intrathecal Injections
	Chemotherapeutic agents
	Penicillin
	Spinal anaesthetics
	Contrast media
	TOCP
	Arsenic
	SMON
Vascular disorders	
	Arteriosclerosis
	Dissecting aneurysm of aorta
	Surgery on abdominal aorta
	Angiography
	Systemic lupus erythematosus
	Polyarteritis nodosa
	Vascular malformations (angiomas, AV malformations)
Physical agents	
	Irradiation myelopathy
	Electrical injury to spinal cord
Metabolic/Nuritional	
	Pernicious anaemia / Vit B12 neuropathy
	Pellagra
	Myelopathy of chronic liver disease
	Hypocupric myelopathy
Tropical spastic paraplegia	
	HTLV – 1 associated myelopathy
Paraneoplastic myelopathy	

Acute anterior poliomyelitis

The clinical syndrome of acute anterior poliomyelitis is a febrile illness associated with flaccid motor weakness or paralysis and signs of meningeal inflammation. However, the enteroviruses, echoviruses, and coxsackie viruses also cause the clinical syndrome of anterior poliomyelitis. In areas where polio vaccination programme has all but eradicated polio, these enteroviruses are responsible for the majority of cases of paralytic poliomyelitis syndrome. However, these non-polio enteroviral poliomyelitis cases do not occur as epidemics. Polio like syndrome also has been reported secondary to mumps virus, infectious mononucleosis and rabies virus.

Post-infectious and post-vaccination myelitis

Post-infectious or parainfections myelitis, post-vaccination myelitis, multiple sclerosis and acute necrotising myelitis are the most common cases of acute transverse myelitis and ascending myelitis. The aetiology of these disorders is unknown. These disorders share a similar pathology and are thought to share similar inflammatory pathogenesis. This group of disorders involve white matter tracts predominantly or both white and grey matter (transverse myelopathy) in contrast to viral myelitis which shows a predilection for grey matter. The exanthematous fevers that are antecedent to myelitis include viral diseases like rubeola (measles), rubella (German measles), mumps, influenza, *Mycoplasma pneumoniae*, infectious mononucleosis and varicella. The incriminated vaccines include those against tetanus, poliomyelitis, rabies and smallpox. However, in many cases myelopathy occurs without an apparent infection or vaccination.

The pathogenesis is immunological and an autoimmune response to a CNS antigen such as myelin basic protein may be responsible. Alternatively circulating immune complexes may induce a vascular injury. The time interval between exposure to the infection or vaccination and the development of the neurological disorder varies but is commonly 7 to 10 days. Pathological changes are found in the blood vessels and the perivascular regions. Hyperaemia, perivascular cellular exudate and oedema and haemorrhage are found in arterioles, venules and capillaries. Even though clinical examination reveals signs of only myelopathy both the brain and spinal cord usually are involved on pathological examination. The clinical features are highly variable. Systemic symptoms including fever, malaise, nausea, vomiting and muscle pain suggesting an infectious aetiology appear first. Paraesthesias in lower extremities, back pain or radicular pain heralds the illness and myelopathy may develop without any of the above features.

Thoracic spinal cord is the most frequent site of involvement. Myelopathy may be accompanied by a polyradiculopathy. Symptoms and signs of cord involvement usually evolve acutely with the majority of patients developing maximal neurological deficit within several days. The specific signs are weakness, sensory loss and sphincter dysfunction. Routine laboratory studies are usually normal or non-specific. The CSF may be normal but typically shows a moderate lymphocytic pleocytosis. Other signs of CNS inflammation may include a slightly elevated protein usually less than 120mg/dL and elevated IgG and the presence of oligoclonal bands. CSF glucose concentration is normal. MRI of brain may reveal areas of demyelination. Spinal MRI with gadolinium enhancement is diagnostic. Therapy is non-specific. Cortiosteroids or ACTH is routinely used. Prednisolone 1 mg/kg/day for a two-week period and tapered over a further one week is preferred.

Myelopathy Due to Demyelinating Diseases

Multiple sclerosis (MS)

(See chapter on Demyelinating Diseases of Nervous System in this section)

Devic's disease

Neuromyelitis optica or Devic's disease is characterised by involvement of the spinal cord and the optic nerves simultaneously and is common at the extremes of age. Pathologically, there is a greater degree of axonal degeneration than in MS and the spinal cord shows a frank necrotic picture. Clinical presentation reflects the sites of pathology and unilateral or bilateral visual impairment is followed within days or weeks by a transverse or ascending myelitis. Because of necrotising nature of the remission of lesions is less likely.

Eales' disease

Neurological involvement in association with classical changes of Eales' disease in eyes (retinal periphlebitis) has been described from India initially by Singhal and Dastur in 1976. Neurological insult is very severe in the very first episode of Eales' disease and severe motor weakness, sensory loss and sphincteric involvement ensue.

Acute Disseminated Encephalomyelitis (ADEM)

Although the incidence of MS is low in India, the incidence of postinfectious or postvaccinial allergic demyelination, i.e. acute disseminated encephalomyelitis (ADEM) is not very low. It is the common experience in India that ADEM is seen following upper respiratory infections, exanthematous fevers and following vaccinations. An approximate incidence of ADEM is 1 per 1,000 cases with measles, 1 per 100,000 cases with varicella and 1 in 1,000 to 1 in 4,000 following vaccination against rabies. ADEM is a monophasic illness with either a solitary site such as cord or brainstem or may have wide spread lesions in both brain and spinal cord.

Toxic Myelopathy

Consumption of khesari dal can lead to neurolathyrism and similarly consumption of edible oil TOCP (Triorthocresyl phosphate) can lead to myelopathy.

Neurolathyrism

(See chapter on Lathyrism in Poisoning and Toxicology Section)

Myelopathy Due to Physical Agents

Radiation myelopathy

The criteria for diagnosis are: the spinal cord must have been included in the area irradiated, the main neurological lesion must be within the area exposed to irradiation and cord compression due to metastasis should have been convincingly excluded. Four major syndromes have been recognised.

Early and transient form: This consists of mild subjective symptoms of paraesthesias and electric-shock like sensations on neck flexion (Lhermitte's sign) and starts at about a latent period of three months after irradiation and disappears in about

three months. The differential diagnosis for the cause of Lhermitte's sign includes spinal metastasis and unrelated disorders such as cervical spondylosis, subacute combined degeneration, post traumatic syndrome, multiple sclerosis and cisplatin chemotherapy. The pathogenesis is thought to be reversible damage to myelin in the ascending sensory tracts of the spinal cord, which allows axons to be abnormally sensitive to mechanical deformation.

Lower motor neuron disease: There is a selective damage to anterior horn cells in the upper or lower limbs. A painless amyotrophy and weakness, usually of the lower extremities, develops subacutely 3 to 8 months following high dose radiation therapy to the spinal cord. Sensory abnormalities are not found and the sphincters remain intact. The course is subacutely progressive but ultimately self-limited.

Acute transverse myelopathy: The third form of radiation myelopathy is that of an acutely developing paraplegia or quadriplegia presumably secondary to infarction of the spinal cord. It may be secondary to radiation induced vascular pathology.

Chronic radiation myelopathy: This is the only form for which pathological correlation has been established. Most typically the neurological symptoms begin five months to many years following therapy. A spinal dose of 3,750 Rads in 3 to 4 weeks should not be exceeded. Symptoms reveal involvement of various fibre systems of the cord resulting in weakness, sensory impairment, and bowel and bladder incontinence ending in a total transverse lesion of the cord. Progressive damage to vascular endothelium may be the primary event leading to spinal cord ischaemia. Corticosteroids may have a role in the management.

Myelopathy due to electrical injuries

The cervical cord is frequently the site of injury because the electrical current often passing from hand to hand or lightning injury sustained during rainy weather. The latter type of injury has been recorded in armed forces personnel travelling in armoured vehicles with helmets in rainy weather. Spinal cord damage may be either acute or delayed. Acute injuries may be secondary to heating of tissue or to tissue ischaemia. Both grey matter and white matter tracts may be damaged, so that sensory, motor and sphincter disturbances may occur. Occasionally, a delayed progressive spinal cord syndrome develops. This syndrome may be difficult to differentiate clinically from spinal muscular atrophy or amyotrophic lateral sclerosis.

Vascular and Autoimmune Causes of Myelopathy

Many systemic diseases predispose to spinal cord infarction. Invasive procedures may be complicated by spinal cord infarction. Causes of spinal cord infarction include aortic dissection, atherosclerosis, collagen vascular disease and other inflammatory/infectious diseases, diabetes, trauma, Caisson's disease, spondylosis and various surgical and other invasive procedures. Fibrocartilagenous embolisation is a very rare but interesting cause of spinal cord infarction. Spinal cord infarction is of two types: arterial and venous.

Arterial infarction

Among the arterial infarctions anterior spinal artery infarction is by far more common than posterior spinal artery infarction. Anterior spinal artery infarction is common in thoracic cord and those affected abruptly develop a transverse level and below the level of the lesion, acute paralysis, dissociated sensory loss and loss of sphincteric function. There will be history of radicular pain in a girdle distribution for two to three days. Usually the motor paralysis below the level of infarction is initially flaccid and areflexic owing to spinal shock. A sensory level to pain and temperature with preservation of posterior column function is typically found. Thoracic cord is most commonly involved because this is the watershed area for blood flow in the rostro-caudal axis. Aortic dissection causes an infarction of spinal cord with a sensory level for pain and temperature near the T4 level. Posterior spinal artery infarction is rare and damage extends into the posterior horns of the spinal cord, resulting in global anaesthesia at the affected level and below the level of infarction there is loss of vibration and position sensations.

Venous infarction

Venous infarction of spinal cord may be either haemorrhagic or non haemorrhagic. Severe sepsis, carcinomatosis and vascular malformations cause venous infarctions. Haemorrhagic venous infarction presents with sudden onset of back, leg or abdominal pain evolving over 1 to 2 days to flaccid weakness and loss of sensation below the level of the haemorrhagic infarction and loss of sphincteric function. Dissociated sensory loss is not a feature of venous infarction. Non haemorrhagic venous infarction presents subacutely with painless progressive lower extremity weakness, sphincteric disturbances and sensory loss below the level of the lesion.

Autoimmune diseases

The spinal cord may be the target of a variety of systemic autoimmune diseases like Sjogren's syndrome, systemic lupus erythematosus (SLE), rheumatoid arthritis, polyarteris nodosa, Wegner's granulomatosis, and Behcet's disease. Twenty per cent of patients with primary Sjogren's syndrome develop CNS involvement. In these cases episodic multifocal involvement of the brain and spinal cord may occur mimicking multiple sclerosis. Acute or subacute transverse myelopathy, chronic progressive myelopathy, neurogenic bladder and other spinal cord syndromes have all been described. An immune vasculopathy is the favoured pathogenetic mechanism in these cases. Myelopathy is a well documented complication of SLE and it is due to vascular disease.

Caisson's disease

In individuals who are subjected to high underwater pressure (like deep sea divers) nitrogen bubbles form and get trapped in spinal vessesls. Most often the upper thoracic cord is involved. There are ischaemic changes mainly in the white mater of upper thoracic cord. Posterior columns are more affected than lateral and anterior columns. There may be complete transverse myelopathy as soon as the individual is resurfaced, but the condition may improve, leaving an asymmetrical and incomplete but permanent residual deficit. Immediate treatment consists of recompression in a hyperbaric chamber and gradual decompression. Treatment of residual deficit is symptomatic with antispasticity drugs.

Metabolic and Nutritional Myelopathy

The common causes of myelopathy due to metabolic and nutritional factors include diabetes mellitus, cyanocobalamin deficiency, pellagra and chronic liver disease.

Subacute combined degeneration of cord

This treatable disease was first described in detail at the turn of the century and results from vitamin B12 deficiency and is often associated with megaloblastic anaemia. Degenerative and demyelinating changes occur in the white matter of the posterior and lateral columns of the spinal cord and also in white matter of brain. Peripheral nerves may show signs of demyelination and axonal degeneration. Symptoms secondary to sensory peripheral neuropathy and/or damage to ascending white matter tracts are first noted and are usually progressive and ascend the extremities. Many patients first note pins and needles tingling or numbness in the feet followed by hands. Vibration and position sensations are disturbed and Romberg's sign usually becomes positive. The motor symptoms generally are weakness and stiffness in the lower extremities. Gait may be spastic or ataxic or combined type. Deep tendon reflexes may be absent in ankles if peripheral neuropathy predominates. Babiniski sign eventually develops. Sphincter disturbances are atypical. When the brain is involved, a variety of neuropsychiatric findings may occur along with visual and other cerebral manifestations. Diagnosis depends on serum B12 level and two stage Schilling test. Treatment consists of parenteral B12 administration.

Copper deficiency/hypocupric myelopathy

Recently copper deficiency has been recognised as a cause of myelopathy in patients who have undergone gastric surgery, with sensory ataxia, spastic gait and demyelination in the CNS, optic neuritis and peripheral neuropathy. The clinical picture is like that of vitamin B12 deficiency myeloneuropathy with normal levels of vitamin B12 and low serum copper levels. Associated myelodysplasia may be present and resolves with copper supplementation. Though progress of deficit can be contained with copper intake, recovery is not complete.

HTLV-1 Associated Myelopathy

A slowly progressive myelopathy characterised by symmetric upper motor neuron paraparesis, sphincter disturbances and mild sensory signs is encountered in tropics (Tropical spastic paraparesis/TSP) and Japan (HTLV-I associated myelopathy/HAM). The retrovirus human T-lymphotrophic virus type-1 has been implicated as the causative agent. TSP and HAM are likely to be the same disease because HTLV-I antibodies are demonstrated in serum and CSF in both the conditions. However, a positive serology without neurologic disease has been reported in up to 26% of some populations studied and the presence of HTLV-I antibody does not necessarily indicate a causal relationship. The usual clinical presentation is progressive lower extremity weakness, often associated with lumbar or thoracic pain. Paraesthesias are common but prominent sensory disturbances are unusual. Bladder dysfunction is common. The signs and symptoms are usually bilateral. Weakness usually involves the legs more prominently than the arms, but spasticity is typically found in all extremities. The serum and CSF HTLV-I antibody titres do not correlate with disease severity. The therapy of HAM is unsatisfactory. Corticosteroid therapy and plasmapheresis may be temporarily effective in some patients.

Paraneoplastic Myelopathy (Non-Metastatic Manifestation of Malignancies)

Paraneoplastic myelopathy refers to spinal cord disease in patients with malignancy where the myelopathy is not due to compression from the tumour, effects of treatment, metabolic or electrolyte imbalance or identifiable disease unrelated to malignancy. The pathogenesis is unknown and paraneoplastic myelopathy occurs as a non-metastatic manifestation of carcinomas. It differs from transverse myelitis in that disturbance is not limited to a single spinal cord level. Pathologically there is an ischaemic myelopathy characterised by symmetric necrosis involving both grey and white matter with a predilection for the thoracic spinal cord. The clinical picture is a rapidly ascending sensory motor myelopathy. The course is typically short with death occurring within a few months. In chronic paraneoplastic myelopathy the symptoms are those of motor neuron disease. Wasting and fasciculations are evident in the affected musculature. The diagnosis of paraneoplastic myelopathy is difficult. It is seen in a variety of carcinomas and lymphomas. There is no specific laboratory test for paraneoplastic myelopathy and it has to be differentiated from intramedullary metastasis, radiation myelopathy and other diseases.

Acute and Subacute Myelopathy of Unknown Aetiology

Transverse myelitis is a syndrome of diverse aetiology. Some pathological processes that may give rise to transverse myelitis include post infectious and post vaccination myelitis, multiple sclerosis and acute necrotising myelitis, viral myelitides, spinal cord infarction, radiation myelopathy, vascular malformations and paraneoplastic syndrome. Despite exhaustive attempts to diagnose the aetiology and pathogenesis of acute or subacute non-compressive myelopathy, there are many cases in which no specific diagnosis can be made at the time of clinical presentation. Such entities are termed as non-compressive myelopathy which is defined as a clinical syndrome of bilateral intramedullary dysfunction, which may be ascending or static and often involves several spinal segmental levels. The diagnosis of non-compressive myelopathy is a clinical after the exclusion of known causes such as cord compression secondary to neoplasm or abscess. This myelopathy of obscure nature occurs in 25% to 40% of patients with paraplegia.

20.29 Peripheral Neuropathy

AK Meena

INTRODUCTION

A common complex neurological disorder seen frequently. There has been an exponential increase in knowledge about its pathophysiology, new avenues of diagnosis and management which has improved its understanding and management significantly.

GENERAL CONSIDERATIONS

The peripheral nervous system (PNS) includes all neural structures lying outside the pial membrane of the spinal cord and brainstem with the exception of the optic nerves and olfactory bulbs, which are but special extensions of the brain. The nerves within the spinal canal and attached to ventral and dorsal surfaces of the cord are called ventral and dorsal roots and those attached to ventrolateral surface of the brainstem are the cranial nerve or roots. Both the roots form the spinal nerves which divide into dorsal and ventral rami. Dorsal ramus supplies the back and the ventral rami supply the limbs and the ventral body wall. The ventral rami in cervical and lumbosacral regions form the plexus.

The thick protective and supporting sheaths of perineurium and epineurium have a vascular supply through longitudinal arrays of richly anastomosing nutrient arterial branches. The perineurium comprises the connective tissue sheaths that surround and separate each bundle of nerve fibres (fascicles) of varying size, each fascicle containing several hundred axons. The sheath that binds and surrounds all the fascicles of the nerve is the epineurium. The fine connective tissue covering of individual nerve fibres is the endoneurium. Longitudinally oriented and widely anastomotic endoneurial vessels also nourish the nerve fibres and are susceptible to the disease.

PATHOLOGIC REACTIONS OF PERIPHERAL NERVE

Several distinct histopathologic changes are recognised in the peripheral nerve, although they are not disease-specific and may be present in varying combinations in any given case. The classic ones are *segmental demyelination*, *Wallerian degeneration*, and *axonal degeneration* (**Figure 1**).

Myelin sheath is the most susceptible element of the nerve fibre, for it may break down as part of a primary process involving the Schwann cells or of the myelin itself, or it may be damaged secondarily as a consequence of disease affecting its axon. Focal degeneration of the myelin sheath with sparing of the axon is

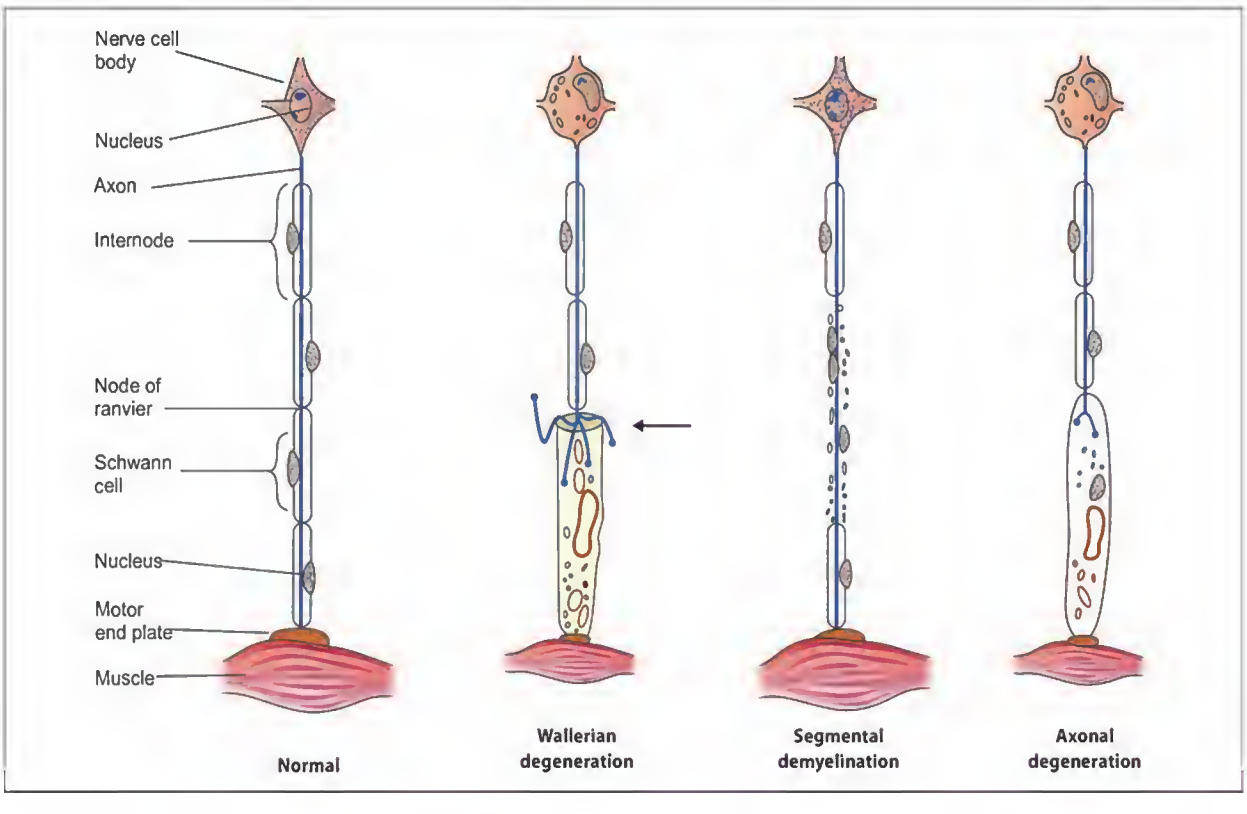

Figure 1: Diagram of basic pathologic process affecting peripheral nerves. Arrow in the figure shows the degeneration of myelin and with chromatolysis. *Courtesy: Dr Arthur Asbury.*

called *segmental demyelination*. The characteristic change of segmental demyelination is the disappearance of the sheath over segments of variable length, bounded on each end by a preserved segment of myelin. Certain diseases affect the neuron primarily rather than the axon and cause either a motor or sensory *neuropathy*. In the former case, the anterior horn cell is affected by a disease process (motor neuron disease or motor neuronopathy) and in the latter; the sensory ganglion cell (ganglionopathy) is destroyed. A type of wallerian distal degeneration of the respective nerve fibres follows. Common to many lesions of peripheral nerves is *Wallerian degeneration* a reaction of both the myelin and axon distal to the site of disruption of the axon along with chromatolysis. (Dying forward phenomenon). *Axonal degeneration* is a process where the axon degenerates as part of the dying back phenomenon due to neuronal disease in more generalised metabolic polyneuropathies.

Clinical Features

The clinical features and examination have been detailed in Chapter 2 of this section. Here these are tabulated in **Table 1** and some of them have been described in following paragraphs.

Table 1: Symptoms Associated with Peripheral Neuropathy

	Positive Symptoms	Negative Symptoms
Somatic nerves	—	—
Sensory	Pain, tingling	Numbness, lack of feeling
Motor	Cramps, fasciculations	Weakness, atrophy
Autonomic	Hyperhydrosis, diarrhoea	Orthostatic hypotension, impotence, anhydrosis, constipation

Orthopaedic Signs

Limb inspection can reveal structural and trophic changes in the feet, lower legs, and hands. High arches (*Pes cavus*) and hammertoe deformities suggest long-standing neuropathies. Fallen arches can also be observed in severe neuropathies. Toes and foot injuries unnoticed by the patient suggest a marked degree of sensory loss.

Autonomic Signs

Autonomic nervous system is involved in many peripheral neuropathies, but symptoms and signs of dysautonomia are uncommonly voiced by the patient and must be asked for. Orthostatic dizziness and changes in blood pressure (a drop of >30 mm Hg systolic pressure and >15 mm Hg diastolic pressure recorded 60 to 90 seconds after standing following 5 minutes of supine rest) support autonomic involvement.

Investigations of Peripheral Neuropathy

Electrodiagnostic studies

Electrodiagnostic studies (EDX) are essential in early evaluation and differential diagnosis of peripheral neuropathies. They are composed of nerve conduction studies (NCS) and needle electromyography (EMG). The procedure should be tailored to the diagnosis. Depending on patients symptoms EDX may be needed: to localise a problem to peripheral rather than central nervous system; differentiate peripheral nerve disease from diseases of neuromuscular transmission and muscle; to localise the pathology to individual nerves, roots, plexus, or motor neurons; to characterise dysfunction as axonal, demyelinating or both. In addition, it tells us whether the neuropathy is generalised or multifocal; information often impossible to discern by the clinical examination. It may indicate severity and chronicity of neuropathy by documenting the degree of axonal loss and motor unit reinnervation (**Table 2**).

Table 2: Simplified Electrodiagnostic Features of Primary Demyelinating and Axonal Pathology

Parameter	Demyelinating Pathology	Axonal Pathology
Distal motor action potential amplitude	Mild to moderate reduction	Normal to moderate reduction
Distal latency	Moderate-gross prolongation	Normal-mild prolongation
Conduction velocity	Moderate-gross slowing	Normal-mild slowing
Conduction block	Present	Absent
Temporal dispersion	Abnormal	Normal
F- latency	Moderate-gross prolongation	Normal-mild prolongation
Needle EMG	Mild-moderate denervation (fibrillation potentials)	Mild-severe denervation

Physiologic tests are available to evaluate qualitatively and quantitatively the autonomic dysfunction by simple as well as sophisticated tests in specialised centres. Quantitative sensory testing is the use of precisely measured and repeatable sensory stimuli to determine the absolute threshold of sensation within specific somato-sensory modalities, which is simple and reproducible.

Nerve biopsy

Nerve biopsy is of little help in diagnosing, early detection and monitoring the progression of peripheral neuropathy. It is useful only in small number of cases. The indications for nerve biopsy are necrotising vasculitis, amyloid neuropathy and Hansen's disease. It may be diagnostic in metachromatic leucodystrophy, Dejerine-Sottas disease, neoplastic infiltrations, and sarcoid neuropathy. Combined muscle and nerve biopsy may be useful in sarcoid and vasculitic neuropathy. Skin biopsy is now gaining importance especially in amyloidosis, vasculitis and to diagnose painful small fibre neuropathy.

Laboratory tests

Minimum essential laboratory tests in the evaluation of peripheral neuropathy include complete blood count, ESR, biochemistry profile, thyroid function tests, vitamin B12 and serum anti-nuclear antibody levels. Other specialised tests should be tailored according to the pattern of neuropathy and clinical suspicion. GTT and serum protein immunoelectrophoresis should also be included especially in chronic neuropathies in adults (**Table 3**).

Approach to the Patient with Peripheral Neuropathy

The classification of peripheral neuropathies and approach are based on several factors like pattern of involvement, disease onset, pathology and aetiology (**Figure 2**). Structural approach to full localisation and characterisation of neuropathy that focuses the differential diagnosis and leads to a rational lists of laboratory tests involves several steps (**Table 4**).

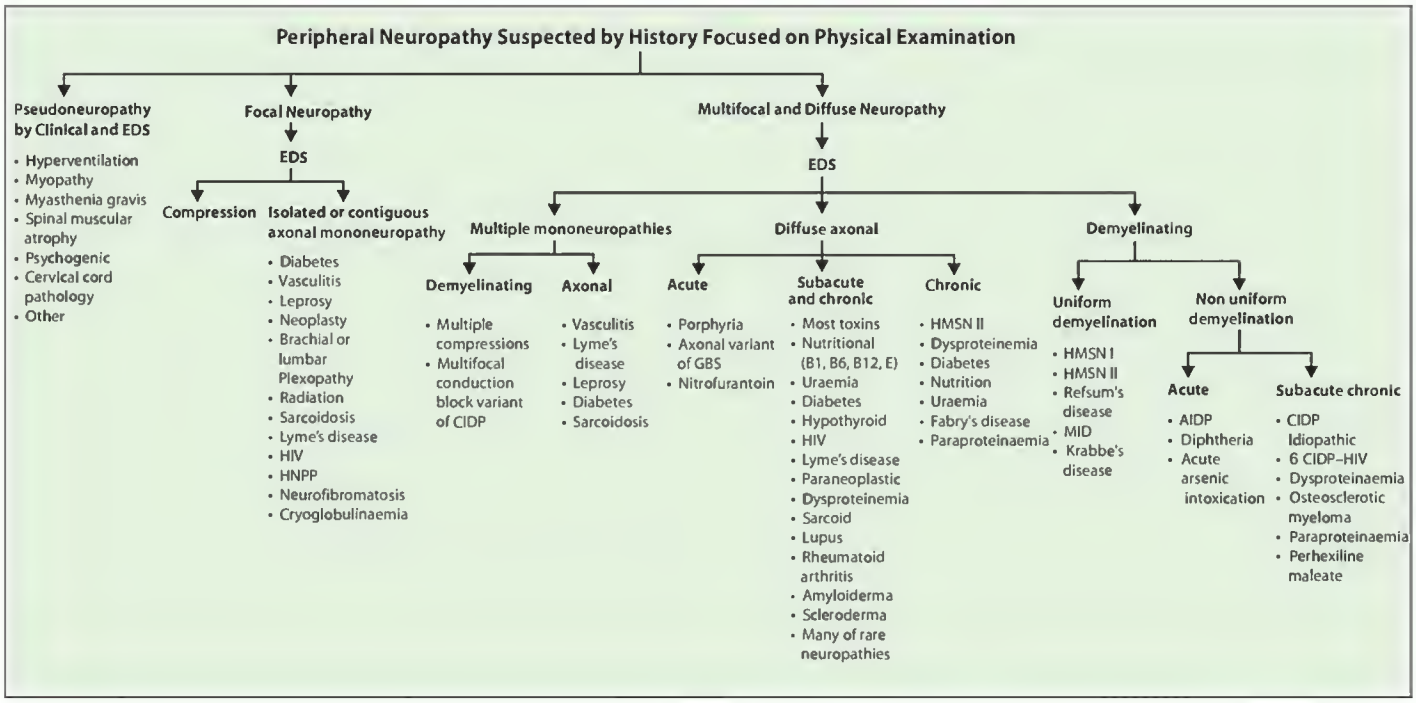

Figure 2: Diagnostic algorithm for PNS disease, with specific diseases.

Table 3: Laboratory Studies in the Evaluation of Patients with Suspected Neuropathy

Routine Tests	Special Tests
Complete blood count with eosinophil count	Rheumatoid factor
Renal function studies	Complement levels (C3, C4, CH50)
Serum glucose and glycosylated haemoglobin (lumbosacral plexus neuropathy)	Serum C-ANCA, and P-ANCA
Liver function studies	Cryoglobulins
Urinalysis	Anti-dsDNA and Sm antibodies
Erythrocyte sedimentation rate	Anti-SSA and SSB antibodies
Anti-nuclear antibody	Anti-Scl 70 and centromere antibody
Serum B12	Lyme titre
	Hepatitis B virus titre
	Hepatitis C virus titre
	HIV
	Cytomegalovirus titre
	Epstein-Barr virus titre
	Serum and urine immunofixation electrophoresis, ACE levels
	GTT

Table 4: Diagnostic Evaluation Steps Leading to Full Neuropathy Characterisation

First step	
Within the peripheral system	Exclude cortical, spinal, psychogenic loci
Second step	
What part of the peripheral nervous system?	Root, plexus, single nerve, multiple nerves Peripheral neuropathy
Third step	
What is the time course?	Acute, subacute, chronic, progressive, relapsing-remitting, event-linked
Fourth step	
What nerve fibres are involved?	Sensory, motor, autonomic, combinations
Fifth step	
What is the primary pathology?	Demyelination, axonal, mixed
Sixth step	
What are the other pertinent features?	Family, medical, social histories

There are several patterns of peripheral neuropathy (**Table 5**). The prototypic and most common pattern is symmetric and length-dependent, involving sensory loss and pain and, less frequently, distal weakness. As progressively shorter nerves are affected, symptoms and signs unroll up the leg as a stocking. Nerve length at knee level is approximately equal to the length innervating the hand, and with further progression, symptoms and signs unroll up the arm as a long glove (Glove and stocking type neuropathy). Most length-dependent polyneuropathies are chronic and involve axonal pathology. Causes of polyneuropathy are many and reflect metabolic abnormalities. Diabetes mellitus is the most common underlying cause of this type, followed by hereditary neuropathies and idiopathic or cryptogenic neuropathies represent up to 25% of polyneuropathies.

Pattern including both proximal and distal limb segments, is usually demyelination at multifocal sites along roots and nerves, e.g. acute inflammatory demyelinating polyradiculoneuropathy (AIDP) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP).

Table 5: Patterns of Peripheral Neuropathy and Examples of Disorders and Causes

Sensory-motor symmetric (length-dependent pattern)	Diabetes, nutritional, medications, toxins, metabolic disorders, hereditary
Sensory-motor symmetric (proximal and distal pattern)	Acute inflammatory demyelinating polyradiculopathy, chronic inflammatory demyelinating polyradiculopathy
Sensory-motor asymmetric (plexus pattern)	Diabetes amyotrophic, idiopathic plexopathy, vasculitic mononeuritis multiplex
Sensory-motor asymmetric (nerve pattern)	Leprosy, systemic lupus, rheumatoid arthritis, leukaemia, polyarteritis nodosa, sarcoidosis, cryoglobulinaemia, Wegener's granulomatosis
Sensory symmetric or asymmetric	Paraneoplastic neuronopathy, Sjogren's syndrome, idiopathic ganglionitis, vitamin B6 toxicity, leprosy
Motor symmetric or asymmetric	Amyotrophic lateral sclerosis, multifocal motor conduction block neuropathy, lower motor neuron syndrome, poliomyelitis, West-Nile syndrome, lead neuropathy
Autonomic symmetric or asymmetric	With other neuropathies (diabetes, acute inflammatory demyelinating polyradiculopathy), isolated involvement (amyloidosis)

Asymmetric patterns are less common and include different lesion sites and pathological processes. Unilateral and focal symptoms and signs in a limb must be distinguished from radiculopathy, plexopathy, or mononeuropathy or mononeuritis multiplex. In some situations like diabetes mellitus, length-dependent neuropathies coexist with radiculopathies, plexopathies, and mononeuropathies. Atrophic weakness without sensory loss that does not follow a radicular, plexopathy, or mononeuropathy pattern suggests motor neuron disease (amyotrophic lateral sclerosis-ALS).

Onset and time course of neuropathy is important in determining the cause of the neuropathy (**Table 6**). Fibre type (pure sensory, motor or autonomic) involvement also helps in aetiological diagnosis of peripheral neuropathy (**Table 7**). Determining the primary pathological process demyelination and axonal loss is important for the diagnosis, treatment and prognosis. Electrodiagnostic tests can differentiate between the two. Nerve biopsy is of limited value in this aspect as it only evaluates a small segment, is not reproducible and is least sensitive for demyelinating pathologies.

Table 6: Peripheral Neuropathy Time Courses and Examples of Associated Neuropathies

Acute apoplectic	Vasculitic mononeuritis multiplex, idiopathic plexopathy
Days to weeks	Acute inflammatory demyelinating polyradiculopathy, porphyria, acute toxic exposure, proximal diabetic neuropathy, paraneoplastic sensory neuronopathy, diphtheritic polyneuropathy, critical illness neuropathy
Chronic, Years insidious	Diabetic polyneuropathy, chronic inflammatory demyelinating poly-radiculopathy, idiopathic hereditary

Table 7: Neuropathies based on Fibre Type Involvement

Motor Neuropathies	Sensory Neuropathies	Autonomic Neuropathies
GBS, porphyria, motor variant of CIDP, MMNCB, lead neuropathy, TOCP, amiodarone, perhexiline	Megadose pyridoxine, vitamin B12 deficiency, paraneoplastic sensory neuronopathy, nutritional neuropathies, Sjogren's syndrome	Diabetes mellitus, amyloidosis, hereditary sensory and autonomic neuropathy, acute pandysautonomia, paraneoplastic sensory and autonomic ganglionopathy

Treatment of Peripheral Neuropathy

Treatment should focus on disease modification if possible (discussed in relevant type of neuropathies) and reduction in neuropathic pain. Anti-epileptic agents, tricyclic antidepressants, and opiates are the mainstay of therapy for neuropathy. All these medications have side effects of drowsiness and reduced mental concentration, which are frequently dose limiting (**Table 8**).

Table 8: Selected Drugs for the Treatment of Neuropathic Pain

Category	Examples	Comments
Analgesics		
Opioids	Morphine, 30 mg/75 kg four times a day Oxycodon 10 to 40 mg	Analgesic tolerance is not inevitable; side effects include constipation
Adjuvant Analgesics		
Tricyclic antidepressants	Nortriptyline, start with 25 mg/day and titrate to 150 mg/day Amytriptyline, start with 10 to 25 mg/day and titrate to 75 to 125 mg/day	Side effects include sedation and mental clouding, cardiac arrhythmias, bladder disturbances, orthostatic hypotension
Traditional anti-convulsants	Carbamazepine, 400 mg three times a day	Side effects include ataxia, aplastic anaemia/agranulocytosis
	Valproate, 750 mg three times a day Phenytoin 100 to 300 mg/day	Side effects include ataxia
Novel anti-convulsants	Gabapentin, 600 mg three times a day	Requires titration; side effects include ataxia
	Lamotrigine, 25 to 100 mg three times a day Topiramate 100 to 400 mg Oxcarbazepine 300 to 600 mg/day Pregabalin 150 to 300 mg/day	Requires titration; side effects include ataxia and rash

ACUTE POLYNEUROPATHIES

A number of polyneuropathies present acutely of which Guillain-Barre syndrome (GBS) because of its frequency and severity is most demanding of the physician's attention.

Landry-Guillain-Barre-Strohl Syndrome

GBS is a prototype of acute onset polyneuropathy. It is usually a monophasic immune-mediated disorder. The term GBS is often considered to be synonymous of AIDP, but with the increasing

recognition over the past few decades of variants, the number of disease that fall under the rubric GBS has grown to include axonal variants and more restricted variants, such as Miller-Fisher syndrome (MFS).

Epidemiology

The reported incidence rates for GBS are 1 to 2 per 100,000 population. The lifetime likelihood of any individual acquiring GBS is 1:1000. The subtypes of GBS have different incidence rates in different parts of the world. In Europe and North America AIDP is dominant contributing to 90% of the cases. In contrast in China and Japan AIDP forms less than 40%, with acute motor axonal neuropathy (AMAN) being the commonest subtype. The picture is intermediate when we look at other population. In Indian series the incidence of AIDP and AMAN are virtually equal, although AMAN is commoner in younger patients. There seems to be a slight preponderance of AIDP in studies by Gupta *et al* and by Meena *et al* (unpublished data from NIMS, Hyderabad). Available Indian literature indicates a peak incidence between June-July and September-October. In the western countries GBS is common in the 5th decade, but in India it occurs more commonly in younger age. GBS is equally common in men and women and can occur at any age. There is a male preponderance among the hospitalised population.

Clinical Features

An otherwise unremarkable infection, such as an upper respiratory infection, often predates the onset of GBS by up to 14 days. Many antecedent infections have been identified, including *Campylobacter jejuni*, cytomegalovirus (CMV), *Mycoplasma pneumonia*, Epstein-Barr virus, influenza virus, JEV. Surgery, immunisation, and parturition have also been associated with GBS. GBS usually begins abruptly with distal, relatively symmetrical onset of paraesthesias and quickly followed by progressive limb weakness. Progression is rapid, with 50% of patients reaching clinical nadir by 2 weeks and more than 90% by 4 weeks. Current diagnostic criteria include <4 weeks of progression to clinical nadir. Approximately 80% to 90% of patients with GBS become non-ambulatory during the illness. Pain is prominent in 50% of patients. Neurological examination is characterised by distal and often proximal, relatively symmetrical, weakness. Though GBS is essentially a motor neuropathy, sensory dysfunction is seen in few patients. It is seen more in demyelinating form of GBS. Sensory examination is often normal in the early phase of the disease. GBS patients often develop cranial nerve weakness, usually in the form of facial or pharyngeal weakness. Diaphragmatic weakness due to phrenic nerve involvement is also common. Approximately one-third of hospitalised patients with GBS require mechanical ventilation because of respiratory muscle or oropharyngeal weakness. Autonomic disturbance usually manifests as tachycardia but more serious autonomic nervous system dysfunction may occur, including life-threatening arrhythmias, hypotension, hypertension, and gastrointestinal dysmotility. The incidence is between 27% and 55% and is much more common in AIDP.

Pathogenesis

Major advances have been made in understanding the mechanisms of some of the subtypes. The histological appearance of the AIDP subtype resembles experimental autoimmune neuritis, which is predominantly caused by T cells directed against peptides from the myelin proteins P0, P2, and PMP22. There is evidence for the involvement of antibodies and complement. Strong evidence now exists that axonal subtypes of GBS, AMAN, and acute motor and sensory axonal neuropathy (AMSAN), are caused by antibodies to gangliosides on the axolemma that target macrophages to invade the axon at the node of Ranvier. About a quarter of patients with GBS have had a recent *Campylobacter jejuni* infection, and axonal forms of the disease are especially common in these people. The lipo-oligosaccharide from the *C. jejuni* bacterial wall injection into rabbits induces a neuropathy that resembles AMAN. Antibodies to GM1, GM1b, GD1a, and GalNac-GD1a are in particular implicated in AMAN and, with the exception of GalNacGD1a, in acute motor and sensory axonal neuropathy.

Diagnosis

The diagnosis is based on both clinical and laboratory criteria. Supportive ancillary testing for GBS includes cerebrospinal fluid (CSF) analysis and electrodiagnostic testing, both of which may be normal in the early phase of GBS. The limitations of ancillary testing in the early phase combined with the importance of prompt treatment of GBS mandates that the clinician at times make the diagnosis based solely on history and examination. Albumino-cytological dissociation, an elevated CSF protein concentration (with normal cell count) is only found on initial CSF analysis in 50% of patients; elevated CSF protein concentration occurs in more than 90% of patients at clinical nadir. CSF pleocytosis is not seen in GBS and raises the question of infectious (HIV, CMV, Lyme, sarcoid), carcinomatous, or lymphomatous polyradiculoneuropathy. Although anti-ganglioside antibodies have been implicated in the pathogenesis of GBS assaying antiganglioside values in a patient with GBS other than MFS at the present time has no diagnostic value in routine practice.

Electrodiagnostic Studies

Electrodiagnostic studies are performed to support the clinical impression. Electrodiagnostic studies of patients with GBS often demonstrates feature of demyelination, such as temporal dispersion and conduction block, significantly slow conduction velocities, and prolonged distal and F-wave latencies. Electro-diagnostic studying features of acquired demyelination (e.g. conduction block, temporal dispersion, non-uniform slowing of conduction velocities) are particularly helpful because these findings are characteristic of immune-mediated demyelinating neuropathies. Another electrodiagnostic study hallmark of GBS is the 'sural sparing' pattern; i.e. the finding of a normal sural sensory nerve response in the setting of abnormal upper extremity sensory nerve results. Low compound motor nerve action potential amplitudes on distal stimulation are a feature in motor axonal variant of GBS. Low CMAPs of 0% to 20% of the lower limit of normal carry a poor prognosis.

Variants of GBS

Commonly recognised variants of GBS include those with axonal forms, variants based on particular fibre type involvement (sensory or autonomic), and MFS. Variants with regional or a markedly asymmetric distribution also occur. There are also differences in abruptness of onset and time to reach nadir, which can complicate diagnosis and decisions about treatment. For example, some patients have progression more

than 4 weeks but clinical features similar to GBS. This disease is referred to as subacute inflammatory demyelinating polyradiculoneuropathy (SIDP). AMSAN and AMAN are the two variants characterised by immune attack directed at axons rather than Schwann cells and myelin. Other regional variants of GBS also occur that affect other specific areas of the body (**Table 9**).

Table 9: Variants of Guillain-Barre Syndrome

Regional	Functional
Miller-Fisher syndrome (ophthalmoplegia, ataxia, areflexia)	Ataxia without dysarthria Pure sensory
Cervicobrachial-pharyngeal, often with ptosis	Pure motor
Oculopharyngeal	Pandysautonomia
Paraparesis	AMAN
Bilateral facial or abducens weakness with distal paraesthesias	AMSAN
Ophthalmoplegia with GQ1b autoantibodies	

AMAN occurs in large epidemics during summer in northern China and more sporadically elsewhere. It mostly affects children and young people, usually from rural areas. Onset of motor weakness is abrupt. In addition to acute motor paralysis, many patients have transient neck and back stiffness early in the course with resolution within a day. There are no sensory symptoms or signs. Sensory nerve conduction studies are normal and motor nerve studies are remarkable for low or absent CMAP amplitudes with normal conduction velocities.

AMSAN shares many pathological features with AMAN but differs clinically from it in patient's age of onset (usually adults rather than children), geographic distribution (can occur anywhere), time of onset (not only summer time), involvement of sensory nerves, course (protracted), and outcome (usually severe residual disability). The course is protracted and outcome is poor, with only 20% ambulating at 1 year.

MFS is more recognisable and distinct regional variant of GBS. Like GBS, onset of MFS often follows an infection, e.g. *C. jejuni*. MFS patients classically present with external ophthalmoparesis, areflexia, and ataxia, although MFS patients often present with fewer components of the classical clinical triad or with additional clinical features (facial weakness, oropharyngeal weakness, internal ophthalmoparesis, and central nervous system involvement). Bicker-staffs brainstem encephalitis (BBE) is a related syndrome in which alteration of consciousness or corticospinal tract signs are seen in addition to ophthalmoparesis and ataxia. Many patients with MFS or BBE also have 'overlapping GBS' with flaccid quadriparesis. Anti-GQ1b antibodies are present in 95% of patients with acute MFS and in approximately two-third of patients with BBE. The recognition of the various clinical presentations and the high sensitivity and specificity of anti-GQ1b antibody testing suggest rubric name of 'anti-GQ1b antibody syndrome'.

MFS is generally a benign, self-limiting condition. Almost all treated and untreated patients return to normal activities within 6 months of disease onset, usually with resolution of ophthalmoplegia within 1 to 2 months and ataxia within 3 to 4 months.

Differential diagnosis include ascending transverse myelitis, toxins, (arsenic, thallium, heavy metal poisoning), acute vasculitis, HIV neuropathy, acute intermittent porphyria, diphtheria, Botulism, poliomyelitis, hypokalaemic paralysis and *myasthenia gravis*.

MANAGEMENT

Patients with GBS who are symptomatic but are able to walk unaided for more than 5 metres and who are stable can be managed conservatively at peripheral centres. However, they should be observed for progression of the disease, especially if they are still within the first week of the onset of the disease. Blood pressure and heart rate fluctuations, clinical signs of respiratory failure should be carefully and meticulously monitored and should be mechanically ventilated during respiratory failure. If any of these signs are detected they should be immediately shifted to higher centres for further management. In the acute phase in bed-bound adult patients require both supportive therapy and immunotherapy can be used taking into consideration the cost factors and the clinical status (staging, complications and other co-morbid conditions) of individual patients. Dysautonomia should be effectively managed depending on the haemodynamic status of the patient.

Hyponatraemia is the common electrolyte abnormality in GBS and is due to SIADH (in majority of the cases) and natriuresis. The treatment is different for both. Both require replenishment of sodium but SIADH need fluid restriction and in case of natriuresis requires intravascular volume expansion. The best way to differentiate these two conditions is by measuring central venous pressure.

Deep Vein Thrombosis Prophylaxis

All patients should be given subcutaneous fractionated or unfractionated heparin and support stockings until they are able to walk independently to prevent deep vein thrombosis. If a prolonged bedridden period is anticipated and a tracheostomy already has been performed, institute oral anticoagulant treatment with warfarin.

Pain and sensory symptoms are reported in majority of patients with GBS and should be treated effectively with opioid analogues. Sedation and bowel hypomotility may become a problem. Other drugs like gabapentin, carbamazepine acetaminophen, NSAIDs and tricyclic anti-depressants also can be tried.

Nutrition

Nasogastric or gastric tube feeding should be instituted early and slowly. High energy (40 to 45 non-protein kcal) and high protein diet (2 to 2.5g/Kg) have been recommended so as to reduce muscle wasting and assist respiratory weaning. Continuous enteral feeding seems to be better tolerated than bolus feeding in these patients.

Surveillance for infections with weekly or more frequent sputum and urine cultures and blood count may be useful but the use of these tests should be guided by clinical circumstances.

Immunotherapy

Plasma exchange (50 mL/kg weight) and intravenous immunoglobulins (0.4 gm/kg/day for 5 days) both are effective

immunotherapies for adult and paediatric patients with GBS if given during the first few weeks of the disease. Potential limitations and complications with plasma exchanges include venous access, line sepsis, hypotension, and rarely air embolus and haemolysis. Intravenous immunoglobulins is relatively safer, easy to administer, with least side effect profile including fever, malaise, headache, aseptic meningitis, reversible renal failure and very rarely hyperviscosity syndrome. The main limitation is the cost.

PORPHYRIA

A severe, rapidly advancing more or less symmetrical relapsing and mainly motor polyneuropathy often associated with abdominal pain, psychosis, and convulsions may be a manifestation of acute intermittent porphyria. See details in Section 18, Chapter 6.

SUBACUTE AND CHRONIC NEUROPATHIES

In this category are neuropathies that evolve over several weeks and months (subacute) to years (chronic, e.g. vasculitic neuropathy, metabolic, nutritional, toxins and paraneoplastic polyneuropathies. Inherited polyneuropathies have a prolonged disease course in several years to decades. Despite considerable increases in the number of identifiable causes of peripheral neuropathy, idiopathic polyneuropathy still accounts for a significant proportion of cases.

DIABETIC NEUROPATHY

Diabetes is the most common cause of neuropathy. The true incidence or prevalence of diabetic neuropathy is not known, due to a lack of agreement on the definition of diabetic neuropathy. There are several reasons for this, including variability in clinical manifestations, a lack of consensus regarding clinical criteria to diagnose early neuropathy, and a lack of minimum electrodiagnostic criteria to diagnose subclinical neuropathy. Thus, the reported prevalence of diabetic neuropathy varies from 5% to 100%. Overall, the incidence of neuropathy in diabetes increases with the duration of diabetes and the degree of hyperglycaemia. See details in Section 9, Chapter 17. A summary is given in **Table 10**.

Table 10: Classification of Diabetic Neuropathy

Generalised Neuropathies	Focal or Multifocal Neuropathies
Distal symmetric polyneuropathy	Compressive focal neuropathies
Large fibre sensory	Carpal-Tunnel syndrome, ulnar neuropathy, peroneal neuropathy
Small fibre painful sensory	Noncompressive focal and multifocal neuropathies
Subclinical neuropathy	Diabetic amyotrophy
Acute painful diabetic neuropathy	Mononeuritis multiplex
Autonomic neuropathy	Cranial neuropathies
	Femoral, sciatic, ulnar, peroneal neuropathy
	Truncal neuropathies

MALIGNANCY RELATED NEUROPATHIES

Peripheral neuropathy can arise in a wide range of situations in context of malignancy. Chemotherapy accounts for the larger group of neuropathies associated with cancer and have largely been documented over the last decades. Oncologists are generally well aware of the toxicity of the main agents. Sequelae of radiotherapy, including plexopathies, lower motor neuron syndrome, cranial nerve dysfunction and exceptional peripheral nerve tumours, have now been well described.

Cancer Neuropathies

Neuropathies may directly result from cancer infiltration either from a solid tumour or from lymphoma. It may also be an indirect consequence of a dysimmune mechanism for instance in paraneoplastic neuropathies or as vasculitic neuropathy. Histopathologically proven vasculitic axonal neuropathies with cancer are seen in 15% of the cases. The complication is more frequent in patients with solid tumours (47.6%) and lymphoid malignancies (35.3%) than in patients with myelodysplastic syndromes (14.3%).

Paraneoplastic Neuropathies

These are associated with autoantibodies called oncogenes which cross react with peripheral nerves. Several types of neuropathies have been reported as paraneoplastic. However, subacute sensory neuronopathy still remains the most typical from in this setting, occurring mostly in small cell lung cancer (70% to 80% of cases) and sometimes in breast or ovarian cancer. See details in Section 21, Chapter 15.

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY (CIDP)

CIDP is a commonly under-recognised acquired neuropathy. Humoral and cellular mechanisms contribute to the autoimmune attack against peripheral nerve myelin. CIDP is distinguished from the subacute and GBS forms based on tempo: progressive weakness of 2 months or more. Sensory loss and decreased reflexes are frequently noted. The disease may progress in a relapsing, or progressive form (steady or step-wise progressive course). The relapsing form peaks in the third decade of life, and the progressive form is more typical in older individuals.

Diagnosis

The classic CIDP phenotype is characterised by symmetric proximal and distal weakness, large fibre sensory loss, increased CSF protein content, demyelinating changes on nerve conduction studies or nerve biopsy, and response to immunomodulating therapy. However, all large series have identified variants of this presentation.

A multifocal variant may present with asymmetric limb weakness. Approximately 50% of patients present with multifocal acquired demyelinating sensory and motor polyneuropathy (MADSAM), later progressing to a more diffuse neuropathy similar to the classical phenotype.

A distal phenotype with distal sensory loss and evidence for demyelination on nerve conduction studies or nerve biopsy may occur in the absence of weakness or with weakness of intrinsic foot/hand muscles, or ankle/wrist flexors or extensors. This phenotype is more common in elderly, and it could be misdiagnosed as lumbosacral radiculopathy or axonal polyneuropathy.

Multifocal motor neuropathy is another phenotype of CIDP. Cranial nerve involvement may also occur in CIDP. Increased CSF

protein occurs in more than 80% of patients, reflecting proximal nerve root involvement. Routine blood tests, including the ESR, are generally normal. Sometime patients with CIDP can be seropositive for P0 protein.

Electrophysiology

Electrodiagonistic studies play a critical role in characterising acquired demyelinating findings, such as slow nerve conduction velocities, prolonged distal motor latencies, prolonged F-wave latencies, conduction block, and abnormal temporal dispersion. Because CIDP is a multifocal disease, the ability to identify demyelination on nerve conduction increases by sampling a larger number of nerves. Some authors have suggested that nerve conductions of 8 motor nerves increased the yield of diagnosing CIDP, compared with unilateral or lower limb studies.

Treatment

Corticosteroids, plasma-exchange and IVIG are the modalities of choice. Steroids regimen consists of 1 to 1.5 mg/kg body weight for 4 to 6 weeks and which is gradually tapered to alternate day regimen of the same dose over a period of 6 months. Azathioprine 2 to 3 mg/kg body weight is commonly used as a steroid sparing drug in the maintenance phase. Plasma exchange produces dramatic responses in relapsing remitting type of CIDP. Often 3 to 4 exchanges on alternate day for a period of 4 weeks is required to obtain a clinical response. IVIG is becoming the treatment of choice due to least side effects and ease of administration even at peripheral centres and clinics. It is usually preferred in elderly patients. The dose is 2 g/kg body weight over 5 days and repeated after several weeks to months to maintain the clinical response. The main limiting factor is the cost. Cyclophosphamide, cyclosporine, lymphoid irradiation are advocated in patients who are refractory to the above treatment.

Multifocal Motor Neuropathy with Conduction Block (MMNCB)

MMNCB is an immune-mediated neuropathy predominates in men. They usually begin as acute or subacute motor mononeuropathy (foot and wrist drop) without sensory deficits. It may be associated with atrophy and fasciculations and mimic ALS. The characteristic feature on electrodiagnosis is multifocal conduction block and normal sensory conduction study. IVIG infusions are the drug of choice and cyclophosphamide can be used.

PARAPROTEINAEMIC NEUROPATHIES

Monoclonal Gammopathy of Undetermined Significance (MGUS)

In patients with neuropathy, particularly demyelinating neuropathies, the paraprotein associated with MGUS is frequently IgM. IgG and IgA are less represented than in the normal population. The paraproteins are usually kappa light chains. Approximately half of the patients with IgM MGUS have anti-MAG antibodies. They are typically older males, in the 6th and 9th decades of life. The characteristic clinical picture goes by the acronym distal-acquired demyelinating sensory neuropathy; as the name suggests, it is an insidiously progressive, distal, predominantly sensory neuropathy, with mild distal weakness. Large fibre sensation is affected more than small fibre sensation, resulting in sensory ataxia. Although the majority of patients with DADS have an M-protein (DADS-M), some do not (DADS). DADS-M is probably a distinct clinical entity from DADS. Whereas most patients show an insidious course with more sensory dysfunction, some may have significant weakness and more aggressive course).

Patients with DADS-M show slowed motor conduction velocities with excessively prolonged distal latencies on electrophysiologic studies, more so than DADS. Sensory responses are often attenuated or absent. Unlike IgM MGUS-related neuropathy there is no clinical homogeneity in the presentation of IgG or IgA MGUS.

Multiple Myeloma

Peripheral neuropathy associated with multiple myeloma can be due to perineurial or perivascular IgG kappa deposition, or due to treatment-related toxicity. Very rarely, IgM paraprotein is seen with multiple myeloma. Patients typically develop mild, symmetric sensory-greater-than-motor symptoms in the distal extremities; with concurrent amyloid deposition, the symptoms are more painful. Electrophysiology shows axonal damage, but histopathology can show demyelination as well, although more recent studies are lacking.

POEMS

The paraprotein found in this syndrome is usually IgG or IgA lambda. The acronym POEMS was coined in 1980 to point out the salient features of this condition (polyneuropathy, organomegaly, endocrinopathy, myeloma, hyperpigmented skin). It can have myriad presentations, and goes by several other names, including Crow-Fukase syndrome and Takatsuki syndrome. Clinically, the patients are younger (late 40s), and have severe sensory and motor weakness. Electrophysiology shows a demyelinating neuropathy with superimposed or secondary axonal loss, and nerve biopsy can show endoneurial deposits and uncompacted myelin lamellae.

WALDENSTROM'S MACROGLOBULINAEMIA

The disorder is rarely associated with peripheral neuropathy, seen only in 5% to 10% of cases. Neuropathy is associated with IgM kappa with or without anti-MAG antibodies. It is clinically indistinguishable from IgM MGUS-related neuropathy with anti-MAG antibodies, or DADS-M. Electophysiologic studies show demyelination; pathological studies show widening of lamellae as in IgM MGUS.

AMYLOIDOSIS

Peripheral neuropathy symptoms are often present for a long time prior to the diagnosis of amyloidosis, a multisystem disorder characterised by IgG or IgA lambda paraproteinaemia and deposition of immunoglobulin light chains in end organs. Either vascular insufficiency or a direct toxic effect of amyloid is the presumptive cause of the neuropathy. The patients experience prominently painful, progressive, symmetric, sensory and motor dysfunction, frequently with autonomic involvement as well. Electrophysiologic studies show an axonal, sensory-greater than motor neuropathy. The overall prognosis is poor, with a median survival of two and half years.

DRUGS AND TOXIN-INDUCED PERIPHERAL NEUROPATHY

Medication and toxin-induced neuropathies constitute a minority of cases, estimated at 2% to 4%, but are crucial to identify because

of potential reversibility, especially if uncovered prior to significant nerve damage. Arsenic, organophosphorous exposure, lead, thallium, gold, mercury and platinum are some of the common causes of toxin-induced polyneuropathy.

Numerous medications (**Table 11**) and toxins have been associated with neuropathy and have been convincingly linked with neuropathy. However, objective proof is lacking for many. Criteria have been applied to establish causation as opposed to simple association: (1) strong dose response relationship; (2) consistent manifestations; (3) close proximity of symptoms to exposure; (4) stabilisation or improvement after drug cessation; (5) reproduction in animal models or characteristic neuropathology; and (6) exclusion of other causes. However, these principles may not be applicable because: (1) some triggers for a neuropathy may be idiosyncratic; (2) low-level chronic exposure is difficult to link to a delayed onset of a disorder; (3) improvement may be minimal or delayed if significant axonal damage has occurred; (4) experimental animals may show different toxic effects from humans; and (5) worsening may continue after stopping the drug (coasting).

Table 11: Drugs Causing Neuropathy

Amiodarone	Nitrofurantoin
Chloramphenicol	Perhexiline
Chloroquine	Phenytoin
Colchicine	cis-Platinum
Dapsone	Pyridozine
Dideoxycytidine (zalcitabine), dideoxyinosine	Simvastatin
Disulfiram	Suramin
Gold	Taxol (docetaxel, paclitaxel)
Isoniazid	Thalidomide
Metronidazole	Vinca alkaloids

The majority of medication and toxin-induced neuropathies affect peripheral nerve axons and cause a distal, symmetric, sensory-predominant axonal neuropathy in a 'dying-back' pattern. However, some stem from direct injury to dorsal root ganglion neurons, peripheral myelin, or Schwann cells that can produce other patterns, including demyelinating features, asymmetry, and even frank conduction block in some examples. Onset is generally over weeks to several months. Sensory neurons and axons are usually more vulnerable than motor fibres. Some toxins produce predominant damage to small-diameter fibers and others to large diameter fibres. Skin lesions like hyperkeratosis, 'Meeslines' are features suggestive of arsenic exposure. Alopecia is seen in thallium exposure. There are a variety of neurotoxic mechanisms, including direct toxicity or toxic metabolites, secondary vitamin deficiency, interference with DNA and metabolic function, mitochondrial injury, apoptosis, and immune triggers.

NUTRITIONAL AND ALCOHOLIC NEUROPATHIES

See in nutritional and toxic disorders.

INHERITED NEUROPATHIES

Amongst the inherited neuropathies hereditary motor sensory neuropathy otherwise called as Charcot-Marie-Tooth disease type 1 and 2 are the commonest forms of chronic neuropathies although more than 50 genetic types have been described (**Tables 12A and 12B**).

Table 12A: Inherited Neuropathies

Type	Clinical Features	EDX Findings	Gene Abbreviation
CMT 1A	Distal symmetric weakness and atrophy; sensory loss and areflexia; skeletal abnormalities	mNCVs <38 m/s; no	*PMP22*
CMT 1B			*PO*
CMT 1C			*LITAF*
CMT 1D			*EGR2*
CMT 2A	Similar to CMT 1, but usually without hypertrophic nerves	mNCVs >38 m/s	*KIF1B*
CMT 2B1			*LMNA*
CMT 2B2			*RAB7*
CMT 2C			Unknown
CMT 2D			*GARS*
CMT 2E			*NEFL*
CMT 2F			Unknown
CMT 2G			*PO*
CMT 3A	Onset in infancy or childhood; prominent proximal and distal weakness; hypertrophic nerves; areflexia	mNCVs <10 m/s	*PMP22*
CMT 3B			*PO*
CMT 3C			*EGR2*
CMT 4A	Autosomal-recessive; early-onset severe neuropathy with hypertrophic nerves; demyelinating pathology	mNCVs <38 m/s	*GDAP1*
CMT 4B1			*MTMR2*
CMT 4B2			*MTMR13*
CMT 4C			*KIAA1985*
CMT 4D			*NDRG1*
CMT 4E			*EGR2*
CMT 4F			*PRX*
HNPP	Recurrent compressive Neuropathies; tomaculous pathology	Mild diffuse slowing of mNCVs; partial conduction block at sites of entrapment	*PMP22*
CMTX	X-linked inheritance; similar presentation as CMT 1; females usually less affected than males	Intermediate slowing of mNCVs; mNCVs >25 m/s	*CX32*
HSAN 1	Neuropathic ulcers; nociceptive loss	Absent or reduced SNAPs	*SPTLC1*
HSAN 2	Painless deformities; nociceptive loss	Similar to HSAN 1	Unknown
HSAN 3	Familial dysautonomic; neonatal onset	Reduced SNAPs	*IKBKAP*
HSAN 4	Congenital insensitivity to pain; fever	Normal	*NTRK1*
HSAN 5	Congenital insensitivity to pain; fever	Normal	*NTRK1*
HMN I	Undefined	mNCVs normal; denervation in clinically weak muscles	Undefined
HMN II	Distal weakness		Undefined
HMN III	Undefined		Undefined
HMN IV	Undefined		Undefined
HMN V	Upper limb involvement		Undefined
HMN VI	Respiratory failure		*IGHMBP2*
HMN VII	Vocal cord paralysis		Undefined
Familial Amyloid Polyneuropathies			
Type 1	Adult onset (Portugese)	Axonal	Transthyretin
Type 2	Adult onset (Indiana)	Axonal	Transthyretin
Type 3	Adults	Axonal	Apolipoprotein A1
Type 4	Adults, lax skin, blood hound face, corticospinal and posterior column deficit	Axonal	Gelsolin

Table 12B: Disorders of Lipid Metabolism and Other Disorders Causing Neuropathy
Metachromatic leucodystrophy
Krabbe's disease
Fabry's disease
Adrenomyeloneuropathy
Refsum disease
Tangier disease
Giant axonal neuropathy
Porphyria
Mitochondrial neuropathies
Severe PNS, CNS demyelination

Diagnosis of a hereditary neuropathy can be challenging and should be included in the differential diagnosis of chronic peripheral neuropathies. The first task is establishing whether there is a family history. This is straight forward when there are reports of similarly affected individuals in multiple generations, but more difficult when there is no known family history. This frequently arises due to the wide range of phenotypic variability in inherited neuropathies; family members may be asymptomatic or only mildly affected and have never sought medical evaluation. Patients may come from small families with a paucity of first- or second-degree relatives. The evaluating neurologist should take a thorough family history, perform a neurological examination, and ideally obtain electro-diagnostic testing. Slow progression of symmetric distal weakness and sensory loss dating to childhood or adolescence supports the possibility of an inherited neuropathy. Questions about motor development, athletic performance, and distal orthopaedic injuries are helpful. Steady progression is consistent with inherited neuropathies; a fluctuating course suggests an acquired condition.

Physical findings suggestive of an inherited neuropathy include Pescavus, hammertoes, and, to a lesser degree, scoliosis. Motor deficits are usually in combination with sensory loss in a symmetric and distal distribution. Muscle atrophy and weakness preferentially affects the anterior compartment of the leg resulting in toe and ankle dorsiflexion weakness. Sensory deficits can be asymptomatic. Patients rarely complain of 'positive' Neuropathic symptoms such as burning, tingling or pain. Electrodiagnostic testing helps guide the decision on which genetic tests to order. Genetic testing should be pursued only for only for patients who understand the implication of testing. A caveat is that none of these genetic testing is 100% sensitive or specific and a negative test does not exclude a hereditary neuropathy.

Treatment

Despite advances in diagnosis, there is no cure for these neuropathies. Treatment consists of patient education and supportive services. The mainstay of treatment is physical and occupational therapy, supports and bracing as well as aids to mobility. Promising therapies may involve the use of neurotrophic factors.

VASCULITIC NEUROPATHY

Causes of vasculitis are many. Peripheral neuropathy is a recognised complication of vasculitis. For the practicing clinician, certain clinical and laboratory features should raise suspicion for a vasculitic neuropathy. Classically, patients have painful sensory loss and weakness in the distribution of multiple peripheral nerves, so-called 'mononeuritis multiplex'. However, perhaps more commonly there is a confluence of multiple mononeuropathies that evolves in a summated fashion to produce a generalised, asymmetric, polyneuropathy or a lumbosacral plexus neuropathy. In some cases, the clinical pattern resembles a nondescript distal, symmetric, pure sensory or sensorimotor polyneuropathy. The course may be explosive at onset, but more often the neuropathy develops in a stuttering or stepwise pattern over weeks to months. Occasional patients have a very chronic, insidious course with symptoms that have been present for years before the time of diagnosis. The course may be indolent and static in some patients with non-systemic vasculitic neuropathy (NSVN).

Virtually all patients with neuropathy caused by systemic vasculitics also have constitutional symptoms, including fever, weight loss, and organ-specific involvement, such as rash, renal, bowel, or pulmonary involvement. Serologic abnormalities frequently indicate a systemic inflammatory process. Others have established diagnosis of a connective tissue or other inflammatory disorder.

Electrodiagnostic studies are especially helpful by demonstrating widespread, subclinical involvement in patients. Skin biopsy establishes the diagnosis of vasculitic neuropathy. In most cases, a nerve biopsy is mandatory to confirm the diagnosis in patients with suspected NSVN. A combined muscle and nerve biopsy may increase the diagnostic yield and is recommended. Characteristic pathological findings include: (1) T-cells and macrophages invading small epineural arteries (often <100 im in size); and (2) destruction or structural damage of the vessel wall with fibrinoid necrosis.

Non-Systemic Vasculitic Neuropathy

The features of NSVN are similar to those of systemic vasculitis; most patients have pain, weakness, and sensory loss in peripheral nerve territories, with slow progression over months to years that conforms to: (1) classic mononeuritis multiplex (13 to 45%); (2) confluent multiple mononeuropathies leading to an asymmetric, sensorimotor, axonal polyneuropathy, plexopathy, or polyradiculoneuropathy involving the arms and legs or legs alone (30 to 85%); or (3) distal symmetric polyneuropathy (2 to 25%). The course of NSVN is more indolent compared with systemic vasculitic neuropathy, and symptoms may be present for several years before the diagnosis is established .Probably less than 10% of patients with NSVN develop systemic features with long-term follow-up.

Treatment

Vasculitic neuropathy is treated with steroids. Other immuno-suppressive drugs that are used are azathioprine and pulse cyclophosphamide in severe cases.

HANSEN'S DISEASE

See in Dermatology Section.

HUMAN IMMUNODEFICIENCY VIRUS (HIV) NEUROPATHY

Several types of neuropathy occur in patients with HIV infection (**Table 13**) and in large urban centres HIV-related neuropathies are seen frequently. Now with the introduction of HAART therapy the opportunistic infections are decreasing on one hand but on the other HIV neuropathy and HIV dementia are on the rise.

Table 13: Peripheral Neuropathies in HIV Patients
Distal Painful Neuropathy
Neuropathy due to nutritional deficiency
Neuropathy due to antiretroviral drugs
Guillian-Barre syndrome
Chronic Inflammatory demyelinating polyradiculoneuropathy
Multiple mononeuropathies
Acute lumbosacral polyradiculopathy

Distal painful neuropathy is very common in the late stages of HIV infection. The main symptom is continuous burning discomfort, mostly in the feet, where some degree of sensory loss also is apparent. Motor involvement usually is minor, although the patients often are debilitated by concurrent infections or weight loss. In some patients with this type of neuropathy there is an identifiable cause, such as vitamin B12 deficiency or treatment with a retroviral drug known to be neurotoxic, e.g. dideoxycytidine, but in most, the cause is uncertain. HIV has been cultured from sural nerve homogenates, and HIV nucleic acid can be found in dorsal root ganglia. Active cytomegalovirus (CMV) infection was found in 9 of 12 patients with distal painful neuropathy in one report, but the role (if any) of CMV in the pathogenesis of distal painful neuropathy is unclear.

Acute and chronic inflammatory demyelinating polyneuropathies typically occur in otherwise asymptomatic patients with HIV infection, sometimes at the time of seroconversion. The clinical picture is similar to that in non-HIV patients, except that a lymphocytic pleocytosis (20 to 50 cells/mm^3) is frequent in the CSF. HIV testing is increasingly considered part of the investigation of any patient with an inflammatory demyelinating neuropathy, and is mandatory if there is a CSF pleocytosis. As in non-HIV patients, both the acute and chronic forms appear to respond well to plasma exchange or IVIG infusions.

MONONEUROPATHIES AND COMMON COMPRESSION AND ENTRAPMENT NEUROPATHIES

The diagnosis of mononeuropathy is based on the motor, reflex and sensory changes confined to the territory of single nerve. Focal neuropathies may result from compression, entrapment, ischaemia, direct trauma, such as lacerations and missile wounds, involvement in fractures or dislocations, brachial mononeuritis, Hansen's disease, diabetes or idiopathic. The terms compression and entrapment are often used more or less interchangeably, sacrificing some accuracy (**Table 14**). Compression neuropathy refers to nerve damage due to pressure applied to a nerve, whether external or internal. The term *entrapment neuropathy* is appropriate when the pressure is exerted by some anatomic or pathoanatomic structure, such are the transverse carpal ligament in carpal tunnel syndrome (CTS). Thus, all entrapment neuropathies are compression neuropathies, but not all compression neuropathies are due to entrapment. Almost any nerve in the body can be compressed

Table 14: Entrapment Neuropathies	
Nerve	**Site of Entrapment**
Suprascapular	Spinoglenoid notch
Lower trunk of medial cord of brachial plexus	Cervical rib or band at thoracic outlet
Median	
Wrist	Carpal tunnel
Elbow	Between heads of pronator teres (pronator syndrome)
Ulnar	
Wrist	Guyan's canal (ulnar tunnel)
Elbow	Bicipital groove, cubital tunnel
Posterior interosseous nerve	Radial tunnel—at point of entrance into supinator muscle (arcade of Frohse)
Lateral femoral cutaneous (meralgia paraesthetica)	Inguinal ligament
Obturator	Obturator canal
Posterior tibial	Tarsal tunnel; medial malleolus – flexor retinaculum
Interdigital plantar	Plantar fascia: heads of 3rd and 4th metatarsals

or entrapped, and by definition involvement is limited to the distribution of a single peripheral nerve. Entrapment neuropathies are all chronic conditions; compression neuropathies due to externally applied pressure can develop acutely over several hours (post-operative ulnar neuropathy, tourniquet paralysis, Saturday night radial nerve palsy), subacutely over days to weeks (peroneal neuropathy at the fibular head due to prolonged bed rest or a short leg cast), or chronically over months to years (ulnar neuropathy in the retroepicondylar (RTC) groove). In some instances, a nerve is injured by relatively low force applied repetitively over a long period (ulnar neuropathy in the RTC groove, ulnar neuropathy at the wrist due to bicycling, peroneal at the fibular head due to habitual leg crossing). The diagnosis of mononeuropathy is based on electrodiagnosis and magnetic resonance imaging in entrapment neuropathies. The treatment of entrapment is surgical decompression.

IDIOPATHIC BRACHIAL NEURITIS (NEURALGIC AMYOTROPHY, PARSONAGE-TURNER'S SYNDROME)

This illness begins abruptly in an otherwise healthy individual, may complicate an infection, vaccination, antibiotics, childbirth, or any surgical procedure. Begins as an ache or deep burning in and around the shoulder neck or in axilla followed several days by motor weakness sensory and reflex loss. Pain subsides with onset of weakness. At times it may be bilateral. Electrodiagnostic studies is helpful in localising the lesion to restricted or diffuse involvement. Therapy is purely symptomatic but steroids may be beneficial. Recovery of paralysis and sensory deficit is usually complete by 6 to 12 weeks.

20.30 Disorders of Autonomic Nervous System

Garima Shukla

One of the most important parts of the nervous system, the autonomic nervous system (ANS) innervates all organs of the body. The visceral and homeostatic functions of the human body, especially the control of arterial blood pressure and body temperature, are vital for survival, but involuntary.

ANATOMIC ASPECTS

Anatomically, most of the ANS is located in close proximity to the visceral organs it supplies. It is divided into the 'craniosacral parasympathetic' and the 'thoracolumbar sympathetic' parts which act in a complimentary fashion to balance various visceral functions.

Parasympathetic System

The cranial part of the parasympathetic ANS commences from visceral nuclei of the brainstem, the Edinger-Westphal nucleus, superior and inferior olivary nuclei, dorsal motor nucleus of the vagus and reticular nuclei. Pre-ganglionic fibres extend from these to the peripheral ganglia located close to the effector organs, viz. pupillary sphincter, ciliary muscle, submandibular and sublingual salivary glands, parotid gland, thoracic and abdominal viscera. Post-ganglionic fibres from these ganglia extend to and supply these effector organs.

The sacral part (pre-ganglionic fibres) originates in the lateral horns of the S2-S4 spinal cord segments, relaying in ganglia located in the walls of pelvic viscera, from where short post-ganglionic fibres arise and supply these organs.

Sympathetic System

Pre-ganglionic fibres of the sympathetic ANS originate in the intermediolateral cell column of the spinal grey matter from C8 or T1 to L2 spinal cord segments; they are small myelinated fibres forming the 'white communicating rami'. These relay in pre- and para-vertebral ganglion chains, from which the short un-myelinated post-ganglionic fibres arise and pass through the 'grey communicating rami' to T5-L2 spinal nerves and form plexuses which supply the heart and all other important viscera of the thorax and abdomen.

AUTONOMIC DISORDERS

Primary Disorders of the ANS

Primary autonomic failure should be diagnosed only after exclusion of common secondary causes enlisted in the next section, since the autonomic symptoms might often be the first manifestations of the underlying aetiology. Presentation may be acute/subacute or it may be chronic. Both these subtypes are entirely different entities.

Acute/subacute pandysautonomia

Acute pandysautonomia (APD) is an autonomic neuropathy characterised by severe widespread sympathetic and parasympathetic failure without somatosensory involvement. Its aetiology has not been established. However, there is a hypothesis regarding it being part of the spectrum of the Guillain-Barre syndrome in view of the following observations:

1. Nearly 50% patients with APD have a presumed viral infection that precedes the onset of symptoms,
2. High protein in cerebrospinal fluid (CSF) may be found in these patients, and
3. Response to intravenous immunoglobulins has been demonstrated in some patients.

There are recent reports of ganglionic acetylcholine receptor (AChR) autoantibodies as anti-neuronal antibodies that could be causative in autonomic neuropathy. Clinical presentation is with various autonomic symptoms like orthostatic dizziness, sweating, urinary and bowel disturbances. The course is generally self-limiting and patients may become symptom free over a period of weeks to months.

This syndrome may purely involve the ANS or may have associated involvement of other neurological systems. It might also completely spare a part of the ANS (pure cholinergic or pure adrenergic pandysautonomia).

Chronic autonomic failure syndromes

Pure autonomic failure: Chronic pure autonomic failure is a chronic degenerative condition, with a possible overlap with the spectrum of multiple system atrophy (MSA). Since the hallmark in MSA is degenerative involvement of more than one neurological system, this rare condition of pure autonomic failure is recognised as a separate entity.

Multiple system atrophy (MSA): MSA is a chronic degenerative disorder, often presenting predominantly either with Parkinsonian (MSA-P) or with cerebellar (MSA-C) features. Autonomic dysfunction is often present early in the course, in fact, may help clinch the diagnosis if it is the presenting feature with marked orthostatic hypotension and dizziness, urinary frequency, hesitancy, urge incontinence and bowel incontinence or more commonly, constipation.

Autonomic failure with Parkinson's disease (PD): Symptoms of autonomic dysfunction may not appear early in the course of PD often. Patients with PD generally respond well to levodopa/carbidopa combination for a number of years. Yet, clinical distinction between MSA-P and PD can sometimes pose a diagnostic challenge. Cardiac I^{123}MIBG (methyliodobenzyl-guanidine) SPECT imaging can serve as a valuable tool for this purpose. In MSA, the autonomic involvement is pre-ganglionic. Hence, cardiac sympathetic innervation tested with this imaging study is normal, while in PD, where there is post-ganglionic sympathetic dysfunction, significant loss of cardiac sympathetic innervation can be found.

Ross syndrome: Ross syndrome is a rare disorder of thermoregulation usually presenting in adulthood with chronic history of heat intolerance or progressive loss of sweating,

initially with patchy involvement, later becoming confluent. It is characterised by the clinical triad of anhidrosis, Holmes-Adie's pupil and generalised hyporeflexia. Cholinergic sudomotor damage has been observed in all patients reported in literature. Nolano *et al* found an involvement of pilomotor and vasomotor fibres and, although to a lesser extent, of somatic unmyelinated and myelinated nerve fibres in the 12 patients they reported and studied for detailed sudomotor function and skin biopsies.

Secondary Disorders of the ANS

A vast variety of neurological and general medical conditions can be associated with secondary involvement of the ANS. Some of these are listed here in **Table 1**. However, a comprehensive review of all conditions is beyond the purview of this chapter.

Table 1: Common Causes of Secondary Autonomic Neuropathy

Hereditary Conditions
- Riley-Day syndrome
- Hereditary sensory autonomic neuropathy

Metabolic Disorders
- Diabetes mellitus
- Chronic renal failure
- Chronic liver disease
- Alcoholism
- Adverse effects of drugs (antihypertensives, anticholinergics, anti-parkinsonian agents, etc.)
- Wilson's disease

Inflammatory
- Guillain-Barré syndrome
- Transverse myelitis

Infections
- Bacterial: Tetanus
- Parasitic: Chagas' disease
- Viral: Human immunodeficiency virus

Neoplasia
- Brain tumours, especially of third ventricle

CLINICAL FEATURES

Symptoms of Autonomic Dysfunction

Cardiovascular manifestations

Orthostatic hypotension: Orthostatic hypotension has been formally defined by expert consensus as a fall in systolic blood pressure (SBP) of at least 20 mm Hg and/or diastolic blood pressure (DBP) of at least 10 mm Hg within 3 minutes of standing. Symptoms typically arise from hypoperfusion of various organs in the erect posture. The common symptoms are presented in **Table 2**.

Table 2: Common Symptoms of Autonomic Neuropathy

Dizziness, syncope, blurring/greying	Due to cerebral of vision, cognitive deficits hypo-perfusion
'Coat hanger ache' (in paracervical regions)	Due to and suboccipital hypoperfusion of muscles
Low backache	
'Subclavian steal' like syndrome	
Oliguria	Due to renal hypoperfusion
Non-specific symptoms like generalised weakness and fatigue	

Hypertension: Severe hypertension can be typically observed in patients with cervical spinal cord trauma, patients with tetanus and the Guillain-Barre syndrome. Patients may manifest only with occipital headache, but sometimes, with more varied and severe manifestations like palpitations with bradycardia, profuse sweating and flushing over the face and coldness of extremities.

Postural orthostatic tachycardia syndrome (POTS): POTS is currently defined as the presence of symptoms of orthostatic intolerance associated with a heart rate (HR) increase of 30 bpm (or rate that exceeds 120 bpm) that occurs within the first 10 minutes of standing or upright tilt, not associated with other chronic debilitating conditions, such as prolonged bed rest or the use of medications known to diminish vascular or autonomic tone. Symptoms resemble those of orthostatic hypotension; however, occurrence of palpitations in the erect posture is often the main feature. Symptoms, if severe, can restrict even routine day-to-day activities.

Facial and peripheral vascular changes: Facial and neck region flushing with coldness of extremities can be observed in patients with autonomic dysfunction, more characteristically in patients with spinal cord trauma and primary autonomic failure.

Sudomotor disturbances: Generalised or focal anhydrosis or hyperhydrosis may be observed in a variety of conditions including the Ross syndrome, hereditary sensory autonomic neuropathies, diabetic neuropathy, etc. Similarly, hypothermia or hyperthermia, both can be seen, the latter typically occurring as a consequence of anhidrosis.

Gastrointestinal disturbances

Reduced salivation can cause dry mouth in various autonomic disorders. This can further lead to dysphagia on eating dry food. Gastroparesis causing distension of the abdomen is seen commonly in diabetics with autonomic neuropathy. Diarrhoea and constipation might occur frequently. Fecal incontinence may particularly be observed in patients with MSA.

Bladder disturbances

Day-time oliguria and nocturnal polyuria can occur due to hypoperfusion of the kidneys in erect posture in day-time, with redistribution of blood supply during sleep in supine position at night. Apart from this, sphincter disturbances can result in hesitancy, urgency and incontinence as well.

Sexual disturbances

Erectile dysfunction resulting from parasympathetic disturbances, is often among the first clinical manifestations of various disorders of the ANS, e.g. diabetic neuropathy, MSA, etc. Retrograde ejaculation and priapism are the other features seen.

Eye manifestations

Horner's syndrome with ptosis and miosis; Holmes-Adie's myotonic pupillary dilatation as well as reduced lacrimation can be frequently found among patients suffering from various autonomic disorders.

Bedside Examination

On general physical examination, dry skin, abnormal sweating, abnormal 'triple response' can be found. Change in blood pressure (BP) and heart rate (HR) in supine *versus* standing

position give important information about orthostatic hypotension and/or tachycardia.

Pupillary abnormalities and the Horner's syndrome, as well as reduced lacrimation confirmed by the Schirmer's test can be easy bedside clues to autonomic dysfunction.

Some other cardiovascular tests which can be performed bedside are the mental arithmetic test, isometric hand grip test and the cold pressor tests (looking for normal *versus* abnormal rise in HR and BP with these manoeuvres).

Detailed systemic and neurological examination give extremely important information about the aetiology of the autonomic disorder, e.g. parkinsonian features in MSA and PD, hyporeflexia pointing towards possibility of peripheral neuropathies or the Ross syndrome, etc.

LABORATORY EVALUATION OF AUTONOMIC FUNCTION

The reader can find a detailed description of the various laboratory tests of autonomic function elsewhere. Most of these may not be available for routine testing at majority of the centres; nevertheless, comprehensive evaluation of a patient with suspected autonomic dysfunction necessitates performing at least some of the simpler, more easily available tests.

Tests of Sudomotor Function

1. Quantitative sudomotor axon reflex testing (QSART): It is a sensitive measure of postganglionic sympathetic axon integrity, in which at the test site, a multi-compartment sweat cell is applied to the skin, acetylcholine (ACh) is iontophoresed in one compartment and the sweat response is recorded in a second compartment.
2. Thermoregulatory sweat testing (TST): The adequate stimulus is a rise of core temperature usually generated by raising ambient temperature so as to raise blood and mean skin temperature. The efferent sympathetic response is mediated by pre-ganglionic centres right from the hypothalamus, up to the white rami; post-ganglionic paths include the sympathetic chain and post-ganglionic sudomotor nerves to sweat glands.
3. Sympathetic skin response (SSR): A very sensitive and simple test which can be easily conducted in any electromyography laboratory with electrical current or physiological phenomena like a deep breath or cough can act as a stimulus. Its major drawbacks are its variability and rapid habituation with high false negative values.

Tests of Cardiovagal Function

1. HR response to deep breathing (or other stimuli like isometric hand grip) can be measured systematically in the laboratory apart from its utility as a simple bedside tool as well.
2. Valsalva ratio: For measurement, the subject, while rested and recumbent, is asked to maintain a column of mercury at 40 mm Hg (not exceeding 50 mm Hg) for 15 seconds via a bugle with an air leak (to ensure an open glottis). The responses should be repeated until two responses of similar beat-to-beat BP and HR responses are obtained.
3. Tilt table testing for orthostatic hypotension. Changes in BP and HR are measured after positioning the patient in a 60 to 75° tilt on the tilt-table, immediately and 3 minutes after change in position.

   Beat to beat measurement of arterial BP can be carried out with the use of special tonometry devices, both for simple measurement of postural changes in BP, and for the calculation of the Valsalva ratio.

MANAGEMENT

Management of the autonomic disorders is often symptomatic. Identifying and targeting the primary aetiology of the dysfunction should be the primary aim of treatment.

Most treatment strategies are directed towards management of symptomatic postural hypotension. The approaches utilised are mostly non-pharmacological, suggesting the patients to avoid the following:

- Sudden head-up postural change (especially, on waking),
- Prolonged recumbency,
- Straining during micturition and defaecation,
- High environmental temperature (including hot baths),
- 'Severe' exertion,
- Large meals (especially, with refined carbohydrate),
- Alcohol, and
- Drugs with vasodepressor properties; along with suggestions regarding
  - small frequent meals,
  - high salt intake,
  - judicious exercise (including swimming), and
  - body positions and manoeuvres.

In severe cases, oral fludrocortisone (50 to 100 µg at night) can be used as an initial drug of choice, however, non-responders can require treatment with ephedrine 15 mg three times daily that may be increased to 30 or 45 mg three times daily, octreotide 25 or 50 mg, ideally 30 minutes before food ingestion to avoid postprandial hypotension or desmopressin 5 to 40 mg intranasally or 100 to 400 mg orally at night to reduce nocturnal polyuria which can worsen day-time postural hypotension.

20.31 Myasthenia Gravis

Sumit Singh, Atma Ram Bansal

Myasthenia gravis is an autoimmune disorder where antibodies against the nicotinic acetylcholine receptors (AChRs) on the post-synaptic membrane of the neuro-muscular junction (NMJ) inhibit neuro-muscular transmission. It is characterised by fatiguable skeletal muscle weakness, and diurnal variation of symptoms. Once considered a fatal illness, *M. gravis* can now be managed safely and effectively due to significant advances in management. Thomas Willis (1672) was the first to describe myasthenia and Osserman (1958) classified *M. gravis* according to severity of clinical symptoms. *M. gravis* is the commonest NMJ disorder, with a prevalence of 14.2 cases per million in the US and 20 to 70 cases per million in the UK.

AETIOPATHOGENESIS AND PATHOLOGY

The NMJ has three components: Pre-synaptic motor nerve terminal where acetylcholine (ACh) is synthesised, packaged into vesicles and released, the synaptic cleft, and the post-synaptic membrane which contains acetylcholine receptors (AChRs) and anticholinesterase enzyme. There is a constant turnover and renewal of AchRs at the NMJ. AchR antibodies are found in nearly 80% to 90% of patients with generalised *M. gravis* and 50% to 60% of patients with ocular *M. gravis*. These antibodies block the AchRs, destroy the muscle end-plate by activating the lytic compliment pathway which causes simplification and distortion of normally folded post-synaptic membrane, and cross link with AChRs and accelerate endocytosis and degradation of AChRs. Extra-ocular muscles are more vulnerable for *M. gravis* because their NMJ has less prominent synaptic folds; fewer post-synaptic AchRs and smaller motor units. The role of thymus gland in *M. gravis* has been proposed since a long time. Thymic hyperplasia occurs in 60% to 70% of *M. gravis* patients, more so in females. Thymomas are frequently associated with autoimmunity and their cells express numerous AChRs like epitopes. The aetiological causes of *M. gravis* are shown in **Table 1**.

Table 1: Aetiological Classification of Myasthenia

Type of Myasthenia	Aetiology
Acquired autoimmune	Autoimmunity
Transient neonatal *M. gravis*	Transplacental transfer of maternal anti-acetylcholine receptors (AChRs) antibodies
Drug-induced *M. gravis*	D-penicillamine, curare, aminophylline, quinine, procainamide and calcium channel blockers
Congenital myasthenic syndromes	Genetic abnormality in acetylcholine receptors

CLINICAL FEATURES

M. Gravis has a bimodal peak of age at onset. The first peak is in adolescence and the second in fifth or sixth decade. Females are more commonly affected at a younger age. Incidence is roughly equal for male and female sex during puberty and between 40 to 50 years of age. *M. gravis* presents with a history of fluctuating proximal muscle weakness which worsens with activity, typically worsening towards evening and improving in the morning and after rest. About 60% to 70% of patients present with diplopia due to extra-ocular muscles involvement, often asymmetrical, mimicking 3rd, 4th, or 6th cranial nerve palsy or internuclear ophthalmoplegia (INO). Pupillary functions are never affected, but weakness of orbicularis oculi may impair eyelid closure as well. The weakness of muscles of eye opening as well as closing is seen in very few diseases of which *M. gravis* is the commonest. Involvement of muscles of mastication causes drooping of the jaw while chewing hard foods. Facial muscle involvement causes lack of facial expression and a 'snarl' on attempted smiling. Bulbar muscle weakness presents with dysphagia and dysphonia and may result in aspiration pneumonia. Speech may have nasal intonation but improves with rest. Cognitive, sensory or autonomic symptoms are absent. The most commonly affected muscles in decreasing order of frequency are: Levator palpebrae superioris, extra-ocular muscles, proximal limb muscles (upper limbs > lower limbs), facial muscles and neck extensors. Intercurrent infections, emotional upset, febrile illness, exposure to heat, menstruation, vaccination, certain drugs, (**Table 2**), pregnancy, hyperthyroidism, and hypokalaemia may precipitate *M. gravis*. In a previously undiagnosed case, delayed recovery after general anaesthesia or a difficult weaning off the ventilator can indicate *M. gravis*. Thyroid disorders may be seen in nearly 13% of the cases.

Table 2: Drugs to be Avoided in *Myasthenia gravis*

Analgesics	Narcotics
Anaesthetics, local	Cocaine, procaine, lidocaine, bupivacaine, prilocaine
Antacids or laxatives containing magnesium	Maalox, mylanta
Antiarrhythmics	Quinidine, lidocaine, procainamide
Antibiotics	Aminoglycosides, quinolones, telithromycin, erythromycin, clindamycin, ampicillin, imipenem, vancomycin, metronidazole
Anticonvulsants	Phenytoin
Antihypertensives	Beta-blockers, calcium channel blockers
Antimanics	Lithium salts
Antipsychotics	Chlorpromazine
Antirheumatic	Chloroquine
Arthritis agents	Penicillamine-induced *M. gravis*
All neuro-muscular blocking agents	Succinyl choline, pancuronium, vecuronium, rocuronium, atracurium, pipecuronium etc.
Anti-malarials	Chloroquine, hydroxychloroquine

On examination, ptosis and squint with a normal pupillary response are characteristic of *M. gravis*. The presence of fatiguable ptosis or double vision is almost pathognomonic of *M. gravis*. Muscle bulk is normal and muscle wasting is rarely seen. Deep tendon reflexes are usually preserved and sensory examination is normal. There is no muscle weakness if the patient is examined after a period of rest; therefore the involved muscles need to be exercised to manifest the weakness.

DIAGNOSIS (FIGURE 1)

Pharmacological Tests

Edrophonium test (tensilon test) or neostigmine test

Edrophonium is a very short-acting ACh esterase inhibitor. In patients with suspected myasthenia, incremental test dosage of 2 mg and then 8 mg is given intravenously and improvement in muscle power is observed, under cardiac monitoring for arrythmias. The test is more useful in patients with ocular myasthenia. Neostigmine methylsulphate is given in doses of 1.5 mg intramuscular or subcutaneously. Improvement in weakness occurs in 15 to 20 minutes and reaches its peak in 30 minutes. It is advisable to give atrophine injection 0.6 mg prior to neostigmine. False positive test can be seen in Lambert-Eaton myasthenic syndrome, amyotrophic lateral sclerosis, neuropathies, and brainstem lesions.

Ice pack test

This test is useful when ptosis is present. Application of ice pack to the eyelids for 2 to 5 minutes improves ptosis in nearly 80% of cases. The test is much simpler and safer than tensilon test.

Electrophysiological tests

Repetitive nerve stimulation test (RNST): RNST is based on the principle of demonstrating electrophysiological evidence of fatiguability in the muscles. The nerves are stimulated at a frequency of 2 to 5Hz and a 10% decrement in the compound muscle action potential (CMAP) indicates fatiguability, suggesting myasthenia. The decrement is enhanced following exercise.

Serological tests

Anti-AchR antibodies: The detection of IgG antibodies against the alpha 1 subunit of nicotinic AchRs in serum is the gold standard test for confirming *M. gravis*. 80 to 85% of generalised *M. gravis* and 50 to 60% of ocular *M. gravis* have high titres of these antibodies. Anti AchR negative (seronegative *M. gravis*) should be tested for anti muscle specific tyrosine-kinase (MUSK) antibodies which are found in approximately 40% of seronegative patients. Patients with MUSK antibodies are usually females, usually have bulbar myasthenia and carry a poor prognosis.

Radiological evaluation

Computed tomography/magnetic resonance imaging of chest should be done in all patients to screen for thymic hyperplasia or thymoma. Patients should also be screened for tuberculosis as they might require long-term immunosuppressants.

Differential Diagnosis

The presentation of a fatiguable proximal muscle weakness with diurnal variation of symptoms and diplopia with evidence of weakness of muscles of eye closure and eye opening with normal pupils virtually establishes the diagnosis of *M. gravis*.

Thyrotoxicosis can present with diplopia and exophthalmos which is not seen in *M. gravis*. Polymyositis presents with muscle pain and high creatine phosphokinase levels and proximal muscle weakness. The extraocular muscles (EOM) are spared and there is no diurnal variation. Psychogenic weakness should be suspected if there is fatiguability, with fluctuating weakness. Motor neuron disease patients have diffuse fasciculations and usually spared eye movements. Gullaine-Barre syndrome patients can have a proximal muscle weakness but the EOM are spared and the reflexes are absent.

APPROACH TO A PATIENT WITH SUSPECTED MYASTHENIA GRAVIS

Treatment

Management of *M. gravis* has been revolutionised in the last decade. Treatment plan depends upon the rate of progression, distribution, severity and pattern of weakness. The treatment of *M. gravis* can be considered to involve 3 steps.

SYMPTOMATIC TREATMENT

Acetylcholine-Esterase Inhibitors (AchEI)

These drugs provide symptomatic relief in *M. gravis* patients by inhibiting the Ach esterase enzyme in the synaptic cleft, thereby increasing the availability of Ach in the synaptic cleft. Neostigmine is administered 15 mg every 3 to 4 hours. Parentral dose is 0.5 to 2.5 mg intravenous, intramuscular or sub-

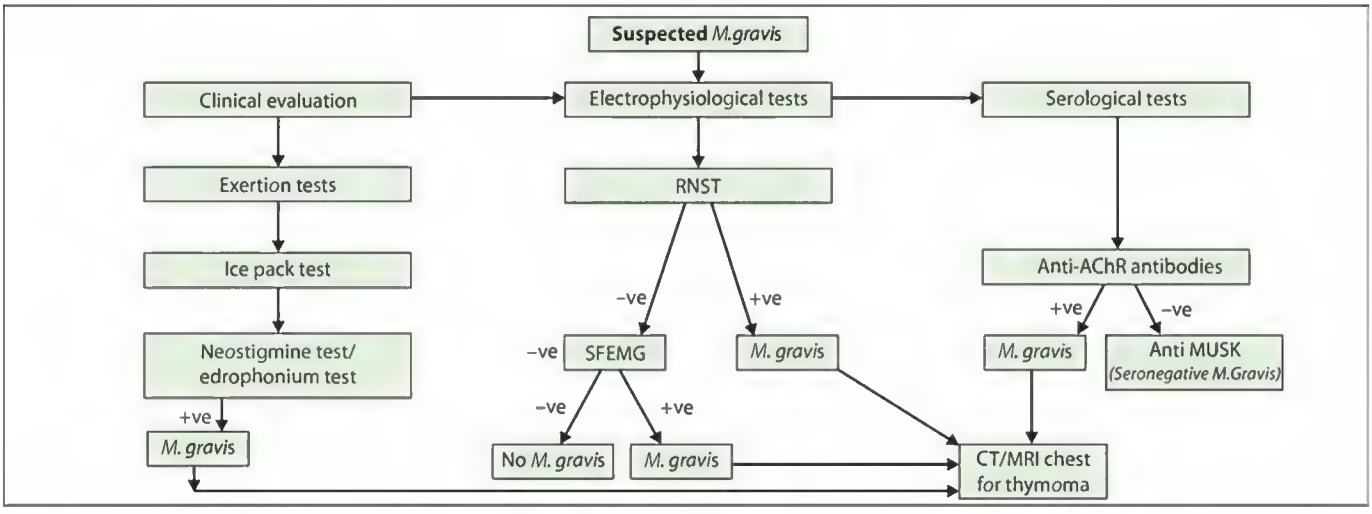

Figure 1: Algorithm for diagnosis of *Myasthenia gravis*.

RNST = Repetitive nerve stimulation test; AChR = Acetylcholine receptor; SFEMG = Single fibre electromyography; MUSK = Muscle specific tyrosine kinase; CT = Computed tomography; MRS = Magnetic resonance imaging; +ve = Positive; –ve = Negative.

cutaneous. Total dose should not exceed 375 mg per day orally or 10 mg per day parenterally. Pyridostigmine is the most common agent used, as it has a longer duration of action. The starting dose is 15 to 30 mg every 4 to 8 hours with a maximum dose of 1,500 mg per day. Sustained release preparations of pyridostigmine can be used to tide over nocturnal/early morning symptoms. Side-effects of these drugs are similar and include salivation, diarrhoea, palpitations and abdominal colic, which if severe can be controlled by giving probanthine and glycopyrrolate. Over dosage of AchEI can cause cholinergic crisis.

Immunomodulating Therapies

Immunomodulation suppresses the immune system to induce a clinical remission and is achieved by the administration of corticosteroids or non-steroidal immunosuppressants.

Corticosteroids

Prednisolone in doses of 1 mg/kg per day has been shown to reduce AChR antibodies levels, which correlates with clinical improvement. The starting dose is low (10 to 20 mg per day), preferably after admission, to avoid early worsening noted in patients on high dose regimen. The improvement usually begins in 2 to 3 weeks and maximum benefit is realised after 2 to 3 months or more. Once remission is attained and the patient remains asymptomatic for 2 to 3 months, a very slow tapering can be tried. Adverse effects of steroids include weight gain, osteoporosis, and increased infections secondary to immunosuppression. Corticosteroids are also needed in patients who experience a relapse after thymectomy. Some patients with ocular myasthenia respond poorly to Ach esterase inhibitor drugs and improve only with steroids.

Nonsteroidal Immunosuppressants

These agents include azathioprine, cyclophosphamide, cyclosporine, methotrexate,and mycophenolate mofetil. Azathioprine is the most commonly prescribed drug and is gradually titrated by 50 mg per week increments to daily doses of 2 to 3 mg/kg per day. It takes 3 to 6 months to start working and might be delayed for as long as 12 months. Complete blood counts, platelet count and liver function tests should be done periodically in all patients who are on azathioprine. Sometimes steroids and azathioprine are started together, and after 2 to 3 months the steroids are tapered off gradually to minimise the side-effects due to them, while azathioprine takes over the immunosuppression.

Cyclosporine (3 to 6 mg/kg per day), cyclophosphamide (2 to 5 mg/kg per day), and methotrexate (7.5 to 15 mg per week) can be tried in patients with severe disease, who do not respond or have unacceptable side-effects to other drugs. Tacrolimus and rituximab are other immunosuppressants which may be used in special circumstances.

Emergency Treatment

Plasma exchange

Plasma exchange is used in myasthenic crisis, in patients with severe disease, or to stabilise patients before thymectomy. Plasma exchange produces temporary improvement by removing Ach R antibodies, complement and immune complexes from the blood. 30 to 50 mL/kg plasma is removed on alternate days for 4 to 6 cycles. The improvement is temporary and lasts for 4 to 10 weeks. The immunosuppressive treatment continues after plasma exchange as well.

Immunoglobulins (IVIG)

IVIG can be used for the same indications as plasma exchange in *M. gravis*. The possible mechanisms are competition with autoantibodies and formation of anti-idiotypic antibodies. The standard dose is 2 gm/kg over 5 days. The advantage of IVIG is low risk of side-effects compared to plasmapheresis. The drug is very costly and the results are similar to plasma exchange.

Surgical Treatment

Thymectomy can be performed using open approach or by videoscopic or robotic means with similar results. The benefit of thymectomy is not immediate and may take 1 to 3 years and in some patients 'benefit' of a remission may take as long as 7 to 10 years. Thymectomy is indicated in patients with anti AchR positive generalised myasthenia with disease onset prior to the age of 60 years. In young children or in patients with non-thymomatous ocular *M. gravis* thymectomy should be avoided. The presence of thymoma is an absolute indication for thymectomy.

MYASTHENIC CRISIS

Myasthenic crisis is defined as sudden worsening of respiratory function in *M. gravis* requiring ventilatory support. Myasthenic crisis needs to be differentiated from cholinergic crisis which results from excessive dosage of AchEI. Miosis and the SLUDGE syndrome (salivation, lacrimation, urinary incontinence, diarrhoea, gastrointestinal upset, hypermotility and emesis) may help in differentiating the two conditions. Injection of tensilon worsens cholinergic crisis but improves the myasthenic crisis. Patients with myasthenic crisis must be treated aggressively. The AchEI medications should be stopped to give drug holiday, and the airway should be secured. Infections should be controlled actively and IVIG or plasma exchange should be used to achieve rapid control of symptoms.

LEMS

It is a rare pre-synaptic disorder of neuro-muscular transmission due to antibodies formed against the voltage-gated calcium channels (VGCCs) on the pre-synaptic motor nerve terminal inhibiting the release of the Ach. Malignancy, particularly small cell carcinoma of the lung, is present or subsequently discovered in 50 to 70% of patients with LEMS. The symptoms include ptosis, diplopia and dysarthria autonomic symptoms like dry mouth. proximal muscle weakness, depressed tendon reflexes and augmentation of power after few seconds of activity. Nerve canduction velocity test shows low amplitude compound muscle action potential, which will show post exercise potentiation. Removal of the causative tumour, immunosuppression, and 3, 4-aminopyridine may be used for treatment.

Transient neonatal M. gravis is seen in 21% of infants born to women with acquired *M. gravis*. Children have poor sucking and generalised hypotonia. Complete recovery is expected in less than 2 months in 90% of patients and in the remaining 10% by 4 months. The disease occurs due to transplacental transmission of the maternal AChR antibodies.

20.32 Diseases of Muscles

SV Khadilkar

INTRODUCTION

Diseases of muscle constitute about 10 per cent of all neurological problems and hence are important for the clinicians. Muscles can be affected by a variety of causes, genetic and acquired. Over the past few years, the fields of genetics and immunocytochemistry have expanded exponentially and this had led to a wealth of understanding of the inherited myopathies. The pathophysiological mechanisms of the disease processes are being elucidated at the molecular level and considering the rapidity of such developments, corrective therapy for these disorders appears to be a possibility. As compared to the inherited myopathies, the acquired disorders have a better outlook particularly if they are inflammatory in origin.

CLINICAL FEATURES

Weakness

The main clinical feature of myopathies is weakness of muscles. Most muscle diseases produce symmetrical weakness of the large muscles of the girdles and trunk. Hip girdle is the most commonly affected and results in difficulty in getting up from squatting position or from low chair and inability to climb stairs. The weakness of the hip abductor muscles result in the characteristic waddling gait. Upper girdle weakness prevents the patient from performing chores like hanging clothes on a clothes line or taking down items from high shelves. A patient having trunk weakness has difficulty in turning in bed and getting up from recumbent position. Neck muscle weakness manifests with inability to control neck while in a vehicle as it rapidly accelerates and decelerates. This results in neck pain and stiffness. Amongst the cranial musculature, facial weakness, ptosis and external ocular movement weakness are seen from time to time. The restriction of the ocular movements is gradually progressive and symmetrical, hence diplopia is not common. This is in contrast with the myoneural junction disorders and nerve diseases, where the asymmetry almost always leads to diplopia. Myopathic patient has to use his/her head and neck movements to compensate the inadequacy of eye movements. Facial weakness presents with inability to close eyes fully and difficulty in drinking with a straw. At the onset of the weakness, myopathies involve the distal musculature only exceptionally, but distal muscles may be affected in many myopathies in the later stages of the processes. Such patients develop difficulty in opening lids of jars, turning keys in key holes and tend to trip easily on uneven ground with repeated falls.

Hypertrophy

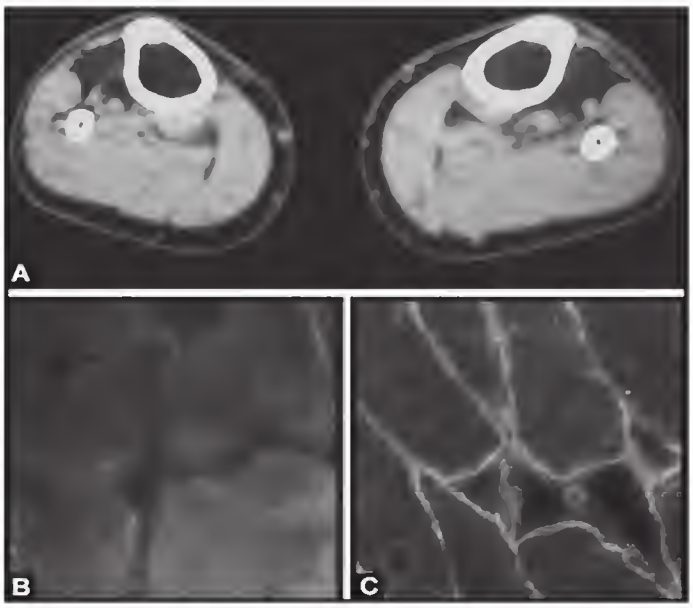
Hypertrophy of muscles is seen in some myopathic patients. Calves, glutei and deltoids are the muscles where the hypertrophy is evident. The hypertrophy is most pronounced in conditions like Duchenne muscular dystrophy and Becker muscular dystrophy (**Figure 1**). To a lesser extent, it is seen in other forms of muscular dystrophies. It can also be seen in patients having infestations of muscles by Cysticercus cellulosae and *Trichinella spiralis*. In these conditions, if the patient is asked to stand on tiptoes, the calves can be seen to knot up in multiple small swellings, unlike the uniform contraction seen in dystrophies. It is important to remember that mild muscular hypertrophy can be seen in conditions of neurogenic origin like the spinal muscular atrophies and radiculopathies.

Figure 1: Severe calf hypertrophy in a patient with Becker muscular dystrophy.

Myotonia

Myotonia, delayed relaxation after sustained contraction, can be elicited by percussion and sustained grip. Myotonic disorders form a distinct subgroup of myopathies. Fasciculations and other abnormal movements of the lower motor neuron unit are very uncommon in myopathies, and the examination of the sensory system is essentially normal. The deep tendon reflexes remain normal for a long time in these illnesses and tend to get diminished, as the patient looses strength significantly and is immobilised.

An important clinical point needs emphasis at this stage. Inherited myopathies like dystrophies tend to have a pattern of muscular weakness. In contrast to this selectively seen in inherited



myopathies, the metabolic and inflammatory myopathies have a more uniform or nonselective distribution of weakness.

DIFFERENTIAL DISORDERS

Any condition affecting the lower motor neuron can present with weakness as the chief symptom and needs to be differentiated from primary muscle disease. The initial step is to differentiate between pure motor disorders from sensorimotor disorders. Sensorimotor disorders arise from either the nerves or the roots. Neuropathies are essentially distal and often symmetrical. Radiculopathies produce pain and asymmetrical loss of sensorimotor function over limited areas of one or two roots as is classically seen in the disc disease. Pure motor disease arises from muscles, as described earlier, they are proximal and symmetrical. Anterior horn cell disorders are almost always asymmetrical, proximal and distal in their distribution and have fasciculations as seen in motor neuron disease and spinal muscular atrophies. Additionally, they may have upper motor neuron signs. The last group of conditions that need to be considered in the differential diagnosis is the myoneural junction diseases like myasthenia gravis. These conditions preferentially involve certain groups of muscles namely the external ocular muscles and swallowing. The symptoms fluctuate and at a given time when the patient has rested, there may not be any clinical signs. Hence it is important to examine the patient when he or she is at the worst. Besides fatigability and weakness, in these diseases, there is no other lower motor neuron sign.

INVESTIGATIONS

Serum creatine kinase (CK) is usually elevated in myopathies to a level higher than that seen with neurogenic conditions. Electrophysiology is a very useful tool to differentiate myopathies from neurogenic conditions. In myopathies, small polyphasic potentials with early recruitment is seen. Inflammatory myopathies tend to show increase in spontaneous activity. CT or MRI can be used to study the pattern of muscular weakness (**Figures 2A to C**). Muscle biopsy is taken from a modestly affected muscle and stained with haematoxylin and eosin. Changes in the fibre size, position of nuclei, inflammation, degeneration, regeneration and changes in connective tissue and blood vessels are noted. When facilities are available, special immunological stains are performed on fresh frozen muscle for analysis of the cytoskeletal proteins. Lastly, DNA diagnosis is performed to confirm the diagnosis.

Figures 2A to C: (A) Selective atrophy of the tibialis anterior and gastrocnemius muscles. Immunocytochemistry shows (B) absence of dystrophin and (C) normal staining.

CLASSIFICATION

Myopathies can be basically classified in two main categories, inherited myopathies and acquired myopathies. These two large categories have been subdivided as shown in **Table 1**.

Table 1: Classification of Myopathies

Inherited myopathies

Dystrophies

X-linked
- Duchenne muscular dystrophy
- Becker
- Emery-Dreifuss
- Scapuloperoneal

Autosomal dominant
- Facioscapulohumoral dystrophy
- Oculopharyngeal dystrophy
- Limb girdle dystrophy (1A -1E)
- Emery-Driefuss dystrophy

Autosomal recessive
- Limb girdle dystrophy (2A-2M)
- Congenital muscular dystrophy

Myotonias
- Myotonia dystrophica DM1
- Myotonia dystrophica DM2 (PROMM)
- Paramyotonia
- Chondrodysplastic myotonia

Congenital myopathies
- Central core disease
- Centronuclear myopathy
- Nemaline myopathy
- Myotubular myopathy
- Minicore myopathy
- Fingerprint body myopathy
- Sacrotubular myopathy

Distal myopathies
- AR: Miyoshi, Nonanka
- AD: Welander, Udd, Markesbery-Griggs, Scapuloperoneal, Desminopathy, Gower-Laing myopathy

Metabolic myopathies
- Glycogen storage disease: Acid maltase deficiency, Myophosphorylase deficiency
- Lipid storage disease: Carnitine Palmitoyl acyl transferase deficiency, defects of Beta oxidation

Mitochondrial cytopathies
- Progressive external ophthalmoplegia
- Kearns-Sayre syndrome
- MELAS, MERRF
- Pure myopathy syndrome

Channelopathies
- Sodium: Paramyotonia congenita, Hyperkalemic periodic paralysis
- Calcium: hypokalaemic periodic paralysis, Malignant hyperthermia
- Potassium: Anderson's disease
- Chloride: myotonia congenita (Thomson's disease), generalised myotonia (Becker's disease)

Acquired myopathies

Infective: viral, bacterial, parasitic, fungal infections, e.g. trichinosis, toxoplasmosis

Inflammatory myopathies: polymyositis, dermatomyositis, inclusion body myositis, eosinophilic polymyositis, granulomatous myositis, idiopathic orbital myositis

Endocrine myopathies: thyroid, parathyroid, pituitary, adrenal disorders, diabetes mellitus, Vitamin D related disease

Drugs and toxins: statins, corticosteroids, anasthetic drugs, amphophilic compounds like chloroquine, HCQ, amiodarone, zidovudine, penicillamine, drugs of abuse like alcohol, LSD, heroin, amphetamine

INHERITED MYOPATHIES

Muscular Dystrophies

Dystrophy is an inherited, progressive, primary disease of the muscle with evidence of degeneration and regeneration of the muscle fibres. Most dystrophies are inexorably progressive, but the rate of progression is variable. Dystrophies have been classified according to their mode of inheritance into X-linked, autosomal and mitochondrial inheritance.

Duchenne's muscular dystrophy (DMD)

It is the most common dystrophy with an incidence of 1:3500 live male births and is seen all over the world. This condition is transmitted as X-linked recessive and hence females are carriers and males are symptomatic. It affects boys at the age of 3 to 4 years. The initial symptoms are of repeated falls and weakness while climbing stairs and getting up from ground. Gower's manoeuvre is seen as children get up from ground, using their hands to straighten up (**Figure 3**). Patients get progressive weakness of the girdle muscles. In the early stages, calf hypertrophy is striking. Weakness is rapidly progressive, the child becomes wheelchair bound by the age of 8 to 10 years, and the lifespan rarely exceeds 20 years. A proportion of patients have mental sub normality and cardiac abnormalities. These are usually accompaniments, but in an occasional patient, assume larger proportions. The genetic abnormality is present on the short arm of the X chromosome at site xp 21; hence, the disease is also called Xp21 myopathy. The gene is one of the largest genes known and has 79 exons and many hot spot regions susceptible for deletions, followed by point mutations and duplications. The gene product is a protein called dystrophin which is a part of subsarcolemmal cytostructural proteins. The deficiency of dystrophin leads to weakness of the sarcolemma, the muscle membrane gives way on traction leading to the cell degeneration. Regeneration possibly is a corrective phenomenon.

In patients with DMD, the serum CK is very high, usually in thousands, and the EMG shows myopathic findings. The muscle biopsy shows features of degeneration and regeneration with increase in the connective tissue. Inflammatory cells are seen eating away the necrotic muscle fibres. Presently, it is possible to perform dystrophin immunocytochemistry on the fresh frozen muscle to achieve an accurate diagnosis. It is also possible to study the gene which has an application in the genetic counselling. Mother and sisters of the patient should be studied for the presence of genetic abnormalities and, if positive, they have a risk of bearing affected children. It is possible to study the DNA from chorionic villous biopsy from an 'at risk' pregnancy and carry out abortion only if the DNA shows gene defect. Knowledge of these aspects has certainly resulted in benefits in antenatal counselling.

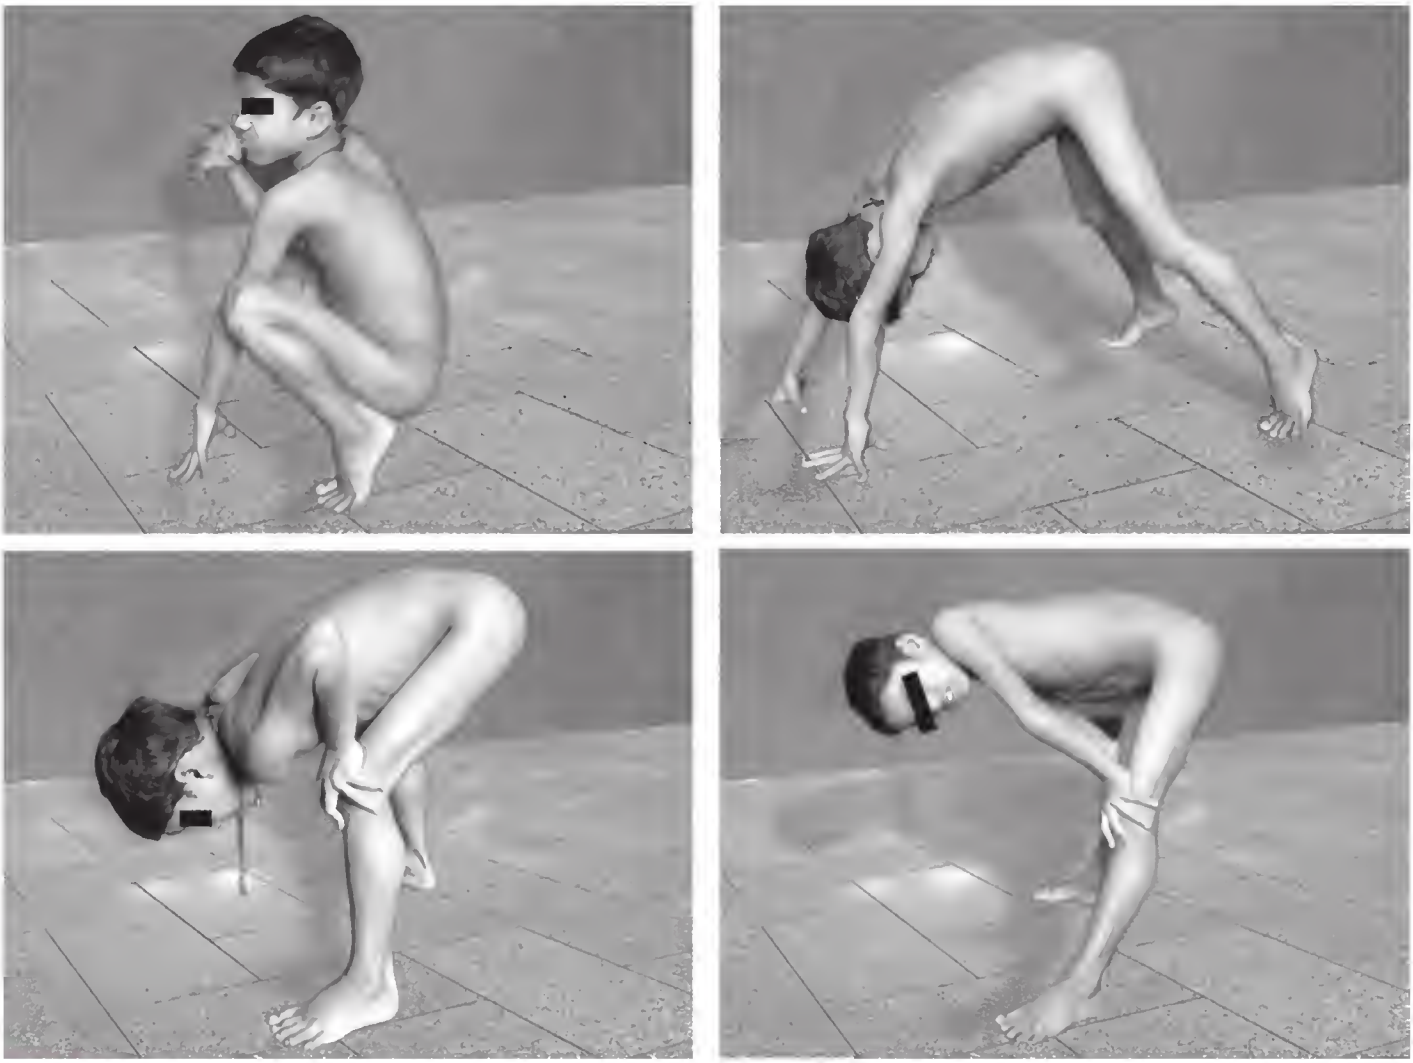


Figure 3: Gower's Sign

Presently, in addition to physiotherapy, some physicians use corticosteroids in the doses of 0.75 to 3.0 mg per kg wt. in various regimens like daily dose, ten day on and 10 day off or 20 day off pattern. This therapy reduces the CK values. Inflammatory response as seen on muscle biopsy also reduces. The muscle strength also tends to improve in a limited manner for the period of 6 to 12 months, leading to reduced falls and improvement in the quality of life. However, substantial lasting clinical improvement is rare and hence the therapy cannot be justified universally. In the author's personal view, a dose of 0.75 mg per kg per day on a ten day on and 10 day off period is perhaps the best in avoiding the changes in the hypothalamopituitary axis. Contracting a disease like tuberculosis is also a genuine concern in our country. Attempts at gene therapy and stem cell therapy are gaining ground and, in recent future, may have practical applications.

Becker muscular dystrophy

It is similar to Duchenne's dystrophy. The genetic defect lies at the same site of the dystrophin gene, but is such that some amount of dystrophin can be synthesised and utilised by muscles. Hence, the clinical disorder is mild and affected individuals can live up to 40 years. The aspects of genetics are identical to the DMD. The mutations in Becker muscular dystrophy tend to be in the central hot spot of the gene and tend to be 'in frame' in nature so that some dystrophin can be functionally relevant.

Facioscapulohumeral dystrophy (FSHD)

It is an autosomal dominant condition with a gradual but step ladder evolution and a characteristic pattern of weakness affecting facial, scapular, anterior tibial muscles and later, the proximal limb musculature. Disease onset is in first or second decade. Sleeping with open eyes, inability to close eyes tightly, to whistle, and abnormal smile suggest facial weakness. Swallowing and chewing is usually unaffected. Scapular winging (**Figure 4**) is very striking. Biceps, triceps, forearm and wrist extensors are predominantly affected and deltoids, forearm and wrist flexors are spared. Beevor's sign is positive in majority of patients with FSHD. In the lower limbs hip flexors, knee extensors and anterior tibial muscles are affected asymmetrically. Association with retinal damage and exudates, sensory neural deafness are noted in some cases (Coat's disease). Cardiac involvement is uncommon but in few cases labile hypertension is seen.

Figure 4: Scapular Winging: FSHD

CK is elevated several fold, EMG study is myopathic and muscle biopsy shows dystrophic changes along with angulated fibres. DNA study confirms the diagnosis. The genetic abnormality is an abnormal deletion of tandem 4q telomere gene leading to over expression of proximal transcriptor gene at FSH locus. Anticipation is also noted in FSHD.

Limb girdle muscular dystrophies (LGMDs)

Limb girdle muscular dystrophies (LGMDs) are heterogenous and are autosomal in transmission. Five types of dominant and ten types of recessive genetic abnormalities have been described by now and the list is increasing. As a group, they have early severe

Table 2: Limb Girdle Muscular Dystrophies

AD	Age of Onset	Gene/Gene Product	Clinical Features
LGMD 1A	3-4 decade	Myotilin	Arm more than leg, proximal muscle involvement. May affect distal limb, facial, pharyngeal muscles, vocal cord
LGMD 1B	1-2 decade	Lamin A/C	Proximal muscle weakness. Early contractures, cardiac abnormalities like conduction defects, cardiomyopathy, arrhythmias
LGMD 1C	Early childhood	Caveolin-3	Leg more than arm proximal muscle involvement. May affect distal limb muscles, asymptomatic CK elevation. Exertional myalgia
LGMD2A	1-2 decade	Calpain-3 (CANP-3)	Proximal muscle involvement. Hip followed by shoulder and posterior thigh muscles and anterior abdominal muscles affected early. Achilles' tendon contracture', later elbow, wrist, finger contractures
LGMD2B	2-3 decade	Dysferlin	Majority have distal and proximal myopathy, early calf muscle weakness and atrophy
LGMD 2C-F	Early childhood	Sarcoglycans (alpha, beta, gamma, delta)	Severe and mild forms, severe forms resemble Duchenne's or Becker's dystrophy with early onset proximal muscle involvement, calf hypertrophy and loss of ambulation
LGMD2G	Childhood	Telethonin	Leg more than arm proximal muscle weakness with significant weakness of quadriceps and anterior tibial muscles
LGMD2H	1-2 decade	TRIM-32	Very slowly progressive proximal muscle weakness
LGMD2I	1-3 decade	Fukutin related peptide	Variable, resemble congenital muscular dystrophy to BMD phenotype. Cardiomyopathy in some cases.
LGMD2J	1-3 decade	Titin	Proximal muscle weakness, later distal involvement

forms resembling the Duchenne's muscular dystrophy and slow forms going in to adulthood. They result in progressive muscular weakness of limb girdles and some have cardiac myopathies as well. A large body of literature has accumulated to date as to the protein products and the pathophysiology of LGMDs. Most genetic defects seem to result in alterations of various proteins responsible for maintaining the integrity of the sarcolemma, thus weakening it and resulting in cell damage. Some others alter the membrane repair processes and the enzymatic intra-cellular reactions. This knowledge is vital for the future evolution of the therapeutic strategies. Following table gives the salient features of the subtypes of autosomal dominant and recessive LGMDs.

Oculopharyngeal muscular dystrophy (OPMD)

It is an AD disorder which begins in 5th to 6th decade of life. OPMD is caused by mutation in the gene that encodes for poly (A) binding protein-2, involved in m-RNA polyadenylation. Patients present with slowly progressive ptosis and restricted eye movements, but contrast to myasthenia gravis these patients don't complain of diplopia as the involvement is symmetrical and slow. Patients find difficulty in swallowing due to pharyngeal weakness, later nasal regurgitation occurs. Occasionally some patients develop proximal limb muscle involvement late in course of illness. Death occurs due emaciation, respiratory infections. Main differential diagnosis is myasthenia gravis. Muscle biopsy shows dystrophic changes with rimmed vacuoles. Hallmark of illnesses is the presence of 8 to 10 mm intranuclear filamentous inclusions.

Emery-Dreifuss muscular dystrophy (EDMD)

There are two forms of EDMD; one is X-linked and another is AD. Disease onset is in 1st to 3rd decade of life. There is progressive weakness and wasting of shoulder, anterior tibial and arm muscles. Early contractures of tendon of Achilles, wrist, elbow and spine are prominent and form a clinical distinguishing feature. Cardiac abnormalities like cardiomyopathy, atrial arrhythmias, conduction blocks are reported and may lead to sudden death. Female carriers can develop cardiac complication at late ages. DNA study confirms the diagnosis. X-linked disease is due to mutation in emerin, a nuclear membrane protein; AD is due to lamin A/C protein, caused by mutation of LMNA gene. Emerin and lamin A/C both are structural proteins, maintaining structural integrity of membrane. Muscle biopsy shows dystrophic features and EMG is myopathic. In these patients, ECG and echocardiography needs to be evaluated at intervals to access cardiac function. Management is supportive. Physiotherapy, prevention of contracture and dealing with cardiac complication are of importance.

Congenital muscular dystrophies (CMD) (Table 3)

Congenital muscular dystrophies (CMD) are disorders of basal membrane proteins like merosin, Golgi organ protein that are involved in glycosylation of sarcoglycan and dystroglycans and extracellular matrix proteins like collagen. A common feature to all is AR inheritance and early age of presentation. Children have diffuse weakness, feeding difficulty, early contractures, delayed milestones and reduced life span. CNS malformations and MRI change in white matter are common, particularly in merosin deficient myopathies. EMG is myopathic and muscle enzymes are elevated.

MYOTONIC DISORDERS

Patients suffering from myotonia have abnormalities of the sarcolemma. On receiving a nerve signal, the muscle membrane undergoes a series of depolarisation and the result is failure of relaxation. This is clinically seen as the inability to relax hand grip. Two distinct types have been identified, dystrophia myotonica type 1 (DM 1) and dystrophia myotonica type 2 (DM 2 or PROMM).

Table 3: Congenital Muscular Dystrophies (CMD)

Type	Locus or Gene	Clinical Features	CNS Abnormalities
Classic CMD			
CMD 1A (occidental type) (merosin negative)	Merosin (laminin α2)	Hypotonia, diffuse weakness, delayed milestones, contractures	Cognitive function relatively spared, seizure in 12-15 %. White matter lucencies on MRI. May
CMD 1B (merosin positive integrin deficiency)	Integrin α7	Hypotonia, diffuse weakness, delayed milestones, contractures	or may not be present
CMD 1C (merosin positive FRRP deficiency)	FKRP 1	Slowly progressive, ambulation preserved till late	
Disorders of glycosylation			
Fukutin	Fukutin	Hypotonia, diffuse weakness, delayed milestones, contractures	Seizures and mental retardation very common. MRI shows hypomyelination, hydrocephalus, lucency especially in frontal white matter
Muscle eye brain disease	POMGnt1	Hypotonia, diffuse weakness, delayed milestones, contractures	Above all plus retinitis, cataract, glaucoma, optic atrophy
Walker Warburg Syndrome	POMT1, POMT2, fukutin, FKRP	Hypotonia, diffuse weakness, delayed milestones, contractures. Severest of all CMDs. Death in 2 to 4 years	Refractory seizure, profound mental retardation, MRI hypomyelination, cortical dysplasia, pontine and cerebellar hypoplasia, many other CNS malformation
Disorder of collagen			
Ulrich CMD	Collagen type 6	Neonatal weakness, joint laxity, contractures	Mental retardation
Other CMDs			
CMD with rigid spine	SEPN1 (selenoprotein n1)	Hypotonia, delayed milestones, contractures,	Rigid spine, scoliosis
LARGE CMD	LARGE	Diffuse weakness, contractures	Profound mental retardation, MRI: significant white mater changes

Dystrophia Myotonica Type 1 (DM1)

It is the most common myotonic disorder. It is a multisystem disease due to genetic defect, on chromosome 19. This is a triplet repeat disease, where the number of CTG repeats expands beyond a point, leading to a gain of function problem. The gene product is a protein kinase which is present in all the cells, hence, the manifestations are seen in many systems. The disease is inherited as autosomal dominant and tends to express more severely in successive generations, the phenomenon of anticipation. Maternal and paternal transmissions may differ in severity. The muscular weakness is pronounced in a characteristic fashion affecting the sternocleidomastoids, temporalis, masseter and facial muscles giving typical facial appearance (hatchet faced) (**Figure 5**). This is also one of the few myopathies resulting in weakness of distal and ocular musculature. Patients have grip myotonia and muscular

Figure 5: Myotonic Dystrophy: Swan Neck, temporal hallowing and facial weakness.

weakness, premature baldness, early cataracts, day time sleepiness and testicular atrophy, loss of libido and other endocrine dysfunction including increase risk of diabetes. There is abnormal sensitivity to anaesthetic drugs. Cardiac complications like cardiomyopathy, congestive cardiac failure and arrhythmia can occur, hampering quality of life.

Physical demonstration of myotonia is better in cool environment. Classical method is to percuss thenar or forearm muscles, or to ask the patient to grip hard for 15 seconds and watch for delayed relaxation. EMG, along with myopathic changes, shows characteristic myotonic discharges (a sound similar to revving of a motorcycle). In muscle biopsy, ring fibres are seen along with dystrophic changes. Myotonia can be reduced by using membrane stabilisers like phenytoin sodium or carbamazepine. Quinine, Tocainide, procainamide and mexiletine are also known to reduce myotonia. Cataracts need surgery. Cardiac manifestations need periodic observation and appropriate therapy.

Congenital myotonic dystrophy is severe form of DM 1, occurring in children of affected mothers. Clinical features are hypotonia, inverted V like tented upper lip, feeding difficulty, failure to thrive, recurrent respiratory infections and severe mental retardation.

Dystrophica Myotonica Type 2 (DM2) or PROMM

It is a proximal variant of DM1, where main feature is proximal limb weakness. Other features are same like DM1, but cardiac and endocrine abnormalities are less manifest and prognosis is better. Mutation in the ZNF9 on chromosome 3q21 is the genetic defect, which result from CCTG expansion in intron 1.

Myotonia Congenita

It is another group of myotonic disorders which presents in the second or third decade of life with hypertrophy of all muscles (Herculean appearance) and grip myotonia. In myotonic patients, exercise helps the patient and the myotonia becomes less obvious as the muscle is repeatedly used. These patients are usually not significantly weak. The response to membrane stabilisers is better in these patients.

Paramyotonia Congenita

It is a rare disease. In these patients, the myotonia worsens with exercise and with exposure to cold temperatures. With repeated use of a muscle, a profound weakness may ensue, lasting for hours. Upper body and facial muscles are more affected. A useful test is to place a towel soaked in ice cold water over the patient's eyelid for two minutes. The patient is asked to look upward for a few seconds and then look down. Eyelid myotonia is seen as baring of the sclera above the iris. On greater cooling, paramyotonia disappears and the eyelid becomes paralysed. These patients often harbour a mutation in the sodium channel gene changing the characteristics of the channel function.

CONGENITAL MYOPATHIES

As a group, the congenital myopathies have some clinical features in common. They present at birth, often as floppy child and unlike most other myopathies, the weakness either remains static or actually improves as the age advances. Progressive deterioration is exceptional in the congenital myopathies. Affected patients are usually very thin, 'skin and bones' but are surprisingly strong for the lack of muscle bulk, associated with skeletal abnormalities, contracture and cardiac complication in some case and recurrent respiratory infection. The main abnormalities are seen only on muscle biopsies and are a result of faulty maturation of the muscle cells. Depending upon the muscle biopsy findings, they are sub classified. Nemaline myopathy, Rod body myopathy, Zebra body myopathy, trilaminar myopathy and central core disease are some of the congenital myopathies. As the natural history is of improvement, the outlook is better than other myopathies and active physiotherapy is advisable. Only a minority of patients from this group tend to deteriorate with time.

DISTAL MYOPATHIES (TABLE 4)

Distal myopathies are those muscle disorders in which there is predominantly distal muscle involvement in the early part of the illness (**Figure 6**). This is in contrast to the common pattern

Table 4: Distal Myopathies

Pattern of weakness	Disease	Age of Onset	Mode of Inheritance	Genetics	Additional Features
Predominantly hand involvement	Welander distal myopathy	4th to 6th decade	AD	Unknown (linked to chromosome 2p13	Slowly progressive
Posterior tibial involvement	Miyoshi myopathy	Childhood to adolescence	AD	Dysferlin	Later involvement of proximal and multiple muscle group
Anterior tibial involvement with distal upper limb weakness	Udd	3rd to 4th decade	AR	Titin	No cardiac involvement
	Markesbery-Griggs	3rd to 4th decade	AD	ZASP gene	Cardiomyopathy common
	Nonaka	<30 year	AR	GNE-gene	Spares heart and quadriceps
	Gower-Laing	<30 year		MYHC 1(MYHC7)	Early foot drop
	Scapuloperoneal	4th to 6th decade	AD/X-linked	FHL-1	Early foot drop
	Desminopathy	3rd to 4th decade	AD	Desmin	Fatal cardiac arrhythmias

Figure 6: Wasting of calf muscles: Miyoshi myopathy.

of proximal weakness seen in most myopathies. In distal myopathies, a close differential diagnosis of neuropathic or anterior horn cell disorders needs consideration and apart from clinical features, muscle enzyme elevation and electrophysiology helps in the differential diagnosis. Following table gives the different forms of distal myopathies with their important features.

MUSCLE CHANNELOPATHIES

These disorders are characterised by episodic muscle weakness, nondystrophic myotonia and occasionally permanent weakness, caused by altered muscle membrane excitability. These are due to mutation in the gene that code for sodium, potassium, calcium or chloride channels.

Periodic Paralysis

Periodic paralysis are a group of disorders wherein the patients get repeated episodes of weakness of the limb muscles. These episodes last for few hours to few days and are often precipitated by exercise, heavy meals or fasting. The basic abnormality is in the handling of potassium by the muscle cells. In an attack, the potassium can be normal, low or high and the values do not necessarily correlate with the degree of weakness.

Hypokalaemic Periodic Paralysis

In hypokalaemic periodic paralysis, attacks occur in the morning, triggered by ingestion of a carbohydrate load or strenuous exercise the previous day. Severe generalised weakness with aching and hyporeflexia is seen. Sensations, level of consciousness and respiratory function are preserved. The weakness also spares the bulbar and facial muscles. Attacks are infrequent and last for several hours. Recurrent attacks lead to persistent weakness in some patients. Thyrotoxicosis and other causes of hypokalaemia like renal, adrenal and gastrointestinal disorders have to be ruled out. This disorder is a calcium channelopathy.

It is important to avoid the precipitating factors and to prevent the attack. During the attack, the serum potassium levels should be checked. It is also useful to do an electrocardiogram. Once the paralytic attack has started, administration of potassium is standard therapy, and it hastens the recovery of the periodic paralysis. It is given mainly to prevent cardiac arrhythmias that potentially can be life-threatening. Potassium is usually administered intravenously, even though there is no proven advantage of using this route of administration. Very rapid intravenous correction of potassium may be counterproductive. Oral supplements may be needed for long time. A low sodium and carbohydrate diet, exposure to cold and acetazolamide may help prevention of further attack.

Hyperkalaemic Periodic Paralysis

In hyperkalaemic periodic paralysis, attacks last from minutes up to an hour and are milder but more frequent. Onset of this sodium channelopathy is earlier in childhood and attacks are precipitated by rest after exercise, stress and potassium load. A useful feature is the presence of myotonia in between attacks. Acetazolamide 125 to 250 mg thrice daily can be used

prophylactically. In acute severe hyperkalaemia intravenous calcium gluconate, glucose-insulin drip and thiazide diuretics may need to be used.

STORAGE DISORDERS

If the glucose or the lipid metabolism of the muscle is defective due to an enzymatic deficiency, the patients get exercise intolerance. They may be totally asymptomatic at rest but when asked to exercise, they develop muscles pain and weakness. Rest improves them. In the cases of lipid metabolism defects, clinically patients sometimes have a 'second wind phenomenon', wherein after the initial weakness, they can go on exercising again for a certain time before finally getting disabled. A detailed study of the muscle biopsy, in particular, staining for glycogen and lipids can show abnormal accumulation of these metabolites, and electron microscopy can further clarify the nature of the deposits. Advanced enzymatic studies are necessary to get down to the exact enzymatic defect. Currently, no therapeutic options are available for most of these conditions, but the future holds promise of enzyme replacement and gene therapy. Avoiding excessive physical exertion is very important.

MITOCHONDRIAL DISORDERS

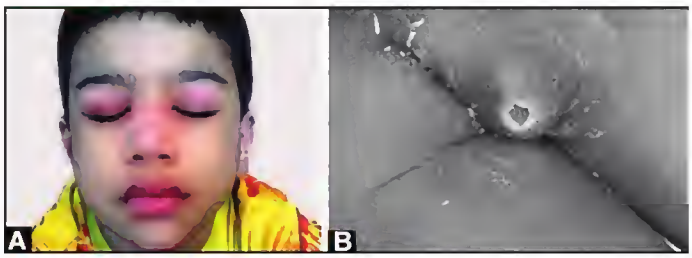
This comparatively newly recognised group of disorders is getting to be seen regularly in muscle clinics. The mitochondrial energy production is affected due to enzyme defects in the mitochondrial respiratory chain. As the mitochondria are derived only from the ovum, these disorders are maternally transmitted. They present with a variety of peripheral and central manifestation. Chronic external ophthalmoplegia, limb weakness, stroke like episodes and myoclonic epilepsy are commonly seen. The combination of central and peripheral deficits should alert the physician about the diagnosis. In addition, skeleton is also affected and short statue is regularly seen in conditions like Kearns Sayre syndrome. The laboratory diagnosis involves sophisticated methods. Serum lactate and pyruvate levels may be elevated in approximately two thirds of patients. Cardiac conduction defects may be seen. The diagnosis can be further substantiated on a muscle biopsy by demonstration of ragged red fibres on Gomori trichrome stain and the demonstration of abnormal mitochondria on the electron microscopy. Care need to be exercised in the interpretation of the muscle biopsy as mitochondrial function deteriorates in normal individuals with age. Exact detection of the enzyme defect needs a specialised laboratory set-up. It is presently possible to sequence the whole of the mitochondrial genome in few centres in India. A proportion of patients having mitochondrial disorders are benefited by supplementing cofactors like riboflavin, thiamine, biotin and coenzyme Q, but the long term outcome is variable and unpredictable.

ACQUIRED MYOPATHIES

Infective Myopathies

The muscle may be attacked by infectious agents. Viruses like influenza, coxsackie and many other viruses can produce acute myositis. This leads to swelling and pain in the muscles with weakness. The condition is acute and often self limiting. At times it can be severe and lead to myoglobulinuria and renal failure. Staphylococci are capable of producing multiple abscesses in the muscle. These patients need urgent antibiotics. Large pockets of pus may need to be drained. Such a situation is more common in immunocompromised individuals but can be seen otherwise as well. Parasites like cysticercus cellulosae and Trichinella spiralis can infest the muscles in large numbers and may lead to pain and hypertrophy of the affected muscles. On asking the patient to contract the large muscles, small lumps can be seen and the biopsy of lump can give the definitive diagnosis. Albendazole in the dose of 15 to 25 mg per kg body weight is given for a period of 1 to 3 weeks for cysticercosis and as well as trichinosis.

Inflammatory Myopathies



Inflammatory myopathies represent a group of disorders characterised by proximal muscle weakness and inflammation of skeletal muscles. Various classifications of inflammatory myopathies exist in literature. Six major categories of myositis can be identified: (1) dermatomyositis, (2) polymyositis, (3) overlap syndromes, (4) cancer-associated myositis, (5) inclusion body myositis, and (6) other forms including rare focal and diffuse variants. Three most common disorder are polymyositis, dermatomyositis and inclusion body myositis.

Polymyositis

Polymyositis patients may present insidiously with a variety of non-specific symptoms including fatigue, malaise, weight loss, myalgias, or arthralgias that may mimic other disorders and result in delay in diagnosis. The muscle involvement is predominantly proximal and affects the pelvic girdle more than the shoulder girdle. The distal musculature is affected to a much lesser extent. Dysphagia is commonly associated with these conditions, as is neck muscle weakness. Facial and ocular muscles are not affected. The evolution of weakness is acute or sub acute. The muscle weakness tends to be non-selective in nature, which is a clinical distinction from the inherited processes like dystrophies.

Dermatomyositis

Dermatomyositis patients have, in addition to proximal muscle weakness, cutaneous involvement in the form a rash affecting the skin over knuckles, eyelids and the anterior part of the chest occurs (**Figure 7A**). The Gottron's papules are considered to be pathognomonic of dermatomyositis and such rashes are rarely seen in other immunological conditions. Skin calcinosis is a vexing and often disabling complication seen in late stages of dermatomyositis, when the activity of myositis is settling down (**Figure 7B**).

Figures 7A and B: (A) Heliotrope rash of dermatomyositis. (B) Gluteal Calcinosis.

Inclusion body myositis

It is a distinct sub group of inflammatory myopathies. Patients are generally older males and the condition develops slowly over months to years. In these patients, the pattern of weakness is different and tends to be much asymmetrical and distal as well as proximal in its distribution. Wrist drop and finger drops

are common. Such cases may be confused with the neurogenic processes like spinal muscular atrophy and other system diseases.

In inflammatory myopathies, in addition to the muscles, other organ systems are affected. Pulmonary involvement in the form of interstitial lung disease is not uncommon, as is dysphagia relate to the GI involvement. Cardiomyopathy and arthralgias are less often encountered. Inflammatory myopathy especially dermatomyositis may be associated with malignancy. The exact nature of the relationship between malignancy and myositis has created continued controversy. However, most authorities agree that there is an increased incidence of malignancy in myositis patients.

The serum CK levels are very high, usually in thousands and the EMG examination shows a myopathic pattern with the additional finding of spontaneous fibrillations. Muscle biopsy done early in the disease course shows evidence of random necrosis of muscle fibres with evidence of muscle regeneration. The blood vessels may be inflamed and interstitial inflammatory cellular response is seen. At times, myositis may be presenting non metastatic manifestation of internal malignancy and hence, a search for malignancy is indicated particularly if the patient is elderly.

Both poly and dermatomyositis respond to corticosteroid therapy steroids are given in the doses of 1 to 2 mg per kg body weight till there is reduction in the serum CK and clinical improvement begins. Later other immunosuppressants like azathioprine or methotrexate can be added and the doses of steroids reduced. In the rare event of acute severe deterioration, intravenous immunoglobulin and plasmapheresis may be used for rapid 'rescue'. The overall outlook of these patients is satisfactory, but long-term immunosuppression may be needed, and steroid dependency may be seen. Rarely malignancy surfaces later and changes the prognosis. Age of onset, severity of illness, associated co-morbidities and delayed treatment are some prognostic factors, influencing ultimate outcome. It is particularly important to recognise and to treat this group of reversible myopathies.

ENDOCRINE AND METABOLIC MYOPATHIES

Thyroid and parathyroid disorders are the common endocrine entities resulting in myopathy. Usually, the myopathies are a small part of the whole endocrine abnormality and hence easy to diagnose, but at times it can be the presenting feature. Other endocrinopathies can also potentially cause muscle weakness. Osteomalacia, osteoporosis, renal insufficiency and many metabolic conditions can lead to mild myopathy. The osteomalacic myopathy results in painful waddle and reflexes may become brisk. This condition is common in multiparous women wearing burkha and other settings of vitamin D deficiency.

DRUG-INDUCED AND TOXIC MYOPATHIES

A wide variety of drugs are capable of damaging muscles. Corticosteroids, statins and anti-epileptic agents are probably the most common ones. Steroids produce myopathy by down regulating the anabolism of the muscle. Toxins also produce muscular weakness as a part of the various system mani-festations. The weakness is reversible to a large extent after the offending agent is withdrawn, but the time lag can be of many months.

CONCLUSION

Muscular weakness can result from wide variety of hereditary and acquired conditions. The inherited myopathies tend to have selective involvement and slow evolution, while the acquired ones produce more generalised weakness and can be rapid. Good history taking, including the family history and the drug intake, coupled with careful examination and investigations like serum CK, EMG and muscle biopsy help in achieving accurate diagnosis. Inflammatory myopathies are most rewarding to treatment and many other acquired ones also respond well. The therapeutic options for the inherited myopathies are limited at the moment, but the genetic advances are opening up the possibilities of more successful therapy in near future.

21.1 Basic Considerations of Oncology

SH Advani

Paradigm shift in diagnostic technology and therapeutic modalities have resulted in revolution in the treatment of cancers and have improved the life of cancer patients (**Table 1**). Studies using molecular biology techniques have underlined the role of viruses in certain malignancies. The development of monoclonal antibody technology has resulted in more precise classification of lymphoproliferative malignancies. Advances in supportive care have minimised the adverse effects of intensive cancer therapy. Bone marrow transplantation has become a major treatment modality. Oncologists are now able to tailor therapy according to clinical risk factor, tumour histology, stage and gene profile analysis. Due to enhanced understanding of the molecular pathways, new targeted therapy is becoming a reality. Soon, we shall see personalised and customised therapy in many cancers.

Table 1: Treatment Results with Modern Chemotherapy

Cancers in which drugs have achieved normal life span for some patients	
Acute lymphoblastic leukaemia (childhood)	Choriocarcinoma
Testicular tumours	Rhabdomyosarcoma
Histiocytic lymphomas	Retinoblastoma
Burkitt's lymphoma	Osteogenic sarcoma
Hodgkin's disease	Gastrointestinal stromal tumour
Ewing's sarcoma	
Cancers in which responders have demonstrated improvement in survival	
Adult acute leukaemia	Ovarian cancer
Multiple myeloma	Breast cancer
Lymphocytic lymphoma	Neuroblastoma
Chronic myeloid leukaemia (CML)	Renal cell carcinoma
Cancers responsive to chemotherapy with no survival advantage	
Head and neck cancers	Malignant melanoma
Gastrointestinal cancers	Malignant carcinoid tumour
Central nervous system cancers	Soft tissue sarcoma
Bladder carcinoma	Oesophageal cancer
Lung cancer	
Endocrine gland tumours	
Cancers only marginally responsive or unresponsive to chemotherapy	
Hypernephroma	Hepatocellular cancer
Pancreatic cancer	Thyroid cancer

MECHANISM OF CARCINOGENESIS

The cancer cell evolves through a series of steps from normal, initiated and pre-neoplastic to pre-malignant and finally to highly malignant neoplasm. The three major steps in this process are initiation, promotion, and tumour progression (**Figure 1**). A single brief exposure to a carcinogen induces changes in the tissue, termed initiation. The nature of the structural alterations in initiated cells is diverse. Chemicals and ultraviolet irradiation directly alter DNA structure. Cancer arising after viral infections may occur through recombination of the viral and host genomes. Promotion is ability of a compound to induce an area of proliferation in initiated tissue and stimulate tumour formation. Dietary fat has been implicated as a tumour promoter in the development of colon cancer. Finally, tumour progression usually refers to the later stages of tumour cell evolution that are irreversible and alter the reactivity and potentialities of neoplastic clones. Proliferating foci in a promoting environment may undergo additional changes and become progressively more malignant. Once the tumour develops, individual traits such as hormone responsiveness, growth rate, histologic type, and invasiveness function as independent variables capable of progression.

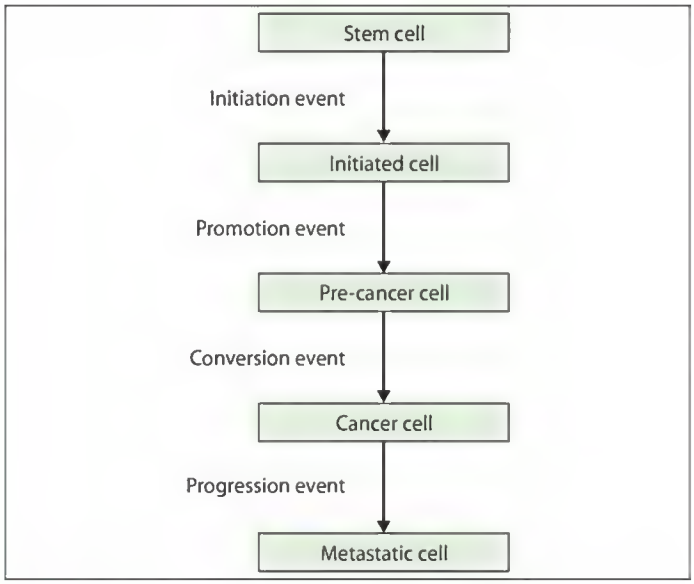

Figure 1: Mechanism of carcinogenesis.

The spread of tumour from a primary lesion to a distant site is a major cause of morbidity and mortality. Metastasis is an active process consisting of three stages: attachment of cells to extracellular matrix, local degradation of extracellular matrix, and locomotion through the locally degraded matrix. This active locomotion of tumour through host tissue barriers is presumed to be affected by both tissue-secreted chemotactic factors as well as motility factors secreted by the tumour cells. Once the tumour cell has migrated to a metastatic site, additional metastatic foci may occur by repetition of these steps.

MOLECULAR BIOLOGY

Human genome project has given insight into biology of human cancer. Many molecular structures serve as markers for diagnosis of cancers. Markers that reflect clonality such as

cytogenetic abnormalities can be useful for the diagnosis of cancer. A number of tests are available for marker detection including fluorescence *in situ* hybridisation (FISH), southern blot hybridisation, polymerase chain reaction, immunohistochemistry, and cDNA microarrays. These techniques can detect numeric changes in chromosomes, translocations, deletions, amplifications, alterations in DNA nucleotide sequence, demonstration of viral DNA sequence in tumour cells, and detection of tumour antigens.

Among cancers in which molecular biology has had greatest impact is chronic myeloid leukaemia (CML). The marker of this disease is the Philadelphia chromosome t(9;22) which is detected by all available molecular diagnostic methods. Now targeted therapies like imatinib mesylate targeting the bcr/abl gene is being used to treat CML. The diagnostic marker in neuroblastoma is amplification of N-myc, a proto-oncogene. In breast cancer, the erbB2 oncogene has helped to select patients for Herceptin therapy. In retinoblastoma, the detection of an inherited defect in the retinoblastoma gene-I (RB-I), a tumour suppressor gene, has been used to assess the risk in individuals with a family history of retinoblastoma.

PRINCIPLES OF THERAPY

The life cycle of both normal and neoplastic cell starts with mitosis or cell division. This is followed by differentiation with distinct phases known in sequence as G1 (first gap phase), S phase (DNA synthesis phase), G2 phase (second gap phase), and mitosis (M phase) (**Figure 2**). Tumours also contain non-cycling but living cells (G0 phase). The growth fraction is the ratio of the proliferating cells to the total cells.

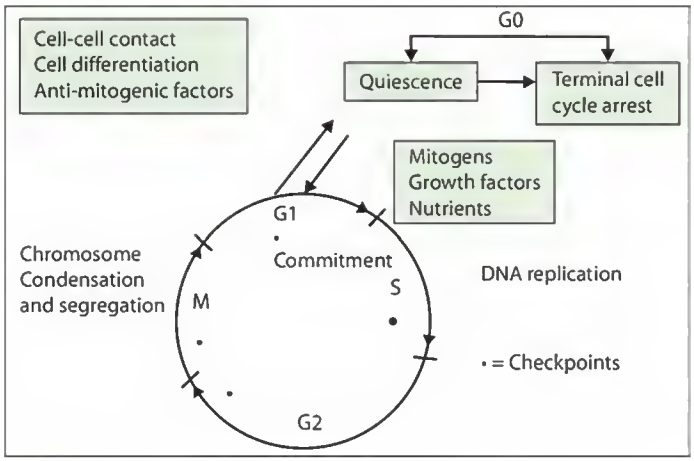

Figure 2: Cell cycle.

G0 = Non-cycling but living cells; G1 = First gap phase; G2 = Second gap phase; M = Mitosis phase; S = DNA synthesis phase.

Cancer cells divide more slowly than their normal counterparts. However, they spend a longer time in cell division, leading to some selectivity in the therapeutic action. It has been postulated that differences in the kinetics of cell proliferation is the basis of differential sensitivity between normal and cancer cells. Alternative explanations for chemotherapeutic efficacy include an ineffective repair mechanism in cancer cells, as well as chemotherapy-induced reduction of growth factor release required for proliferation of tumour cells.

The treatment of cancer has two aspects; specific and supportive treatment. Specific therapy consists of surgical removal, irradiation and chemotherapy, most patients require a combination in these three modalities, and advances in supportive care have contributed remarkably to improvement in the quality of life during therapy for these patients.

The use of blood product transfusions, indwelling central catheters to maintain ready venous access, enteral and parenteral nutrition, and colony-stimulating factors have greatly reduced the morbidity and mortality in patients undergoing chemotherapy. Right atrial catheter insertion is now mandatory to provide proper supportive care. Partial correction of thrombocytopaenia to maintain a platelet count of greater than 10,000/mm^3 reduces the risk of haemorrhage. In tumour lysis syndrome the use of allopurinol along with forced diuresis can be life-saving. Good nutritional support including parenteral nutrition when required improves the outcome. Use of 5-HT3 receptor blockers (granisetron) has transformed the quality of life of patients undergoing highly emetic therapies.

Infection prevention is now considered more important than interventional therapy. The best tested and most effective initial empirical antibiotic regimen for treating patients with febrile neutropaenia is a combination of aminoglycoside or an aminoglycoside with cephalosporin. Availability of growth factors (G-CSF) has reduced the duration of febrile neutropaenia. Antifungal drugs and antiviral drugs have improved the morbidity and mortality of patients.

Biologic Response Modifiers

Manipulation of the host immune response to cancer is the major goal of biological therapy. Antitumour immune responses are difficult to demonstrate in patients of cancer; however, cancer immunotherapy seeks to evolve effective immune responses to human tumours. These agents act as biologic response modifiers, and function by altering the host response to cancer, however some cause direct toxicity. They demonstrate peak activity within a narrow concentration range, higher or lower concentrations may cause a suboptimal effect. Optimal clinical dose is that which produces maximum desired effect and may not be the highest dose tolerated without unacceptable toxicity.

Antibodies in Cancer Therapeutics

Unconjugated antibodies have been used since the earliest trials of monoclonal antibodies in humans, but limitations of its use are absence of suitable tumour cell surface targets, antigenicity of the immune monoclonal antibodies in humans, modulation of the target structure from the tumour cell surface and poor recruitment of immune effector mechanisms.

IDEC-C2B8 is an anti-CD20 antibody with humanised framework and Fc regions. The antibody fixes human complement and elicits antibody-dependent cellular cytotoxicity. When used in patients with B-cell lymphomas, it produces good tumour regression rate with minimal toxicities and low rate (approx 10%) of anti-antibody development. Anti-CD20 antibody (rituximab) is being routinely used in B-cell lymphomas.

Trastuzumab is (C-cerb2) antibody used for Her-2 amplified breast cancer with promising results. Alemtuzumab is being used for chronic lymphocytic leukaemia (CLL). Cetuximab is EGFR antibody (epidermal growth factor receptor) which has shown promising result in metastatic colorectal cancer along with chemotherapy (irinotecan). Bevacizumab, vascular endothelial growth factor receptor (VEGFR) along with

chemotherapy has shown improved response rate in colorectal cancer against chemotherapy alone.

Anti-Idiotype Therapy

Antibody approaches defined only a single tumour-specific antigen which is the idiotype of clonally distributed antibody on the surface of certain B-cell lymphomas. Because it represents a unique protein structure in the combining site of antibody, the idiotype can serve as an antigen for antibody production. An immunological response to the idiotype could lead to tumour protection.

Common side effects seen are chills and fever, transient shortness of breath, headache, nausea, emesis, diarrhoea, myalgias, transient leucopaenia or thrombocytopaenia, and transient elevations of hepatic enzymes.

Radioimmunotherapy

In theory, the radio-labelled antibody homes to its antigenic target and delivers a cytotoxic assault on only the tumour cell to which it attaches, thus limiting collateral damage to surrounding normal tissues. Ibritumomab, tiuxetan, and tositumomab is being used for non-Hodgkin's lymphoma. Limitation of radioimmunotherapy is that conjugation of antibody to radionuclide is not always stable, leading to inappropriate destination of radioactivity. Besides, antibodies tend to be taken up in a non-specific fashion by the reticulo-endothelial system and antibodies, large molecules can be excluded from the space occupied by the target tumour.

Immunotoxins and Fusion Toxins

These reagents are chemicals and targeting is provided by antibodies or by lymphokines, growth factors, and so on that specifically bind receptors on the surfaces of target tumour cells. Attached to the targeting moiety is the cytolytic moiety which is usually derived from plants or bacteria. These toxins work by inhibiting protein synthesis and kill either resting or dividing cells and require fewer than 10 molecules in the cytosol to be effective. Toxins being investigated include ricin A, pokeweed antiviral protein, pseudomonas exotoxin A, and diphtheria toxin.

Bispecific antibodies

These are antibody constructions that recognise a tumour-associated antigen with one arm and recognise and activate an immune effector cell structure with the other arm. Approximation of a tumour cell with an activated immune effector could result in tumour cell elimination. These bispecific antibodies can be obtained either by chemical hetero-conjugation or by fusion of two hybridomas of desired specificity to yield a tetradoma. The desired product can be isolated either by chromatographic or other separation techniques. In pre-clinical models, anti-idiotype X anti-CD3 bispecific antibodies have demonstrated the ability to inhibit tumour cell growth.

Cytokines

Interferons

Interferons are potent cytokines that possess antiviral immunomodulatory and antiproliferative actions. These proteins are synthesised by cells in response to various inducers and in turn cause biochemical changes leading to an antiviral state in cells of the same species. Most animal viruses are sensitive to the antiviral actions of interferons, but many DNA viruses are relatively insensitive. Interferon biological activity is measured in terms of antiviral effects in cell culture and expressed as international units (IU). Two major classes are seen, Type I which consists of α and β; and Type II which consists of γ. Type I interferons are produced by different cell types whereas the Type II are produced by T-lymphocytes.

Absorption, distribution and elimination

Oral administration does not result in detectable serum levels or increases in 2-5 (A) synthetase activity in peripheral blood mononuclear cells. Plasma levels are dose-related, peaking at 4 to 8 hours and returning to baseline by 18 to 36 hours. After intramuscular (IM) or subcutaneous (SC) injection of interferon (IFN)-α, absorption is more than 80%. Levels of 2-5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 hours and last for 4 days after a single injection (marker of biologic activity). The antiviral state peaks at 24 hours and slowly decreases to baseline by 6 days after injection. IFN-β following IM or SC injections result in negligible plasma levels but increases in 2-5 (A) synthetase levels may occur. After systemic administration low levels are detected in respiratory secretions, cerebrospinal fluid, eye, and brain. After intravenous dosing, clearance of interferon from plasma occurs in a complex multiexponential manner. Plasma elimination half-life of IFN-α is 2 hours, recombinant IFN-β is 1 hour and IFN-γ is 0.5 hour. After IM or SC injection of IFN-α, the plasma levels increase over a 5 to 9 hours period and then slowly decline. Elimination from the blood relates to the distribution to the tissue's cellular uptake and catabolism primarily in the kidney and liver. Negligible amounts are excreted in the urine.

Side effects

Acute influenza-like syndrome is common; it is characterised by fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhoea. Fever resolves in 12 hours and can be controlled by antipyretics. Dose-limiting toxicities include bone marrow suppression with granulocytopaenia and thrombocytopaenia, neurotoxicity manifested by somnolence, confusion, behavioural disturbances, seizures, debilitating neurasthenia with fatigue and weight loss, thyroid dysfunction, cardiotoxicity, elevated hepatic enzymes, hypertriglyceridaemias, hepato-toxicity, alopaecia, proteinuria, azotaemia, interstitial nephritis, and impaired fertility. Clinical unresponsiveness can occur secondary to development of serum neutralising antibodies to exogenous interferons.

Interferons may reduce the metabolism of various drugs like theophylline by the hepatic P450 system and increase bone marrow toxicity of myelotoxic drugs, like zidovudine.

Therapeutic Uses

Chronic phase of chronic myeloid leukaemia

Interferon-α can control blood counts and induce complete haematological response in 70% of patients and complete cytogenetic response in 15% patients. Recommended schedule is 5×10^6 units/m^2/day or thrice a week. With the advent of imatinib mesylate, interferon is not the treatment of choice.

Hairy cell leukaemia

Splenectomy has been the first treatment approach in this disease. However, interferon-α has been an effective non-surgical treatment. Seventy five per cent of treated patients achieved a complete or partial remission. First relapse was seen after a period

of 12 to 24 months post therapy. These patients responded to repeat course of IFN-α. Mechanism of action is probably antiproliferative or immunomodulatory in nature.

Interleukin-2

This was first recognised as a growth factor for T-lymphocytes because of its ability to stimulate the production of T-helper and cytotoxic cells. It is currently available as a recombinant protein. Interleukin-2 (IL-2) treatment led to increased cytotoxicity in T-lymphocytes and natural killer cells.

Pharmacokinetics

Half-life of IL-2 is very short (α-13 minutes, β-83 minutes), thus it is used as a continuous infusion or multiple intermittent doses. Liposome encapsulated IL-2 and conjugation of IL-2 with polyethylene glycol has been used to extend the half-life of IL-2 and to enhance its delivery to immune cells in tumours. The most significant antitumour responses have been seen with continuous intravenous infusion for 5 days every other week for 2 cycles or intravenous bolus dosing every 8 hours daily for 5 days every other week.

Toxicity

Toxicities are likely to be related to the activation and expression of lytic lymphocytes in the organs and within vessels resulting in the release of cytokines like tumour necrosis factor and interferons. Common side effects are fever with chills, capillary leak syndrome with hypotension, weight gain, respiratory distress requiring intubation, oliguria, renal dysfunction, and death (1%). Minor side effects are nausea, vomiting, diarrhoea, anaemia, thrombocytopaenia, liver dysfunction, cardiac arrhythmias, and occasionally mental status changes. It is mainly used in metastatic melanoma and renal cell carcinoma.

Erythropoietin (EPO)

Anaemia is common in cancer patients. It may occur solely as a result of the anaemia of chronic disease (ACD) or it may be caused or exacerbated by myelosuppressive therapy and radiation therapy. Clinically, ACD is typically mild to moderate in severity (haemoglobin of 8 to 10 gm/dL). The pathophysiology of ACD has three features: mild decrease in RBC survival; a decreased reutilisation of bone marrow iron stores; and inadequate erythropoietin (EPO) response to the degree of anaemia.

Anaemia in cancer patients develops slowly. Patients develop symptoms when haemoglobin levels are less than 8 gm/dL. Blood transfusion has been the mainstay of therapy, but recombinant genetically produced EPO is a potential option in addition to transfusion.

Indications of EPO in cancer

Myelodysplastic syndrome (MDS) results from a stem cell defect with dyserythropoiesis and not true EPO deficiency. However, the inadequate endogenous EPO response relative to the degree of anaemia suggests that at least some MDS patients may benefit from recombinant human EPO.

Recommended dose is 150 units/kg thrice a week with a step-wise escalation to 300 units/kg thrice a week if no response is seen in first 4 weeks. The desired erythroid response is expected within 4 weeks and usually occurs in 8 weeks. The hormone is administered parenterally by intravenous or subcutaneous routes. The basis for thrice weekly administration of EPO is because absorption of subcutaneous recombinant human EPO occurs more slowly with relatively low serum EPO levels being maintained for 48 hours.

EPO does not affect haematopoietic stem cells but acts on more mature erythroid progenitor [Burst-forming unit-erythroid (BFU-E)] cells. It appears that the hormone does not alter the natural history of MDS in terms of possible disease progression or leukaemic transformation.

CELLULAR APPROACHES

Graft versus Leukaemia (GvL) Effect

The molecular and cellular mechanisms that underline the GvL effect are not well understood. The relationship between GvL effect and graft *versus* host disease (GvHD) is blurred. Major histocompatibility complex differences have long been associated with GvHD. The role of minor histocompatibility antigen expression in GvHD and GvL effect is becoming apparent. T-lymphocytes play an important role in these reactions of which CD4+ T-lymphocyte is particularly important in GvL effect. Natural killer (NK) cells may also be involved in the GvL effect.

Haematopoietic Transplantation as Adoptive Immunotherapy

Allogenic bone marrow transplant was initially considered as a means to deliver supralethal doses of chemotherapy and total body radiation for the treatment of haematological malignancies. The marrow transplantation was considered as a supportive care modality to restore haematopoiesis. The high-dose therapy, however, in many cases does not eradicate the malignancy and that the marrow transplant itself confers an important graft *versus* malignancy effect that is critical to prevent relapse.

Donor Leucocyte Infusion

In patients relapsing after bone marrow transplantation, the leukaemia typically recurs in host-derived cells, but residual normal haematopoiesis and immunity remain largely donor-derived. Infused donor lymphocytes are, therefore, not subject to rejection; but acute GvHD is a major problem. After infusion of donor lymphocytes, there is initially little change in peripheral blood counts, but after a median of 4 months, responding patients may suddenly become hypoplastic. The hypoplasia is followed by recovery from donor-derived haematopoietic cells and return to complete chimerism.

Immunisation Strategies

Passive administration of anti-idiotype antibodies has been used to induce active immune responses against the idiotype. In a pilot clinical trial, autologous dendritic cells pulsed *ex vivo* with tumour-specific idiotype protein were infused intravenously. This procedure was followed by injection of idiotype antigen 2 weeks later. The cycle of pulsed dendritic cells and antigen was repeated two times at monthly intervals and again at approximately 6 months. Each of the patients in the study developed measurable tumour-specific cellular immune responses.

Cytokine-Driven Cellular Vaccines

Creation of local high concentrations of cytokines in proximity to tumour cells can lead to immunoinflammatory responses that are capable of tumour elimination, induction of specific resistance to tumour challenge, and in certain cases to

eradication of established tumour. Local destruction of cytokine gene transfected tumour cells can lead to systemic immunity against transfected tumour cells.

EVOLVING THERAPIES IN CANCER

Uncontrolled proliferation is the hallmark of malignant cell behaviour. Many of the growth factors that are frequently upregulated in tumour trigger tyrosine-kinase signalling pathways. Presently, research is directed at these dysfunctional signalling pathways and oncogene targets.

Unregulated Cell Division

Malignant cells escape from the normal control mechanisms that regulate the rate and frequency at which they divide. It has been found that tumour cells appear to have unregulated cyclin-dependent kinases (CDKs), which trigger cell cycle progression and cell division. Another target is to develop drugs that regulate the cell cycle in an effort to block uncontrolled cell multiplication and force the malignant cell into apoptosis or cell death.

Cell Survival and Immortality

Normally, repeat genetic sequences called telomeres, which are found at the ends of chromosomes, shorten following each cell division. In this way, the length of the telomere indicates its age to the cell. The cell is pre-programmed, so that after a certain number of divisions, it will undergo apoptosis. Tumour cells however contain an abundance of telomerase, which causes the telomeres to be readjoined to the ends of the chromosome. Telomerase immortalises malignant cells by preserving the integrity of telomeres. An approach to cancer therapy for the future is to identify telomerase inhibitors that prevent malignant cells from evading apoptosis.

Dissemination and Metastasis

Tumour cells emit substances known as matrix metalloproteases (MMPs), which allow metastatic cells to permeate blood vessels and invade distant tissues. MMP inhibitors will potentially curtail the metastatic spread of tumours.

Sustained Angiogenesis

Tumours are dependent on the formation of new blood vessels to support growth and metastasis. Many tumours produce large amounts of VEGF, which signals normal blood vessels to grow. Angiogenesis inhibition is an extremely promising approach.

Signal Transduction Inhibitor

The nucleus of a cell controls gene expression, macromolecule production and cellular proliferation via signals delivered from the cell membrane. These signalling pathways involve transmembrane receptors that can be stimulated by circulating growth factors. The intracellular domain of many of these receptors contains protein kinases. Once activated, these kinases initiate a phosphorylation cascade that is thought to result in increased tumour cell growth. Several targets within these signalling pathways are of interest for therapeutic intervention.

Imatinib mesylate, oral bcr/abl tyrosine kinase inhibitor has brought a paradigm shift in the treatment of malignancy. It has shown complete haematologic, cytogenetic and molecular remission, even in blast phase of CML. Imanitib can also inhibit C-Kit related tyrosine kinase and help in controlling gastrointestinal stromal tumor. Gefitinib, another EGFR receptor inhibitor has also shown good disease control in lung cancer. Sorafenib and sunatinib, oral tyrosine kinase inhibitors, have shown promising results in renal cell cancer. Thalidomide, with its immunomodulatory and anti-angiogenic effects, has shown good response in multiple myeloma. These are the results of translational research from the laboratory to the bedside. Resistance has been observed to these newer oral targeted molecules too. Trials with combination of these drugs are in progress, the results appear promising and eventually cure will be possible.

Tumour microenvironment consisting of stromal cells and extracellular matrix appears to play an important role in carcinogenic process. Thalidomide, an inhibitor of tumor-stromal interaction has become an important therapeutic agent in multiple myeloma.

21.2 Principles of Cancer Biology and Pathology

Anita M Borges

Cancer is a chronic condition with a genetic basis. Some normal cells grow faster to cancer cells. Cancer is better defined as a clonal disorder of dysregulated growth and differentiation leading to a persistent accumulation of phenotypically altered cells and tissues, which if left unchecked, will result in death or severe morbidity. This explains many of the observed characteristics of cancer (**Table 1**).

Table 1: Commonly Observed Characteristics of Cancer Cells and Tissues

Enhanced response to growth promoters
Relative resistance to growth inhibitors
Genetic instability
Neoangiogenesis
Loss of contact inhibition of growth
Invasion of natural boundaries
Abnormal locomotive properties
Immune evasion
Ability to grow at other sites (metastasis)
Immortalisation
Tendency to manifest a stem cell phenotype (loss of differentiation)

THE MOLECULAR BASIS OF CANCER

Cancer is a clonal acquired genetic disease. All cells in a tumour are the progeny of one transformed cell. This cell differs from its normal counterpart in the expression of key genes involved in growth regulation, apoptosis, DNA repair, cell adhesion and angiogenesis. These genetic events leading to cancer confer the cell and its progeny properties of the malignant phenotype (**Table 1**). Much is known about the molecular mechanisms of carcinogenesis, but there is no single molecular definition of cancer.

MULTISTEP CARCINOGENESIS

Important steps in carcinogenesis, initiation, promotion, and malignant progression (**Figure 1**) may take years. Molecular genetic events underlying the multistep model of carcinogenesis are best characterised in the adenoma-carcinoma model of colonic cancer (**Figure 2**). Genetic instability is a hallmark of cancer with a tumour continuously undergoing clonal evolution (**Figure 1**). Cancer starts as a single clone. As genetic events occur randomly within tumour cells, the tumour becomes genetically heterogenous. Genetic instability as discussed later is critical to the evolution of cancer. Genetic instability is also a cause of treatment failure. Genes involved in cancer are of two types: Gatekeeper genes (e.g. TP52) are those genes which directly regulate tumour growth and caretaker genes (e.g. BRCA1, BRCA2).

Molecular pathogenesis of colorectal cancer illustrates the intricacies in tumour development. The adenomatous polyposis coli (APC) gene is the major gatekeeper of the colon. Patients with inherited mutations of this gene develop thousands of

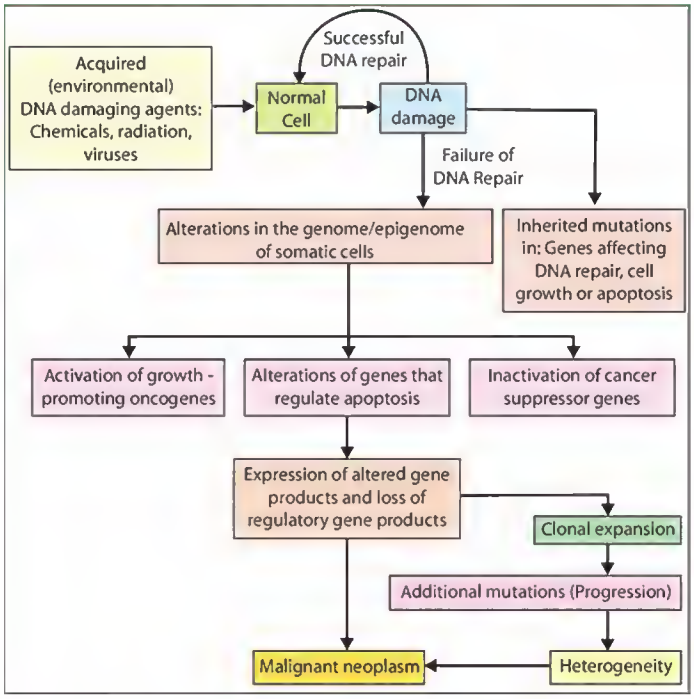

Figure 1: The molecular basis of cancer.

colonic adenomas. APC mutations are sufficient to initiate growth of small benign tumours but are insufficient for tumour progression. Other genetic pathways participate in progression including:

1. Transforming growth factor-beta (TGF-β) is a small polypeptide hormone that negatively controls colon cell growth.
2. H-ras is involved in signal transduction.
3. p53 gene is an important component of response to DNA damage that inhibits growth of cells with DNA damage by blocking the cell cycle. It also stimulates programmed cell death (apoptosis). Mutations in the p53 gene allow cells with damaged DNA to divide and propagate mutation. These cells are also resistant to apoptosis. Cells with mutations accumulate and tumour progresses.

The mismatch repair system, a system that repairs subtle mistakes made during copying of the genome, is a caretaker system. Inherited alterations of these genes lead to hereditary non-polyposis colorectal cancer (HNPCC). Mismatch repair genes in humans include hMSH2, hMSH1, hPMS2, GTBP. Sporadic colorectal cancers generally do not have defects in mismatch repair but have a different form of caretaker defect, named CIN, for chromosome instability. CIN tumours develop losses or gains of whole chromosomes at a rate that is 10 to 100 times higher than that of normal cells. The chromosomes involved include those containing gatekeepers. Alterations of chromosomes containing gatekeepers impede the ability of cells to control

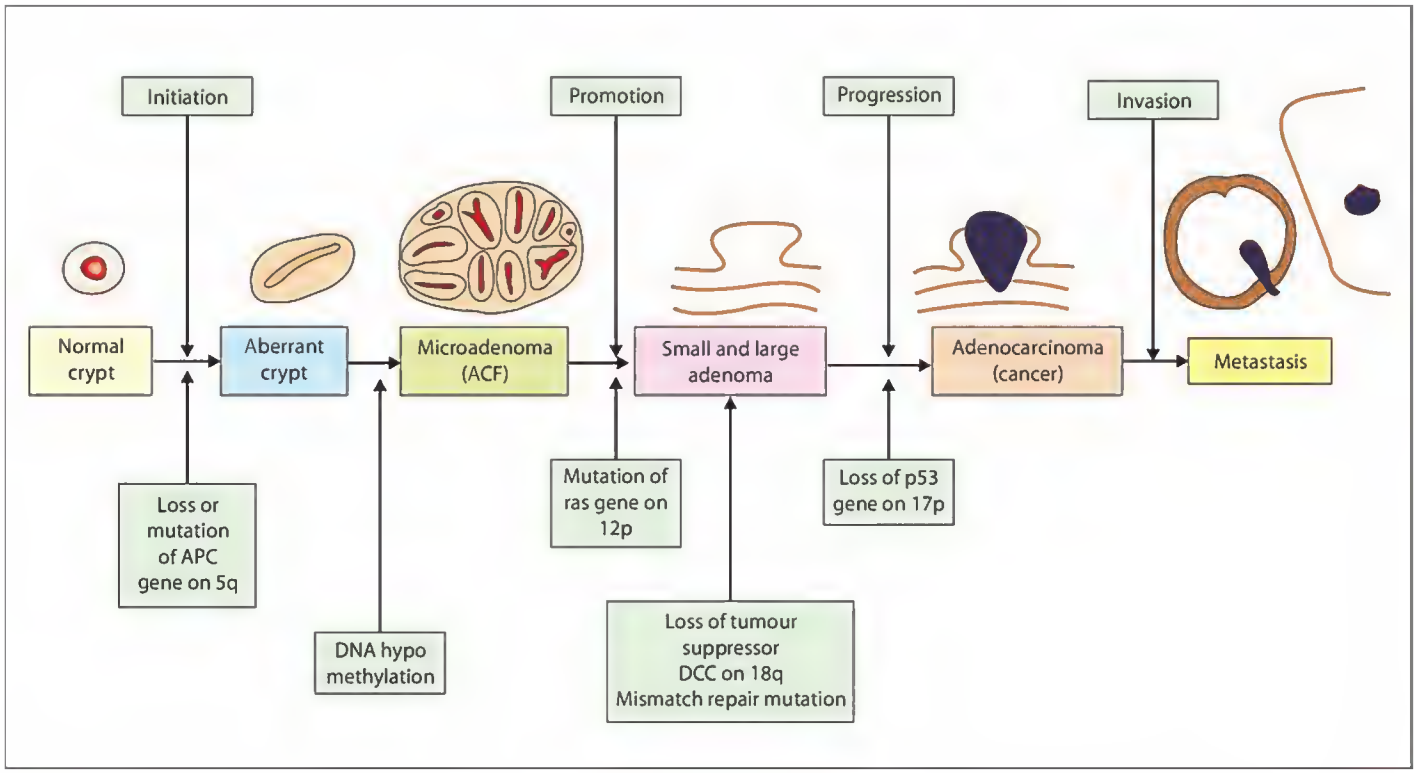

Figure 2: Adenoma carcinoma sequence.

cell growth properly. CIN develops very early during the tumourigenic process in the colon.

ONCOGENES AND TUMOUR SUPPRESSOR GENES

Oncogenes

Transforming retroviruses are oncogenic RNA viruses. Surprisingly they have a homology with highly conserved vertebrate genes. These segments are vertebrate genes, known as proto-oncogenes, that had been pirated by the virus. Most proto-oncogenes are involved in normal growth and differentiation coding for growth factors, growth factor receptors, G proteins, and cytoplasmic kinases involved in signal transduction, and nuclear proteases. Their deregulation leads to transformation and proliferation. Involvement of c-Myc in Burkitt's lymphoma, H-ras in oral cancer and thyroid cancer, K-ras in pancreatic cancer, and RET in medullary thyroid carcinoma. Oncogene activation occurs by gene amplification e.g. HER-2neu in breast cancer and N-myc in neuroblastoma are examples of oncogene involvement in cancer.

Tumour Suppressor Genes

In contrast to oncogenes, tumour suppressor genes check proliferation. Loss of function of these genes deregulates the cell cycle and contributes to tumour formation. Knudson had predicted the existence of a tumour suppressor gene from his epidemiologic studies on hereditary, and sporadic forms of retinoblastoma. Knudson hypothesised that children with hereditary retinoblastoma (early, multiple and bilateral tumours) carried a germline mutation of a key gene on one allele, and that a second genetic event occurred after birth that affected the function of the unaffected allele in the retinal cells. The retinoblastoma gene was the first tumour suppressor gene to be described. Documentation of Rb mutations in familial retinoblastoma proved Knudson's hypothesis. The Rb gene product pRB binds to the E2F family of transcription factors. Unbound E2F pushes the cell into S phase. The retinoblastoma gene function is disrupted in a variety of cancers including osteosarcoma, breast cancer, small cell carcinoma of the lung, and oesophageal cancer. Other tumour suppressor genes are p53, APC, WT1, and VHL.

CANCER CYTOGENETICS

Numerical and/or structural changes in chromosomes are common. Aneuploidy (chromosome number less than a multiple of the haploid number) is one of the most common cytogenetic findings in solid tumours. Some tumours, especially haematopoietic malignancy and solid tumours in children, exhibit tumour specific chromosomal abnormalities. These are of three main types:

Balanced Translocations

Philadelphia chromosome seen in chronic myeloid leukaemia and some cases of adult acute lymphoblastic leukaemia, is a reciprocal translocation between chromosomes 9 and 22, t(9;22)(q34;q11) (**Figure 3**). The resulting fusion between parts of BCR and ABL genes has transforming properties. The t(8;14)(q24;q32) in Burkitt's lymphoma juxtaposes the oncogene c-Myc on chromosome 8 to the enhancer region of the Ig heavy chain gene. Other translocations include t(11;22) (q24; q11.2-12) in Ewing's sarcoma and the t(X;18) (p11.2;q11.2) in synovial sarcoma.

Deletions

Deletions are responsible for abrogation of tumour suppressor genes in familial retinoblastoma and Wilms tumour.

Gene Amplification

Gene amplification leading to overexpression of N-myc is seen in neuroblastoma. The gene is situated on 2p. Karyotypically, multiple repeats of the gene sequence result in one of two appearances; double minutes where fragments of the repetitive

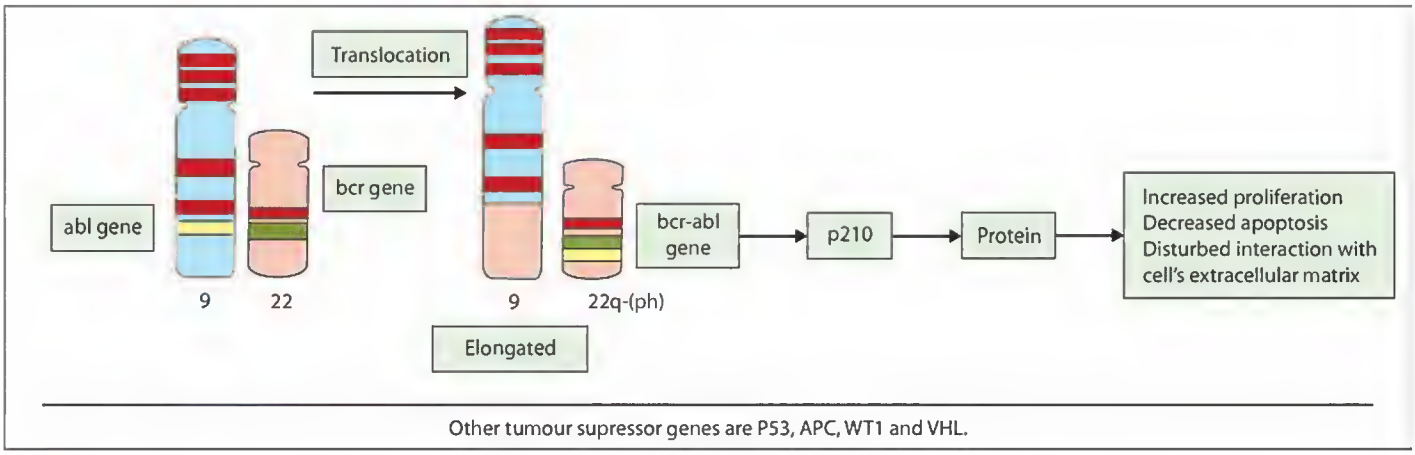

Figure 3: Philadelphia chromosome in CML – t(9,22).

DNA appear as tiny extra chromosomes or as homogeneously staining region (HSR) in G-banded preparations (**Figure 4**).

INHERITED CANCER SYNDROMES AND GERMLINE MUTATIONS

Germline Tumour Suppressor Inactivation

Familial retinoblastoma, familial APC, Wilms tumour, and Li-Fraumeni syndrome result from inactivation of tumour suppressor genes.

Germline Oncogene Activation

Multiple endocrine neoplasia (MEN), hereditary papillary renal cell carcinoma (MET), and familial melanoma (CDK4) result from germline oncogene activation.

DNA Repair Defects

Failure to repair DNA defects lead to increase in mutation rates and cancer risk. Xeroderma pigmentosum, ataxia telangiectasia (hypersensitivity to radiation), Bloom syndrome, Fanconi's anaemia, familial breast and ovarian cancer syndrome and hereditary non-polyposis colorectal cancer are examples of DNA repair defects predisposing cancer.

Non-Syndromic Hereditary Cancer

Clinicians regularly come across families in which multiple members have had cancers at various sites, without fitting into one of the distinct cancer family syndromes. Studies on such families will throw further light on the problem of heredity and cancer.

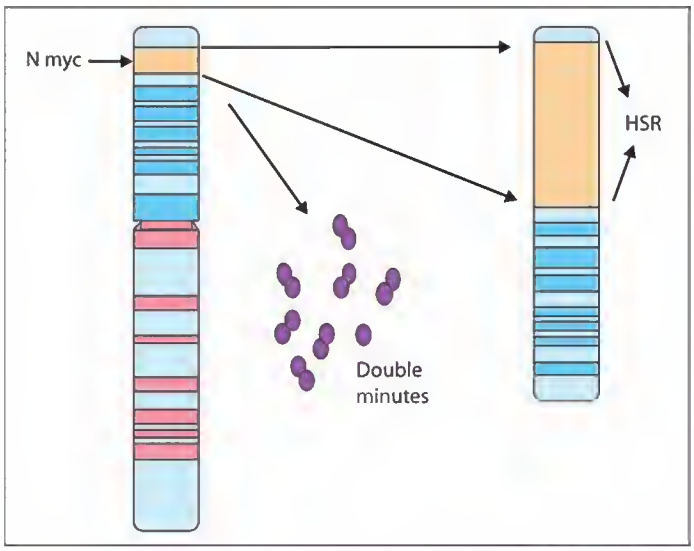

Figure 4: Amplification of the N-myc gene on chromosome 2p in human neuroblastoma.

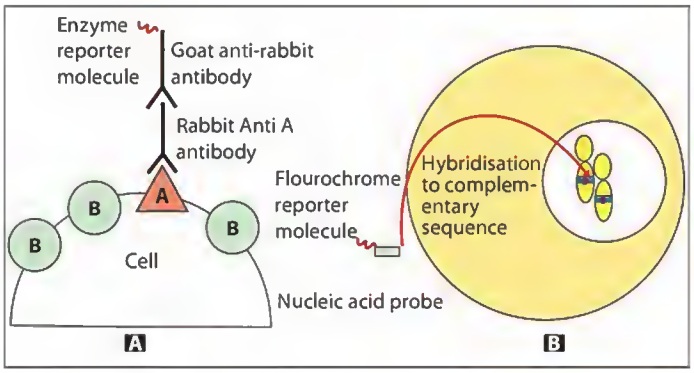
MECHANISMS OF INVASION AND METASTASIS

Metastasis, the establishment of tumour cells at distant sites in the body, is the hallmark of cancer. Metastasis is known to occur from very small tumours and the incidence increases with tumour size and stage. Metastasis is a multistep active process. The tumour cells must acquire the ability to invade stroma, stimulate neoangiogenesis, transgress stroma, invade vessel walls, extravasate into the extravascular environment and grow in a new microenvironment to establish metastasis. The entire set of abilities is needed for metastasis and each of these is independently acquired because of the genetic instability referred to above. Metastatic cascade is inefficient. Very small proportion of the cells breaking away from the tumour establish metastasis.

TUMOUR INVASION INTO THE EXTRACELLULAR SPACE



Invasive tumours show downregulation of cell-cell adhesion and alterations of normal cell-stromal interactions. Cancer cells also secrete a variety of proteolytic enzymes that degrade extracellular matrices and display greater motility. Tumour cells are able to detach themselves from their normal positions, break through basement membranes, and move through the extracellular space (ECS).

NEOANGIOGENESIS

A growing tumour needs vessels to prevent its centre from becoming hypoxic. Hypoxia stimulates new vessel formation by secretion of angiogenic factors, e.g. vascular endothelial growth factor (VEGF). Tumours that are unable to stimulate angiogenesis are unable to grow beyond 2 mm in diameter and have a very low metastatic potential. New vessels formed in the tumour bed are usually poorly formed and are particularly vulnerable to invasion by tumour cells that are present in the ECS.

APPLIED BIOLOGY OF CANCER

For more than a century the microscope has been the mainstay in the diagnosis and classification of malignant tumours. However, ancillary techniques (**Figures 5A and B**) such as immunohistochemistry (IHC) and fluorescent in-situ hybridisation (FISH) have improved diagnosis and classification. They have also identified potential targets for therapeutic intervention viz. receptors, amplified genes and aberrantly expressed proteins involved in deranged signalling pathways.

Figures 5A and B: Diagrammatic representation of (A) immunohistochemistry (B) FISH.

WHAT CLINICIANS WANT FROM PATHOLOGISTS

Clinicians expect from pathologists diagnosis of precancer and early cancer (screening); diagnosis and classification of established cancer; tumour grading wherever appropriate; staging; information on completeness of therapy (margins of resection and minimal residual disease); prediction of tumour response to treatment (identification of targets, chemoresponsiveness, radiotherapeutic responsiveness); monitoring the course of the disease and identification of early relapse; and prognostication.

PRACTICAL APPLICATIONS OF CYTOGENETICS AND MOLECULAR GENETICS

Specific cytogenetic markers in haematology viz. the Philadelphia chromosome in CML are used in routine diagnosis. The monitoring of the clearance of bcr-abl transcripts from the bone marrow of CML patients is today the gold standard in evaluating response to treatment and early relapse. Several solid tumours also show diagnostic cytogenetic markers. The t(11;22) translocation which represents the EWS-FLI1 fusion gene is manifested in the majority of Ewing's sarcomas. In atypical cases, techniques such as FISH or RT-PCR are used to arrive at an accurate diagnosis which is necessary for a good therapeutic response. Cytogenetics has helped to classify common soft tissue sarcomas – rhabdomyosarcomas in children and liposarcomas in adults.

Targeted therapy is the current buzzword in cancer therapeutics. Targeted therapy often needs documentation of target molecules by IHC and DNA studies. In patients with breast cancer demonstration of oestrogen and progesterone, receptor is needed for anti-oestrogenic therapy, and c-erbB2 for trastuzumab. Similarly, documentation of CD20 is needed for rituximab and c-Kit for imatinib therapy in gastrointestinal stromal tumours. Several other monoclonal antibodies against a variety of targets are now in use in clinical oncology and several others are in the pipeline. With each new target, a method of demonstrating it in the tissues becomes necessary, expanding the role that pathology plays in clinical therapeutics.

Prediction of susceptibility to cancer is now possible in families with known cancer syndromes by screening family members. This is regularly advised in patients with hereditary colon cancer especially those with familial adenomatous polyposis coli where prophylactic colectomy saves lives. Screening for RET mutations allows prophylactic thyroidectomy in patients with the MEN 2 syndrome. This prevents medullary carcinoma, a cancer that is difficult to eradicate once it is overt. Screening for HNPCC and BRCA mutations for familial colon, and breast and ovarian cancer respectively is also possible. However, psychological trauma can result when knowledge of susceptibility comes without the availability of definitive prevention strategies. Judicious patient counselling is, therefore, required before these tests are ordered.

GENE EXPRESSION PROFILING

One of the conundrums in everyday clinical practice is why patients with similar tumours have such different outcomes. The answers may lie in the molecular heterogeneity of tumours with similar appearances, the differential host response to the tumour, or differential host metabolism of common drugs. Gene expression profiling or DNA microarray technology, as it is often known, is currently being used to answer these questions (**Figure 6**). The hope is that differences in gene expression between tumours will not only explain why they behave differently, but may identify tumours that can be treated less or more aggressively or differently in different individuals. Pharmacogenetics, a specific treatment for a specific patient, which was once a distant dream, is now a very achievable goal.

SERUM TUMOUR MARKERS

Many tumours secrete substances into the blood stream that are useful in diagnosing the presence of the tumour and monitoring relapse. β-Human chorionic gonadotropin (β-hCG)was the first and still remains the most often estimated of these so called tumour markers. These markers are by no means specific to tumours. All of them are expressed by normal cells in foetal life or during repair and regeneration. They are, therefore, not useful for screening or the primary diagnosis of cancer. However, they are routinely used for monitoring the progress of tumour control.

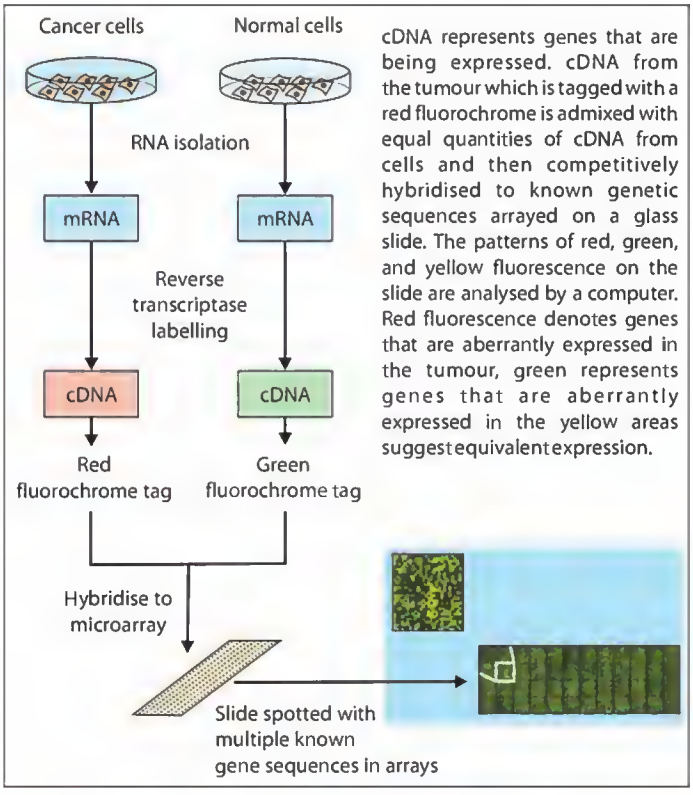


Figure 6: Gene expression profiling – DNA microarray.

21.3 Cancer Screening and Prevention

Atul Sharma, MP Ram Prabhu

INTRODUCTION

Cancer has not been considered a major health issue in developing countries where an overwhelming number of infectious diseases and rampant sanitary problems were higher priorities but according to a 2005 report by the World Health Organization (WHO) unfortunately, cancer is now becoming more of a global burden than it was ever before. An increase in the incidence of cancer in developing nations means that the international implications of the disease now require greater attention. This increase can be attributed to increased life expectancy in highly populated countries like China and India, a rise in the number of smokers in developing nations and an increase in lung cancer incidence.

As per the American Cancer Society, the worldwide estimate of cancer incidence is 12 million (2007) out of which 6.7 millions are in economically developing country of Asia. Lung cancer is the most common cancer world wide. WHO has estimated that by 2020, 15 million new cases will be diagnosed each year globally. In India, according to National Cancer Registry Programme estimates, 700,000 to 900,000 new cancer cases occur in India every year. With the cancer incidence further rising, it poses a huge public health and economic challenge.

The increase in cancer trends in the developing nations could be controlled and the economic burden of fighting this disease could be lessened by effective measures of cancer screening and prevention.

CANCER SCREENING

Cancer screening is a method wherein physical examination and investigative methods are used in an asymptomatic population in order to detect cancer at an earlier stage and rendering it more amenable to treatment and cure. Thereby, it reduces overall mortality of that cancer in that particular population. Screening is a form of secondary prevention because it does not prevent the occurrence of cancer; rather it helps cancer to be detected at an earlier stage.

Screening of cancer began in 1941 when George Papanicolaou published his work on cervical cancer screening using Pap smear. In 1960s, breast cancer screening with mammography came into practice when it was shown to reduce breast cancer mortality in a study by Health Insurance Plan of New York.

For a cancer to be eligible for screening, certain criteria should be met. First of all, the particular cancer must be an important public health problem in terms of morbidity and mortality. It should have a detectable pre-clinical phase which is sufficiently long when screening tests can be employed. An effective treatment should be available and the treatment should be more effective in the pre-symptomatic phase. The screening test should be accurate, acceptable to the population, easy to administer, cost-effective, and safe. An appropriate screening strategy in terms of age and interval of screening should be available.

Accuracy of screening test implies that it should be able to distinguish between diseased and non-diseased people. It is measured by sensitivity and specificity. Sensitivity refers to ability of the test to identify diseased subjects among a screened population and is given by the number of people who test positive divided by those who actually have the disease. Specificity refers to ability of the test to correctly identify the subjects without that particular disease. It is given by the number of people with a negative test divided by actual number of people who do not have the disease.

None of the screening test available currently is 100% sensitive and specific. Sensitivity and specificity are inversely related. A highly sensitive test can also give false positive results wherein the subject who actually is disease-free may be labelled positive by the test. This leads to futile diagnostic procedures and mental stress for subject. Similarly, highly specific tests can have false negativity wherein subjects who actually have the disease are labelled negative and an opportunity to treat and perhaps cure the disease is lost.

Screening in Specific Cancers

Colorectal cancer (CRC)

Colorectal cancer (CRC) is the third most common in incidence and mortality in United States although it is not among 10 leading cancers in most of Indian cancer registries. Colorectal cancer screening has shown to not only reduce the mortality by 3% but also incidence by 2%. Cancer screening tools currently available for CRC are faecal occult blood testing (FOBT), double contrast barium enema, colonoscopy, and flexible sigmoidoscopy. FOBT has been proven to be effective in 3 randomised controlled trials and a Cochrane review which showed 16% reduction in CRC mortality. Virtual colonoscopy wherein contrast enhanced CT scan is used to visualise whole colorectum is also currently being tested. American cancer Society Guidelines (based on US Multisociety Task Force on CRC) for an average risk individual include annual FOBT testing, flexible sigmoidoscopy once every 5 years, colonoscopy once every 10 years and double contrast barium enema once every 5 to 10 years beginning at the age of 50 years. For high-risk individuals, screening should start at an early age and tests should be done more frequently.

Cervical cancer

Pap smear is the standard test to screen cervical cancer. United States Preventive Task Force recommends screening to start within 3 years of earliest sexual activity, not later than 21 years of age. Pap smears are to be performed annually till 3 consecutive tests are normal where after it is performed once in 3 years till 65 to 70 years of age. Sensitivity of 50% to 75% and a specificity of 69% to 94% have been reported. Human

papillomavirus (HPV) DNA testing has been recently used to screen for cervical cancer, and has been approved by United States Federal Drug Authority (USFDA) for primary screening in cervical cancer along with Pap smear. In a large study of 130,000 patients in India, a single HPV test that is performed 15 to 20 years after the median age of first sexual intercourse detected many easily treatable, persistent infections and pre-cancers while limiting over-treatment and lowering the rate of death from cervical cancer within 5 to 10 years when compared to routine Pap smear or visual inspection of cervix with acetic acid (VIA).

Cervical cancer is the most common cancer among women in India. In the developing countries including India, cervical cancer screening programmes are in rudimentary stage and are hampered by many issues like lack of education and awareness and by social issues. Pap smear testing requires expertise to interpret results, infrastructure, and a long follow-up of patients. VIA by trained nurse-midwives is an easy, simple screening method which does not require any expertise or infrastructure. This has been tested in large studies in Zimbabwe and recently in India and was found to have a sensitivity of 76.7% and specificity of 64.1% .

Breast cancer

Breast cancer is the most common cancer in western countries among females and second leading cause of cancer related mortality in females. In India, breast cancer is most common cancer in urban areas like Delhi and Mumbai. Breast cancer screening helps to detect the disease at an early stage as a result of which mortality comes down as does the requirement of extensive surgery and chemotherapy. Breast self examination (BSE), clinical breast examination (CBE), and mammography have all been used in breast cancer screening. Randomised studies have shown reduction in relative risk of death due to breast cancer using mammography.

In United States, there was a 2.1% reduction in breast cancer mortality due to screening in 1990s. For normal females, the screening recommendations are to do mammogram annually starting from the age of 40 years. However, for high-risk individuals (positive family history or chest wall irradiation) it should be started at an early age. MRI of breast is recommended for patients with BRCA1 and BRCA 2 mutations. Recently, the US Preventive Services Task Force has come up with recommendations against routine screening mammography in women aged 40 to 49 years and recommends biennial screening mammography for women between the age of 50 and 74 years.

Prostate cancer

Prostate cancer although not the commonest cancer in India, is the most common cancer in the developed countries. Serum Prostate Specific Antigen (PSA) and digital rectal examination are the two methods used in prostate cancer screening. Screening with PSA has resulted in significantly increased numbers of cancers and also at an earlier stage. However, the benefit from prostate cancer screening remains controversial since many patients diagnosed with prostate cancer may not die of cancer and treatment may not benefit.

Screening has not been found to be beneficial in ovarian and endometrial cancer. In lung cancer, screening the role of annual chest CT scans is still under investigation.

CANCER PREVENTION

Cancer screening aims to detect pre-cancerous and early cancer while primary preventions of cancer aims at reducing the incidence of cancer. Tobacco consumption in any form, alcohol consumption, viral oncogenesis, industrial exposure to carcinogens, and hereditary cancer syndromes are some important risk factors for cancer. Risk factors in many cancers are now known.

Tobacco consumption accounts to 50% of the cancers in India including head and neck cancer, lung cancer, oesophageal, gastric, breast, and bladder cancers. Lung cancer incidence has fallen in United States following reduction in incidence of smoking. Given the high mortality rate of lung cancer (5-year survival rate of 15% only), prevention by smoking control appears to be the best possible option to reduce lung cancer mortality. Nicotine replacement therapy, anti-depressants like bupropion and other drugs like clonidine have been used to promote quitting. Preventive measures have been carried out by the Indian Government in the form of ban on smoking at public places.

Chemoprevention is defined as the use of natural or synthetic compounds to block, prevent, or reverse the development of invasive cancer. Retinoids and beta-carotene have been tried in head and neck cancers for the prevention of second primaries but have not shown consistent benefit. In fact, beta-carotene was found to be detrimental in some lung cancer trials. Vitamin E and selenium did not reduce incidence of prostate cancer in a large study.

Vaccination against hepatitis B has caused significant reduction in incidence of hepatocellular carcinoma in children in Taiwan. Two HPV vaccines, namely, Gardasil (quadrivalent) and Cervarix (bivalent) have shown efficacy in preventing cervical pre-cancerous lesions in females. Both vaccines are approved in various western countries and Gardasil has been approved by the Indian Academy of Paediatrics in India.

Improvement in socio-economic status has resulted in reduction of incidence of cervical cancer. On the other hand, obesity is an important risk factor for the development of gastroesophageal junction cancer, colorectal cancer, endometrial, and breast cancer. Dietary and lifestyle modifications like consumption of high fibre diet, fruits and vegetables and physical exercise can lead to drop in the incidence of such cancers.

Helicobacter pylori, a normal commensal organism of gastric mucosa has been implicated in gastric adenocarcinoma. Eradication of *H. pylori* has been recommended in certain high-risk groups, like patients with atrophic gastritis, first degree relatives of gastric cancer patients and in patients after resection of low-risk gastric adenocarcinomas. But problems of emergence of resistance to antibiotics and re-infection hamper such an approach. Dietary carcinogens like nitrosoamines are also implicated in gastric cancer. Reduction in use of canned foods and preservative added foods has resulted in the decline of gastric cancer.

Chronic asbestos exposure is a risk factor for the lung cancer. Similarly, exposure to other industrial carcinogens like coal tar, aromatic dyes, cadmium, and radiation exposure are implicated to be carcinogenic.

Familial cancer syndromes like BRCA-1 and BRCA-2 mutations, Hereditary non-polyposis colon cancer (HNPCC) syndrome, familial adenomatous polyposis (FAP) colon cancer syndrome confer high risk to individuals in that family. Prophylactic bilateral mastectomy reduces breast cancer risk by 90% in BRCA-1 gene mutation carriers. Similarly, bilateral oopherectomy reduces the risk of breast cancer by 50% in addition to reducing the risk of ovarian cancer. Both are options against screening in genetic breast-ovarian cancer syndromes. Prophylactic proctocolectomy is done in FAP and genetic counselling should be offered to such individuals and surveillance measures should be continued.

CONCLUSIONS

Creating awareness of cancer among public, advocating and implementing smoking control measures, protection from industrial carcinogens and vaccination against preventable cancers can help reduce the burden of cancer. Screening in cancers of breast, cervix, and colorectal has great potential in reducing the incidence of advanced disease and thereby, mortality. Although benefit from cancer screening is straightforward, realising the fullest benefit is often not possible due to difficulties in large scale implementation and adherence to screening recommendations even in the developed nations. However, dedicated effort to attain such goals will definitely benefit population at risk.

21.4 Principles of Drug Treatment of Cancer

Lalit Kumar, Prabhat Singh Malik

INTRODUCTION

The systemic treatment of cancer has its roots in the initial work of Paul Ehrlich, who coined the term chemotherapy. Chemotherapy, which includes newly developed targeted treatments, has been the main mode of drug treatment of cancer for the past five decades. Initial studies in 1960 to 70's led to the development of concept of combination chemotherapy and provided effective treatment for childhood acute lymphoblastic leukaemia, advanced Hodgkin's lymphoma and diffuse large B-cell lymphomas and testicular germ cell tumours. These lessons have been subsequently applied to other cancer types as well. Major limitations to the clinical efficacy of chemotherapy have been toxicity to the normal tissues of the body and the development of drug resistance. In the past decade, better understanding of molecular biology and pathways/targets have led to the target specific therapy. This has resulted in a paradigm shift in the management of many cancers.

Tumour Growth and Response to Cytotoxic Chemotherapy

The key principles of chemotherapy were initially defined by Skipper *et al* using the murine leukaemia model. Cytotoxic effects of anticancer drugs are predicted to follow logarithmic cell kill kinetics. Thus, if an individual drug leads to a 3 log kill of cancer cells and reduces the tumour burden from 10^{10} to 10^{7} cells, the same dose used at a tumour burden of 10^{5} cells reduces the tumour mass to 10^{2}. On the other hand, human solid cancers support a Gompertzian model of tumour growth and regression. According to the Gompertzian model, the growth fraction peaks when the tumour is approximately 37% of its maximum size. In general, when patients with advanced solid tumours are treated, the tumour mass is larger, its growth fraction is low, and the fraction of cells killed is, therefore, small.

CELL CYCLE AND THERAPEUTIC TARGETS

The cell cycle of cancer cells is qualitatively similar to that of normal cells. Each cell begins its growth during a post-mitotic period, a phase called G_1(Gap1), during which enzymes necessary for DNA production, other proteins, and RNA are produced. G_1 is followed by a period of DNA synthesis (S), in which essentially all DNA synthesis for a given cycle takes place. When DNA synthesis is complete, the cell enters a pre-mitotic period -G_2 (Gap2), during which further protein and RNA synthesis occurs. This gap is followed immediately by mitosis (M), at the end of which actual physical division takes place, two daughter cells are formed, and each cell again enters G_1. G_1 phase is in equilibrium with a resting state called G_0. Cells in G_0 are relatively inactive with respect to macromolecular synthesis and are consequently insensitive to many chemotherapeutic agents, particularly those affecting macromolecular synthesis.

INDICATIONS FOR CHEMOTHERAPY

Chemotherapy as Primary Therapy

For a number of cancers, chemotherapy is the main treatment and is considered curative even in advanced stage. These include: childhood malignancies, e.g. acute lymphoblastic leukaemia (ALL), Burkitt's lymphoma, Wilms' tumour, and embryonal rhabdomyosarcoma; in adults: choriocarcinoma , Hodgkin's and non-Hodgkin's lymphoma (NHL), acute lymphoblastic and myelogenous leukaemia, germ cell cancer, ovarian and localised small-cell lung cancers, are examples of cancers treated primarily with chemotherapy.

Neoadjuvant Chemotherapy

For many chemosensitive tumours in advanced stage, 3 to 4 cycles of chemotherapy may be administered prior to local treatment (e.g. surgery/radiation therapy), this is called *neoadjuvant or induction chemotherapy*. This results in reduction in the size of primary tumour facilitating local treatment, e.g. better chance of complete resection with local treatment, e.g. surgery (e.g. locally advanced breast cancer, epithelial ovarian cancer, etc.) or radiation (e.g. cancer of head and neck, cervix, anal canal, urinary bladder) while reducing the potential spread of micro-metastatic spread. Osteogenic sarcoma, rhabdomyosarcoma, Ewing's sarcoma, and Wilms' tumour, etc. are common paediatric tumours treated with this approach in advanced stages. Clinical benefit is usually optimised when chemotherapy is administered in combination with radiation therapy (concurrently), e.g. locally advanced cervical cancer, head and neck cancer, cervix, anal canal cancer, etc.

Adjuvant Chemotherapy

It is administered after local treatment, e.g. after surgery for breast and ovarian cancers and has been demonstrated to improve outcome. This is called *adjuvant chemotherapy* and helps to prevent local and systemic relapse by eradicating micro metastasis. Advanced colon cancer, non-small cell lung cancer, head and neck cancer, cervical cancer, Wilms' tumour, and osteogenic sarcoma are other cancers where such an approach is beneficial.

Route of Administration

Most chemotherapeutic drugs are administered intravenously (IV) either as slow IV push through a running drip or as IV infusion over a longer period. Oral formulations of few chemotherapeutic drugs (e.g. alkylating agents, antimetabolites) are also available. In certain situations, chemotherapeutic drugs can be instilled locally. The common examples are: (a) intrathecal use of methotrexate and/or cytarabine for (CNS) prophylaxis/ treatment of CNS leukaemia, (b) intra-arterial use for chemo-embolisation in hepatocellular carcinoma and limb perfusion for malignant melanoma.

Consolidation Chemotherapy

It refers to the phase of treatment after achieving remission with induction chemotherapy. The goal is to eradicate residual disease. This term is mainly used in the context of haemato-logical malignancies, e.g. acute lymphoblastic and myeloblastic leukaemias.

Maintenance Chemotherapy

ALL or acute promyelocytic leukaemia (APML), subtype of AML prolonged low-dose therapy is required (usually 1.5 to 2 years) to maintain remission and prevent relapses. This is termed as *maintenance therapy*.

Palliative Chemotherapy

In advanced cancers when cure is not possible, the aim of therapy is to improve symptoms, and improve quality of life. The use of chemotherapy with such intention is termed as *palliative chemotherapy*. A careful decision should be taken in such situations and main consideration should be to minimise toxicities (including cost and hospitalisation) with adequate efficacy and convenience of the patient.

Salvage Chemotherapy

Chemotherapy used for the treatment of relapse after initial response is termed as *salvage chemotherapy*. This is with chemo-sensitive tumours at advanced stage, e.g. Hodgkin's lymphoma, aggressive NHL, leukaemias, and certain paediatric cancers.

High-Dose Chemotherapy

High-dose chemotherapy regimens are based on the observation that in chemo-responsive cancers, the dose-response curve for many anti-cancer agents is rather steep, and an increased dose of chemotherapeutic drug(s) can produce markedly increased therapeutic effects. Although, it is associated with potentially life-threatening complications that require intensive support, usually in the form of haematopoietic stem cell support from the patient (*autologous*) or from human leucocyte antigen (HLA) matched sibling or unrelated donor. High-dose regimens have definite curative potential in defined clinical settings like chemosensitive relapsed Hodgkin's and non-Hodgkin's lymphoma, multiple myeloma, and childhood neuroblastoma (stage III-IV). Its role is currently under investigation in conditions like high-risk testicular germ cell tumours, Ewing's sarcoma, etc.

CLASSIFICATION OF CYTOTOXIC CHEMOTHERAPY DRUGS

Conventionally, most chemotherapeutic agents can be grouped according to whether their activity is greater when the cell is in a specific phase of the cycle. Agents that are most active against cells in a specific phase of the cell cycle are called *'cell cycle phase specific drugs'* (**Table 1**). The implication of the phase specificity is that a short exposure by the drug even in high doses would not kill a large proportion of the tumour cells because all the cells would be in different phase of cell cycle. Rather, a prolonged exposure either by repeated administration or by increasing the duration of infusion would achieve a better cell kill as most of the cells will pass through that specific phase of the cell cycle.

1. *Cell cycle phase non-specific drugs:* This group includes agents that are effective while cells are active in cycle but are not dependent on the cell being in a particular phase. Main examples are most of the alkylating agents and the antitumour antibiotics.
2. *Cell cycle non-specific drugs:* A third group of drugs appears to be effective whether cancer cells are in cycle or are resting. Drugs in this category include: mechlorethamine (nitrogen mustard) and the nitrosoureas.

Table 1: Cell Cycle Phase Specific Drugs

Phase of Greatest Activity	Class of the Drug	Drug
Gap 1 (G_1)	Enzyme	Asparaginase
	Corticosteroid	Prednisone
G1/S junction	Purine analogue	Cladarabine
DNA synthesis (S)	Pyrimidine analogue	Cytarabine, fluorouracil, gemcitabine
	Folic acid analogue	Methotrexate
	Purine analogue	Thioguanine, fludarabine
	Topoisomerase-I inhibitor	Topotecan
	Substituted urea	Hydroxyurea
Gap 2 (G2)	Antibiotic	Bleomycin
	Topoisomerase-II inhibitor	Etoposide
	Microtubule polymerisation and stabilisation	Paclitaxel
Mitosis (M)	Mitotic inhibitor	Vinblastine, vincristine, vindesine, vinorelbine

Table 2 presents classification of cytotoxic chemotherapeutic drugs according to their chemical structures and clinical activities.

MECHANISM OF ACTION OF CHEMOTHERAPEUTIC AGENTS

Alkylating Agents

These are cell cycle specific but not phase specific and act by means of cross-linking of DNA strands. These agents may have serious long-term toxicities on bone marrow stem cells and gonads.

Topoisomerase Inhibitors

The DNA topoisomerases are enzymes that alter DNA topology by causing and resealing DNA strand breaks. Topoisomerase-I relaxes supercoiled DNA for a variety of crucial cellular processes. Topoisomerase-II catalyses the double stranded breaking and resealing of DNA, thereby allowing the passage of one double helical segment of DNA through another. So these enzymes are essential for cellular events like transcription, replication, and mitosis. These enzymes are targets of this group of cytotoxic agents. Topoisomerase-I is inhibited by campothecin derivatives, like topotecan and irinotecan while topoisomerase-II is inhibited by anthracyclines and epipodophyllotoxins (etoposide and teniposide).

Antitumour Antibiotics

These drugs have been derived from micro-organisms. They are usually cell cycle non-specific agents and act through intercalation, by inserting itself through DNA basepairs, and thereby preventing DNA replication.

Mitotic Spindle Inhibitors

These agents are especially active in M and G2M phase of cell cycle. They act by inhibiting microtubule assembly by binding to tubulin (Vinca alkaloids) or by stabilising microtubules and preventing their disassembly and producing non-functional microtubules (Taxanes). Some of them are natural products (vincristine, vinblastine, paclitaxel) while others are semi-synthetic products (vinorelbine, docetaxel).

Anti-Metabolites

These agents are cell cycle S-phase specific and kill tumour cells by acting as a false substrate in biochemical pathways. Based on their chemical structures, these are sub-classified as pyrimidine analogues, purine analogues, antifolate, and others.

TOXICITY OF CHEMOTHERAPEUTIC DRUGS

No chemotherapeutic agent is free of toxicities or side effect. Depending on their biological properties, the tissue/organ specific toxicities manifest. Common side effects of chemotherapeutic agents are nausea, vomiting, myelo-suppression, alopaecia, mucositis, etc. These can be group specific or particular drug specific. Common adverse effects of these agents are shown in **Table 2**.

RESISTANCE TO CHEMOTHERAPEUTIC AGENTS

Resistance to antineoplastic chemotherapy is a combined characteristic of a specific drug, a specific tumour, and a specific

Table 2: Classification of Cytotoxic Chemotherapeutic Agents

Group	Drug	Uses	Adverse Effects
Alkylating Agents			
Classical	Cyclophosphamide	Lymphomas, acute leukaemia, breast cancer, childhood tumours, e.g. rhabdomyosarcoma, PNET	Myelosuppression, nausea/vomiting, alopaecia haemorrhagic cystitis
	Ifosfamide	Lymphomas, sarcomas, germ cell tumours, etc.	Haemorrhagic cystitis, neurotoxicity, nausea, alopaecia, mild myelosuppression
	Busulfan	As a part of conditioning regimen for stem cell transplantation (CML-not used routinely now)	Cumulative myelosuppression, sterility, pulmonary fibrosis
	Chlorambucil	CLL, Indolent B cell NHL	Myelosuppression, mild gastrointestinal upset
	Melphalan	Multiple myeloma, as part of high-dose therapy for stem cell transplantation	Myelosuppression, mucositis (in high doses), nausea/vomiting, alopaecia
	Thiotepa	Cancers of breast, ovary and intracavitary for malignant effusions	Myelosuppression, chemical cystitis (during intravesical administration)
Nitrosoureas	Carmustine (BCNU)	Astrocytoma, as part of high-dose therapy for stem cell transplantation, especially for lymphomas	Delayed myelosuppression,nausea/vomiting, hypotension (with rapid administration), mucositis, interstitial lung disease
	Lomustine (CCNU)	Astrocytoma	Delayed myelosuppression,nausea/vomiting, mucositis, interstitial lung disease, secondary leukaemia
Platinum compounds	Cisplatin (CDDP)	A wide variety of tumours	Nausea/vomiting, nephrotoxicity, peripheral neuropathy, ototoxicity, hypomagnesaemia
	Carboplatin	Nearly same as cisplatin	Thrombocytopaenia, nausea, hypersensitivity
	Oxaliplatin	Colorectal cancer, gastic, pancreatic, and biliary cancers	Peripheral neuropathy, acute dysaesthesias, allergic reactions
	Satraplatin	Prostate cancer	Myelosuppression
Antitumour antibiotics	Actinomycin D	Sarcomas, gestational trophoblastic neoplasms, Wilms' tumour, germ cell tumours	Myelosuppression, nausea/vomiting, alopaecia, hyperpigmentation, radiation recall
	Bleomycin	Lymphomas, germ cell tumour, malignant effusion	Pulmonary fibrosis, hypersensitivity, fever, hyperpigmentation of skin
	Mitomycin C	Breast cancer and stomach cancer	Haemolytic uraemic syndrome, myelosuppression, nausea, alopaecia
Topoisomerase Inhibitors			
Epipodophyllotoxins	Etoposide (VP-16)	Testicular cancer, Lung cancer, lymphomas, ALL, AML	Myelosuppression, nausea, hypotension (with rapid infusion), mucositis
	Teniposide	ALL, lymphomas	Myelosuppression, nausea, mucositis
Camptothecin derivatives	Irinotecan	Colorectal cancer, small cell lung cancer	Diarrhoea, myelosuppression
	Topotecan	Ovarian cancer, small cell lung cancer	Myelosuppression, nausea
Anthracyclins	Daunorubicin	Acute leukaemias (AML,ALL)	Cardiotoxicity, myelosuppression, nausea, vomiting
	Doxorubicin	ALL, NHL, HL, breast cancer, ovarian cancer, stomach cancer	Cardiotoxicity, myelosuppression, nausea/vomiting, radiation recall
	Epirubicin	Breast cancer, gastric cancer	Cardiotoxicity, myelosuppression, nausea, vomiting
	Idarubicin	AML	Cardiotoxicity, myelosuppression, nausea/vomiting
Mitotic Spindle Agents			
Taxanes	Paclitaxel	Ovarian cancer, breast cancer, lung cancer	Peripheral neuropathy, myelosuppression, hypersensitivity
	Docetaxel	Cancers of breast and lung	Myelosuppression, fluid retention, alopaecia, mucositis
	Ixabepilone	Metastsatic breast cancer	Myelosuppression, alopaecia, peripheral neuropathy
Vinca alkaloids	Vincristine	ALL, NHL, HL, sarcomas	Peripheral neuropathy, paralytic ileus, constipation, jaw pain
	Vinblastine	HL, germ cell tumour	Myelosuppression, abdominal cramps, jaw pain
	Vinorelbine	Cancers of breast, lung, ovary	Myelosuppression, nausea, allergic-type pulmonary reactions
	Vindesine	Leukaemias	Myelosuppression, peripheral neuropathy

Contd...

Contd...

Group	Drug	Uses	Adverse Effects
Antimetabolites			
Pyrimidine analogues	Cytarabine	AML, ALL, NHL	Myelosuppression, nausea, mucositis, cerebellar toxicity (in high dose), fever
	5-Flourouracil (5-FU)	Cancers of breast, colon, oesophagus, stomach, head and neck	Myelosuppression, mucositis, diarrhoea, reversible cerebellar toxicity
	Capecitabine	Cancers of breast,colon, gall bladder	Diarrhoea, hand foot syndrome
	Uracil/Tegafur	Same as 5-FU	Diarrhoea, hand foot syndrome
	Gemcitabine	Cancers of pancreas, lung, ovary, urinary bladder, breast	Myelosuppression, nausea, flu-like syndrome
Purine analogues	6- Mercaptopurine	ALL (maintenance)	Myelosuppression, mild nausea, reversible cholestasis
	6- Thioguanine	ALL and AML	Myelosuppression, mucositis, diarrhoea
	Cladarabine	Hairy cell leukaemia, Indolent B cell NHLs	Myelosuppression,immunosuppression with decreased CD4 cells
	Fludarabine	CLL, Indolent B cell NHLs	Myelosuppression (may be prolonged), prolonged immunosuppression
	Pentostatin	Hairy cell leukaemia	Myelosuppression, immunosuppression, altered taste
Miscellaneous Agents			
Others	Methotrexate	Gestational trophoblastic neoplasia (GTN), ALL, lymphomas (NHL), Osteosarcomas	Renal dysfunction, myelosuppression, mucositis
	Pemetrexed	Mesothelioma, non-squamous lung cancer	Myelosuppression, hand foot syndrome, mucositis
	L- Asparaginase	ALL	Hypersensitivity reactions, hepatic dysfunction, coagulopathy, hyperglycaemia, encephalopathy
	Procarbazine	CNS lymphoma, astrocytoma	Prolonged myelosuppression, flu-like syndrome
	Dacarbazine	HL, sarcomas	Myelosuppression, flu-like syndrome, phlebitis, mucositis
	Temozolamide	Glioblastoma	Myelosuppression, nausea
Immuno-modulators	Thalidomide	Multiple myeloma	Constipation, somnolence, peripheral neuropathy, venous thrombosis
	Lenalidomide	Multiple myeloma, myelodysplasia	Myelosuppression, venous thrombosis, diarrhoea
Proteasome inhibitors	Bortezomib	Multiple myeloma, refractory NHL (Mantle cell)	Peripheral neuropathy, thrombocytopaenia, fatigue, diarrhoea

PNET = Peripherol neuroectodermol tumour; CLL = Chronic lymphocytic leukoemio; NHL = Non-Hodgkin's lymphomo; ALL = Acute lymphoblostic leukoemio; AML = Acute myeloblostic leukoemio; HL = Hodgkin's lymphomo

host, whereby the drug is ineffective in controlling the tumour without excessive toxicity. Resistance to chemotherapeutic drugs has been postulated to arise either from cells not being in the appropriate phase of the cell cycle to allow drug lethality, or from decreased uptake, increased efflux, metabolism of the drug, or alteration of the target, e.g. by mutation or over expression. Indeed, p170 (p170 P-glycoprotein; *mdr* gene product) was recognised from experiments with cells growing in tissue culture as mediating the efflux of chemotherapeutic agents in resistant cells. Certain neoplasm, particularly haematopoietic tumours, have an adverse prognosis if they express high levels of p170, and modulation of this protein's function has been attempted by a variety of strategies.

COMBINATION CHEMOTHERAPY

Combination chemotherapy using conventional cytotoxic agents is aimed to provide maximal cell kill and to prevent and/or slow the development of drug resistance. It provides a broader range of interaction between drugs and tumour cells with different genetic abnormalities in a heterogeneous tumour population. Certain principles have been useful in guiding the selection of drugs in the most effective drug combinations, and they provide a paradigm for the development of new drug programmes.

1. Only drugs known to be partially effective against the same tumour when used alone should be selected for use in combination.
2. When several drugs of a class are available and are equally effective, a drug should be selected that has toxicity that does not overlap with the toxicity of other drugs to be used in the combination.
3. Drugs should be used at their optimal dose and schedule, and drug combinations should be given at consistent intervals. Because long intervals between cycles negatively affect dose intensity, the treatment-free interval between cycles should be the shortest possible time necessary for recovery of the most sensitive normal target tissue, which is usually the bone marrow.
4. There should be a clear understanding of the biochemical, molecular, and pharmacokinetic mechanisms of interaction between individual drugs in a given combination, to allow for maximal effect.

Precautions During Administration of Chemotherapy

Most of the chemotherapeutic drugs are available as parenteral therapy for intravenous administration. Different solvents might be required (normal saline for cisplatin while D5W for its analogues like carboplatin and oxaliplatin). The clinician, pharmacist, and the nurse should be aware of this and a readily available chart must be kept at the work-place. As a rule of thumb, not to mix two chemotherapeutic agents in a single solvent pouch so as to avoid incompatibility. The duration of administration as per the protocol, provided in the literature should be adhered to unless a new approach is explored in an

experimental protocol. Drugs to be administered through different routes (e.g. methotrexate for intrathecal route and vincristine for IV route) must be kept in separate trays. It is uncommon but anecdotal cases have been reported where vincristine (highly vesicant drug) has been administered by intrathecal route with fatal outcome.

Extravasation

This is defined as the leakage or infiltration of drug into the subcutaneous tissues. Vesicant drugs that extravasate are capable of causing tissue necrosis or sloughing. Irritant drugs cause inflammation or pain at the site of extravasations. Common signs and symptoms of extravasation are pain or burning at the intravenous site, redness, swelling, and inability to obtain a blood return, and change in the quality of the infusion. Any of these complaints or observations should be considered symptom of extravasation(s) until proved otherwise. Common drugs with vesicant and irritant properties are tabulated in **Table 3**.

Following guidelines are helpful in the management of extravasation.

1. Stop administration of the chemotherapeutic agent.
2. Leave the needle/catheter in place and immobilise the extremity.
3. Attempt to aspirate any residual drug in the tubing, needle, or suspected extravasation site.
4. Administer the appropriate antidote (**Table 3**). This may include instillation of a drug antidote or application of heat or cold to the site.
5. Provide the patient and/or caregiver with instructions, including the need to elevate the site for 48 hours and the continuation of antidote measures as appropriate.

Table 3: Common Vesicant and Irritant Drugs and Potential Antidotes

Chemotherapeutic Agent	Pharmacologic Antidote	Non-pharmacologic Antidote
Doxorubicin, daunorubicin epirubicin, darubicin, mitoxantrone	None	Topical cooling
Vincristine, vinblastine vinorelbine	Hyaluronidase 150 units/1 mL SC	Warm compresses
Etoposide (VP-16)	None	Warm compresses
Paclitaxel	None	Topical cooling
Cisplatin, oxaloplatin	Sodium thiosulphate	None
	Case reports of use of anti-inflammatory drugs and high dose dexa-methasone	Case reports of topical cooling but may make neuropathy worse

6. Discuss the need for further intervention with the physician, and photograph, if indicated.
7. Document extravasation occurrence according to institutional guidelines.
8. Continued monitoring of extravasation site at 24 hours, 1 week, 2 weeks, and additionally as guideline recommends.

Secondary complications, such as infection and pain may occur. Follow-up photographs at these periods, if possible, are helpful in monitoring extent of injury and progress in healing.

Hormonal Therapy

The family of steroid hormone receptor-related molecules has emerged as prominent targets for small molecules useful in the treatment of cancers. When bound to their ligands, these receptors can alter gene transcription and, in certain tissues, induce apoptosis. Certain cancers are very sensitive to hormonal treatment. Common examples are steroids for lymphomas, leukaemia (ALL, CLL), myeloma, anti-androgen agents for prostate cancer, and anti-estrogens for breast cancer.

Glucocorticoids

Glucocorticoids are generally given in 'pulsed' high doses in leukaemia and lymphomas, where they induce apoptosis in tumour cells. Commonly used steroids are prednisolone, methylprednisolone, and dexamethasone. While using such high doses of steroids, one need to remember common complications of steroids like Cushing's syndrome, inadvertent adrenal suppression, hyperglycaemia, and infections particularly fungal and pneumocystis pneumonia and herpes reactivation.

Anti-Oestrogens

Tamoxifen is a partial estrogen receptor antagonist; it has a ten fold greater anti-tumour activity in patients with breast cancer, whose tumours express oestrogen receptors than in those who have low or no level of expression. Tamoxifen is commonly used for patients with breast cancer expressing estrogen receptors, as adjuvant therapy in both pre- and post-menopausal women for at least 5 years after surgery. Side effects include a somewhat increased risk of oestrogen-related cardiovascular complications, such as thrombo-embolic phenomenon, and a small but increased risk (1.5 times compared to population) of endometrial carcinoma, which appears after chronic use (usually more than 5 years).

Aromatase

It refers to a family of enzymes that catalyse the formation of estrogen in various tissues, including the ovary and peripheral adipose tissue and some tumour cells. Aromatase inhibitors are of two types, the irreversible steroid analogs, such as exemestane and the reversible inhibitors such as anastrozole or letrozole. Anastrozole is superior to tamoxifen in the adjuvant treatment of breast cancer in post-menopausal patients with estrogen receptor-positive tumours. Letrozole treatment affords benefit following tamoxifen treatment. Adverse effects of aromatase inhibitors may include an increased risk of osteoporosis.

Progestins

Medroxyprogesterone and megesterol acetate have some activity in breast and endometrial cancers. They act by disrupting hypothalamic pituitary-gonadal axis, and thus, alter expression of oestrogen receptors or have androgenic effect. Main adverse effects are fluid retention, hepatic dysfunctions, and increased risk of thromboembolic events.

Anti-Androgens

Prostate cancer is classically treated by anti-androgens. Bilateral orchiectomy is the standard treatment in metastatic prostate cancer. If orchiectomy is not accepted by the patient, testicular androgen suppression can also be effected by lutenising hormone–releasing hormone (LHRH) agonists such as leuprolide and goserelin. These agents cause tonic stimulation of the LHRH receptor, with the loss of its normal pulsatile activation resulting in decreased output of lutenising hormone by the anterior pituitary. Therefore, as primary hormonal manipulation in prostate cancer, one can choose orchiectomy or leuprolide, but not both. The addition of androgen receptor blockers, including flutamide or bicalutamide is of additional benefit; the combined use of orchiectomy or leuprolide plus flutamide is referred to as *total androgen blockade*.

Others

Adrenocortical carcinomas can cause Cushing's syndrome as well as syndromes of androgen or oestrogen excess. Mitotane can counteract these by decreasing synthesis of steroid hormones. Islet cell neoplasms can cause debilitating diarrhoea, treated with the somatostatin analogue octreotide. Prolactin-secreting tumours can be effectively managed by the dopaminergic agonist bromocriptine.

MOLECULAR TARGETED THERAPY

A number of molecular targets have been identified during the past decade. These targets often play a key role in the signal transduction pathway that regulates tumour cell growth, proliferation, migration, angiogenesis and apoptosis. Molecular targeted therapy is a broad term comprising of several classes of agents including tyrosine kinase inhibitors and monoclonal antibodies (MAbs) (**Table 4**).

Tyrosine Kinase Inhibitors

Tyrosine kinase (TK) plays a key role in the transduction of the signals within cellular cascades that are responsible for the regulation of gene transcription within the nucleus. Tyrosine

Table 4: Molecular Targeted Therapy

Drug	Indication	Mechanism of Action	Adverse Effects	Dose
Bcr-Abl tyrosine kinase inhibitors (TKI)				
Imatinib	CML, c-Kit +unresectable or metastatic GIST	Inhibition of Bcr-Abl, c-Kit receptor and PDGF TK, thereby inhibiting cell proliferation and induction of apoptosis	Oedema (fluid retention) nausea, rash and musculoskeletal pain	CML CP-400 mg/day; CML AP/BC - 600-800 mg/ day; GIST 400-600 mg/day
Dasatinib	CML CP/AP/BC, Both as first line and second line	Multi-targeted TKI affecting BCR-ABL, the SRC family, c-KIT, EPHA2 and PDGFR tyrosine kinases	Myelosuppression, oedema/fluid retention, nausea, fatigue, rarely QTc prolongation	70 mg twice daily
EGFR Inhibitors				
Gefitinib	Locally advanced or metastatic NSCLC	Inhibits intracellular phosphorylation of the EGFR tyrosine kinase	Acneform rash, GI upset (diarrhoea, nausea, vomiting and anorexia) and rarely, interstitial lung disease	250 mg daily
Erlotinib	Locally advanced or metastatic non-small cell lung cancer, metastatic carcinoma pancreas	Inhibits intracellular phosphorylation of the EGFR TK	Gastrointestinal upset (diarrhoea, nausea, vomiting and anorexia), mucositis, acneform rash, fatigue and rarely deep vein thrombosis	150 mg daily for NSCLC 100 mg daily for pancreatic cancer
Cetuximab	Metastatic colorectal cancer and squamous cell carcinoma of head and neck	Binds to extracellular domain of the EGFR	Acneform rash, dry skin, fissuring, malaise, and rarely, interstitial lung disease	Loading dose: 400 mg/ m^2/IV followed by 250 mg/m^2 once every week
HER 2 Inhibitors				
Trastuzumab	Breast cancer over expressing HER2/neu protein (both adjuvant and metastatic setting)	Binds to extracellular domain of the HER2/neu protein	Infusion-related reactions (fever, chills), and cardiomyopathy	Loading dose of 4 mg/kg IV followed by 2 mg/kg once every week
VEGF Inhibitors				
Sunitinib	Metastatic renal cell carcinoma	Inhibits multiple tyrosine kinases including VEGFR 1, 2 and 3; SCF (-KIT); PDGFR and FMS	Hypertension, rash, hand foot syndrome and yellow skin discolouration	50 mg daily for 4 weeks in a 6-week cycle
Bevacizumab	Metastatic colorectal cancer	Recombinant humanised Mab that binds and neutralizes VEGF	Hypertension, proteinuria, impaired wound healing and thromboembolic events	5-10 mg/kg IV every 2 weeks
Raf tyrosine kinase inhibition				
Sorafenib	Advanced renal cell carcinoma	Multi-targeted TKs	Rash, hand foot syndrome, hypertension, fatigue and rarely, thromboembolism	400 mg twice daily

Contd...

Contd...

Drug	Indication	Mechanism of Action	Adverse Effects	Dose
Other Monoclonal Antibodies				
Alemtuzumab	Chronic lymphocytic leukaemia	Anti-CD52 antibody	Hypotension, rash, fever, chills, pancytopaenia and rarely pulmonary fibrosis	Initial dose 3 mg IV, to be increased to 30 mg daily once tolerated. Maintenance dose: 30 mg three times a week
Rituximab	CD20 + NHL	Anti-CD20 antibody	Cytokine release syndrome (Hypotension, fever, chills, bronchospasm, urticaria and angioedema), myelosuppression	375 mg/m^2 IV 3 to 4 weekly
Ofatumumab	Chronic lympocytic leukaemia, follicular NHL	Anti-CD20 antibody	Infusion reactions, progressive multifocal encephalopathy, reactivation of hepatitis B	12 doses administered as follows: 300 mg dose (dose 1), followed 1 week later by 2,000 mg weekly for 7 doses, followed 4 weeks later by 2,000 mg every 4 weeks for 4 doses
Gemtuzumab ozogamicin	Relapsed/refractory acute myeloid leukaemia	Anti-CD33 antibody conjugated with a cytotoxic antitumour antibiotic, calicheamicin	Infusion related reactions VOD cerebral haemorrhage, epistaxis, and rarely, ARDS	9mg/m^2 on day 1 and 15 every 4 weeks

PDGF = Platelet-derived growth factors; CML = Chronic myelogenous leukaemia; GIST = Gastrointestinal stromal tumour; SRC = steroid receptor co-activator; EPHA = Ephrin type A2; ARDS = Acute respiratory distress syndrome; TK = Tyrosine kinase; EGFR = Epidermal growth factor receptor; GI = Gastrointestinal; NSCLC = Non-small cell lung cancer; IV = Intravenous; SCF = Stem cell factor; FMS = McDonough Feline sarcoma virus; NHL = Non-Hodgkin's lymphoma; VOD = Veno-occlusive disease

kinases (TKs) are further classified into receptor or non-receptor tyrosine kinases. Examples of receptor tyrosine kinase include epidermal growth factors (EGFR) (ERB/HER) family members, vascular endothelial growth factor receptors, and platelet derived growth factor receptors. Example of the non receptor tyrosine kinase includes BCR-ABL, c-Kit, and c-Src.

Monoclonal Antibodies

Monoclonal antibodies (MAbs) are targeting agents that recognise the cell surface proteins/receptors as antigens, particularly on the surface of the tumour cells. There are three main classes of MAbs: conjugated, unconjugated, and radioimmunoconjugate. Commonly used targeted therapy, their uses, mechanisms of action, adverse effects, and doses are summarised in **Table 4**.

Unconjugated MAbs directly affect the signalling pathways by inhibiting ligand-receptor interactions. These may also indirectly stimulate host defense mechanism, such as antibody dependent cellular cytotoxicities (ADCC). Examples of unconjugated MAbs include rituximab, trastuzumab, cetuximab, alemtuzumab, and bevacizumab.

Conjugated MAbs are MAbs combined with protein toxins or cytotoxic agents. Examples of conjugated MAbs include gemtuzumab ozagamicin and deninleukin difitox. Radioimmunoconjugates are MAbs in combination with radioisotopes intended to deliver a sterilising dose of radiation to the tumour and include ibritumomab tiuxetan and tositumomab.

MAbs are manufactured from multiple sources of B-lymphocyte (i.e. murine, human, and primate). Murine MAbs are derived entirely from mice. Chimeric MAbs are composed of murine variable regions of the antibody with a constant region derived from human, making 65% to 90% of the agent of human origin. Humanised MAbs consist of variable and constant region derived from humans with complementary determining regions from mice, making approximately 95% of the agent of human origin. Human MAbs are derived entirely from humans.

The United States Adopted Names (USAN) council has developed guidelines for the nomenclature of the MAbs for standardisation purposes. In general, the product source identifiers precede the suffix *–mab*. **Table 5** lists the product source identifiers.

Table 5: Product Source Identifiers

Source	Identifiers
Human	- u -
Mouse	- o -
Rat	- n -
Humanised	- zu -
Pimate	- i -
Chimeric	- xi -

CONCLUSIONS

Development of targeted therapy (molecules) have already made significant impact in the management of certain diseases, e.g. imatinib mesylate, a TKI, is now the first-line of drug in the management of all phases chronic myeloid leukaemia. Similarly, development of immunomodulators, e.g. thalidomide and lenalidomide and immunomodulators have revolutionised the management of multiple myeloma. The EGFR inhibitors for non-small cell lung cancer, sunutinib for renal cell cancer are other examples which have made significant impact in the management of these cancers. Among monoclonal antibodies, rituximab and trastuzumab have been incorporated along with chemotherapy in the first-line management of B-cell NHL and

Her-2-neu positive breast cancer, respectively. Many more agents are currently under phase-I and II trials are likely to enter in phase-III studies in the coming years. Optimising regimens/schedule with or without concurrent chemotherapy with aim to reduce the toxicities, and the development of resistance are likely to be areas of research in future studies.

21.5 Principles of Radiotherapy

GK Rath

INTRODUCTION

Radiotherapy is defined as the treatment of diseases (mostly malignant) with ionising radiation. It is relatively a new subject as compared to other medical specialties. However, there is no other medical field which had more speedy evolution than radiation oncology.

RADIATION PHYSICS

Radiation therapy produces its effect by depositing the energy in the tissues. The source of radiation can be either radioactive isotopes or high energy X-rays or electrons. The other forms of radiation energy which are relatively less common in use are neutrons, protons, and heavy ions. Radioactive isotopes occur naturally and can be generated artificially. Becquerel recognised radioactivity in 1896 and is honoured by having the unit of activity named after him. The activity of a radioisotope decays over time. Its energy spectrum, decay spectrum, and half-life characterise the isotope. A particular isotope may decay via the production of alpha particles or beta particles, through electron capture, internal conversion, or a combination of these reactions. The commonly used radioactive isotopes are enlisted in **Table 1**, along with their physical characteristics.

The basis of radiation therapy is the interaction of ionising particles (X-rays, γ rays, or electrons) with tissues at the molecular level. This interaction depends on the energy created by the production of secondary charged particles, usually electrons, which can break chemical bonds and inflict cellular injury. The interaction of a photon beam with matter results in the attenuation of the beam. Five major types of interactions typically occur, namely, coherent scattering, photoelectric effect, Compton scattering, pair production, and photo-disintegration. The particular type of interaction is related to photon energy. In radiation therapy, the photoelectric effect, Compton effect, and pair production are of interest, with the Compton effect being the predominant interaction.

Table 1: Radioactive Isotopes with their Characteristics

Isotope	Half-life	Energy (MeV)
Ra-226	1600 years	0.047 to 2.45 (0.83 avg)
Co-60	5.26 years	1.17,1.33
Cs-137	30 years	0.662
Ir-192	74.2 days	1.36 to 1.06 (0.38 avg)
I-125	60.2 days	0.028 avg

Photoelectric effect involves the interaction of the photon with the tightly bound inner electrons and is proportional to the cube power of the absorbing matter's atomic number. This interaction is responsible for the different radiographic densities seen on diagnostic radiographs.

Compton effect involves interaction with outer electrons that are bound more loosely. This effect is related to electron density and, therefore, results in much more uniform tissue absorption than lower energy photons. In radiation therapy, Compton effect predominates; therefore, the contrast observed on therapy port films is inferior to diagnostic radiographs.

Pair production involves interaction of the photon with the atomic nuclear electromagnetic field. This interaction becomes significant at high energies (>10 MeV) and is proportional to the atomic number of the absorbing matter.

UNITS OF RADIATION

The dose of radiation absorbed correlates directly with the energy of the beam. Therefore, an accurate measurement of absorbed dose is critical in radiation treatment. The deposition of energy in tissues results in damage to DNA and diminishes or eradicates the cell's ability to replicate indefinitely. The basic unit of radiation absorbed dose is the amount of energy (Joules) absorbed per unit mass (kg). This unit, known as the gray (Gy), has replaced the unit of rad used in the past (100 rads = 1 Gy; 1 rad = 1 cGy).

In order to measure dose in a patient, one must first measure the ionisation produced in air by a beam of radiation. This quantity is known as exposure. One can then correct for the presence of soft tissue in the air and calculate the absorbed dose in grays. The dose absorbed by tissues due to these interactions can be measured and plotted to form a percentage depth dose curve. As energy increases, the penetrative ability of the beam increases and the skin dose decreases.

RADIATION BIOLOGY

The exact mechanism of cell death due to radiation is still an area of active investigation. Double-stranded breaks of nuclear DNA is the most important cellular effect of radiation. This breakage leads to irreversible loss of the reproductive integrity of the cell and eventual cell death.

Radiation damage can be directly ionising; however, in clinical therapy, damage is most commonly indirectly ionising via free-radicals produced from the radiolysis of cellular water.

Radiation can also affect the processes of the cell cycle necessary for cell growth, cell senescence, and apoptosis (programmed cell death). Many of these processes are only now beginning to be understood and manipulated to make radiation therapy more effective.

The therapeutic mechanism for radiation is based on the intrinsic ability of cells to repair damage and the ability of the radiation oncologist to take advantage of any geometric separation between the malignant and non-malignant tissues.

A logarithmic curve of survival versus dose characterises cell survival after exposure. The curve forms an initial shoulder followed by a logarithmic decline in survival, which varies with the dose. Sublethal damage, which must be overcome with each

fraction of radiation therapy, is thought to cause the initial shoulder. Repeated small doses of radiation are less damaging to a sensitive cell than a single fraction of equivalent total dose. Manipulation of the cellular environment can alter the shape of the survival curve.

In addition to the intrinsic cellular radiosensitivity, cell survival is found to be related to oxygen concentration, position of the cell in the mitotic phase, and dose rate. These features are responsible for the 4 *R*'s of radiobiology, viz. repair, redistribution, repopulating, and reoxygenation.

CLINICAL USE OF RADIATION

Radiation therapy is administered to those cancers where there is a selective ability for the radiation to destroy cancer cells while allowing the adjacent normal cells to repair themselves from injury. Cancer cells vary in their sensitivity to destruction by radiation. This sensitivity depends on the origin of the cancer. For example, skin cancer is generally more sensitive, meaning more easily destroyed, than a cancer originating in the brain.

In addition, cancer cells in the same tumour may vary in their sensitivity to radiation depending on their location in the mass. Generally, the outer areas of the tumour are more sensitive. This is related to the amount of oxygen reaching the cancer. The peripheral regions are better oxygenated and are destroyed more easily than tumour cells at the centre. Some cancers, such as melanoma, are usually resistant to radiation therapy and little or no benefit is achieved by using it.

The goal of radiation can be first, curative or radical in which radiation therapy is given with the intent of eradicating the tumour; second, palliative, that is, to alleviate or reduce symptoms of pain; and third, adjuvant where radiation is delivered after the primary treatment like surgery to reduce the risk of tumour recurrence.

There are basically two types of radiation treatment; external beam radiation therapy (EBRT) and brachytherapy. A patient may receive one or the other, or a combination of both EBRT or teletherapy which signifies treatment of patient when the source of radiation lies outside the body. The various equipments of EBRT are linear accelerator (**Figure 1**), telecobalt unit, etc. The treatment with EBRT spares the skin (skin sparing effect). Linear accelerator is preferred for the treatment of deep seated tumours like thoracic tumours, pelvic tumours, etc. Telecobalt unit is the backbone of any radiotherapy department in developing countries like India because it is cost-effective and requires low maintenance cost. Modern sophisticated equipments like stereotactic radiotherapy (X-knife) and stereotactic radiosurgery (gamma knife) are expensive machines but very useful in selective patients.

Figure 1: Linear accelerator.

EBRT treatment with conventional fractionation is done once a day with 1.8 to 2.0 Gy, 5 times a week and lasts for about 5 to 7 weeks. Majority of the tumours require EBRT doses in the range of 50 to 70 Gy (**Table 2**). It is a painless and non-invasive procedure. Inoperable patients can be treated with reasonably good results. Radiotherapy can be given on emergency basis in certain situations like severe bleeding from cervical cancer, spinal cord compression, etc. The irradiated organs are preserved in contrast to the surgical treatment. The treatment can be carried out on an outpatient department basis. Disadvantages of radiotherapy include prolonged treatment and associated toxicity in some patients.

Table 2: Radiation Dose Schedules for Different Tumours

Tumour	Radiotherapy Doses (Gray [Gy])
Head and neck	60 to 70
Cervix	80 to 90
Breast	50 to 60
Seminoma	25 to 35
Lymphomas	25 to 45
Brain	50 to 60
Lung	50 to 60
Wilm's tumour	10 to 20
Soft tissue sarcoma	60 to 70
Oesophagus	60 to 65
Ewing's sarcoma	45 to 55
Anal canal	50 to 55

Brachytherapy is the treatment with radioactive material implanted into the tumour bearing area. The various radioactive materials used are Iridium-192, Cesium-137, Iodine-125 and Palladium-103, etc. Currently, the brachytherapy treatment is performed with the help of remote afterloading units (**Figure 2**) where there is no risk of radiation exposure to the staff. Brachytherapy has the advantage of delivering high dose of radiation in shorter time simultaneously sparing the surrounding normal structures. The usual treatment with low dose rate brachytherapy takes about 3 days and requires one or such fractions. On the other hand, high dose rate brachytherapy treatment is delivered in minutes but multiple fractions (average 3 to 7 fractions) are required. The tumours where brachytherapy is preferred are cancers of cervix, endometrium, oesophagus, head and neck and chest wall tumours.

EFFECTS OF RADIATION ON NORMAL TISSUES

Radiation effects on normal tissues are divided into acute and chronic effects. Acute effects occur during the course of therapy and during the follow-up period (approximately 2 to 3 weeks after the completion of a course of irradiation). Chronic effects can manifest after 6 months to 1 year of the treatment. Every tissue or organ tolerates a certain dose of radiation beyond which it shows significant deleterious

Figure 2: Remote afterloading brachytherapy unit.

effects. **Table 3** shows the radiation tolerance of different organs in the human body.

The mucous membranes of the oral cavity and the oropharynx respond early to fractionated radiation. Erythema is often evident after 1 week of treatment at conventional doses. This condition progresses over the next few weeks through various stages of mucositis, ranging from small patches to confluent or even ulcerated areas. Healing begins while the patient is still undergoing treatment but may continue for several weeks after the radiation is completed.

Table 3: Normal Tissue Tolerance of Various Organs to Fractionated Conventional Radiotherapy

Organ	Radiation Tolerance (Gy)
Kidney	23
Femoral head	52
Spinal cord	45
Brainstem	50
Eye lens	10
Lung	30
Parotid	32
Heart	40
Liver	30

Loss of taste is a common acute effect of radiation treatment in the head and neck area. Taste loss begins early and progresses rapidly during the 3rd to 5th week of treatment. Patients may report diminished acuity, odd sensation, or complete absence of taste. Xerostomia is often present and exacerbates this loss of taste. This condition is often accompanied by loss of appetite and weight loss. Recovery of taste is a slow and, frequently, an incomplete process.

The major salivary glands (i.e. parotid and submandibular glands) are responsible for nearly 80% of salivary production. The parotid glands primarily consist of serous acini, while the submandibular glands produce mucinous and serous secretions. The minor salivary glands, which are distributed throughout the oral mucosa, produce mostly mucinous secretions. The loss of salivary function is usually complete after modest doses of radiation to the parotid glands. The basal flow rates correlate with the response to radiation therapy. With 40 to 60 Gy, fewer than 20% of patients have a measurable salivary flow. For patients receiving fewer than 30 Gy, some function may return after 6 to 12 months. However, at dose levels exceeding 50 Gy, xerostomia usually is irreversible. Dry mouth is probably the most common problem for patients who receive therapeutic doses of radiation. Numerous approaches have been tried to address this problem. Pilocarpine 5 mg three times a day has been shown to stimulate residual salivary function. Some patients use artificial saliva substitutes, but most patients find them inadequate.

Skin effects, which were at one time dose-limiting, are rarely a problem. While erythema is common after several weeks of radiation, severe skin reactions, such as those observed in the orthovoltage era, are uncommon. Even with megavoltage treatment, skin tanning, and dry desquamation can occur. The addition of certain chemotherapeutic drugs can enhance skin and other effects.

The late effects of radiation can be a source of ongoing morbidity from a course of radiation therapy. Just as with the acute effects, the chronic effects are related to site, dose, volume, and time. Other therapies, such as surgery and chemotherapy, can increase the probability and severity of radiation-related morbidity.

RECENT ADVANCES IN RADIOTHERAPY

There have been significant advances in radiotherapy in the recent years. Delivery of radiotherapy has become very precise and has moved from conventional planning approach to more and more conformal approaches. The main advantages of these are that we are able to give more and more dose to the tumour, at the same time limiting the dose to the normal structures. Intensity modulated radiotherapy is a type of conformal radiotherapy where we can modulate the intensity of the radiation within the beam leading to a better dose distribution inside the tumour. Image guidance for delivering radiation has come into a routine practice now which is called image guided radiotherapy. This technique helps to rectify errors of positioning of the patient or due to organ motion. There have also been tremendous advances in the stereotactic approach in the delivery of radiation. In stereotactic radiotherapy we deliver fractionated radiation to a target to ablate the tumour. In stereotactic radiosurgery which is done by gamma-knife or a linear accelerator, single sitting of ablative dose is given in a sterotactic set up. Stereotactic body radiotherapy (SBRT) is a new approach in treating very small lesions anywhere in the body. SBRT is highly promising and has the potential to replace surgery for early stage lung cancers.

21.6 Head and Neck Cancers

VP Gangadharan

INTRODUCTION

Head and neck cancers, a heterogeneous group of neoplasms involving mucosal surfaces of the lips, tongue, oral cavity, pharynx, nasopharynx, hypopharynx, larynx, and paranasal sinuses, are typically squamous cell carcinomas and have distinct clinical presentations and prognosis and management. Patients who present with early stage disease (stage I and II) are treated with radiation therapy (RT) or surgery. Stage III or stage IV disease requires a multidisciplinary approach with chemotherapy, radiation, and surgery.

EPIDEMIOLOGY AND AETIOLOGY

Head and neck cancers are among the 10 most frequent cancers in the world. These constitute 12% of male and 7% of female cancers in the developing world and 7% of male and 2% of female cancers in the developed world. The age-standardised rates of head and neck cancers in 1990, in males exceeds 30 per 100,000 in regions of France, Hong Kong, India, Central and Eastern Europe, Spain, Italy, Brazil and among US Blacks. High rates (more than 10 per 100,000) in females are found in India, Hong Kong, and Philippines. Head and neck cancers are amongst the top five cancers in almost all parts of India.

Smoking, particularly *bidi* smoking, alcohol drinking, and chewing betel quid with tobacco are main aetiologic factors for head and neck cancers in India. Epstein-Barr virus infection is associated with nasopharyngeal carcinoma which occurs endemically in some countries of the Mediterranean and Far East. Incidence of second primary cancers in upper aerodigestive tracts of patients with head and neck cancers is about 5% at the time of diagnosis and 20% subsequently. The multiple synchronous and metachronous neoplasms suggest that the entire respiratory mucosa is predisposed to carcinogens, so is at risk of development of pre-malignant or malignant lesions (so called field defect).

MOLECULAR PATHOLOGY

Mutations in tumour suppressor genes (commonly p53 gene) and alterations involving chromosomes 3, 9, 13, and 17 have been identified in both pre-malignant and malignant head and neck cancers. Amplification of oncogenes is less common.

CLINICAL PRESENTATION AND STAGING

The manifestations vary according to the stage and primary site of the tumour. Oral cavity cancers present as non-healing ulcers or painful lesions. White (leucoplakia) or red (erythroplakia) plaques may represent dysplasia, hyperplasia or carcinoma *in situ* and must be differentiated from candidiasis (can be wiped off) or lichen planus (white lines related to denture irritation). Tumours at the base of tongue or oropharynx cause alteration in speech and tongue mobility. Cancers of nasopharynx, oropharynx, or hypopharynx rarely show early symptoms. Hoarseness of voice may be an early symptom of laryngeal cancer. High-risk patients (>40 years of age, history of tobacco or alcohol abuse) with non-specific manifestations in head and neck need thorough otolaryngologic examination, particularly if symptoms persist longer than 2 to 4 weeks.

Advanced head and neck cancers cause pain, bleeding, otalgia, serous otitis, sinusitis, nasal obstruction, cranial neuropathies, dysphagia, odynophagia, trismus, decreased tongue, mobility, fistulas, skin involvement and massive unilateral and bilateral cervical lymphadenopathy.

Physical examination includes inspection of all visible mucosal surfaces and palpation of the floor of mouth, tongue, and neck. All visible lesions should be biopsied and the patient should have complete otolaryngological examination.

Staging work-up documents the extent of disease and excludes coincident second primary cancers or pre-malignant lesions in upper aerodigestive tract. It includes endoscopic examination of nasopharynx, larynx, hypopharynx, cervical oesophagus and proximal trachea with multiple biopsies of high-risk areas (nasopharynx, pharyngeal tongue, tonsillar fossa, and pyriform sinus) particularly in patients without obvious primary tumour. A chest radiograph and a computed tomography (CT) or magnetic resonance imaging (MRI) from the base of the skull to the thoracic inlet can be performed. Patients with cervical lymphadenopathy and no detectable primary should undergo excision biopsy of suspected lymph nodes if fine needle aspiration cytology fails to reveal the tumour.

TNM staging system of the American Joint Committee on Cancer is used to classify head and neck cancers. This classification varies according to the specific anatomic subsites. Head and neck cancers have a high tendency to spread to adjacent sites and to the cervical lymph nodes. Distant metastases are found in less than 10% of patients at initial diagnosis.

TREATMENT

The choice of treatment depends not only on stage but also on the specific site of the disease. It is important to maintain adequate nutrition, to treat opportunistic infections and to have adequate dental care and hygiene during the treatment.

Localised Disease

Less than one-third of the patients present with early lesions without detectable lymph node involvement or distant metastases. Such cases are treated with curative intent by surgery or RT. Generally, RT is preferred for laryngeal cancers to preserve voice, and surgery is preferred for oral cavity lesions to avoid long term-complications of RT, such as xerostomia and dental decay. Overall, 5-year survival rate is 60% to 90%.

Most head and neck cancers (except cancers of vocal cord, paranasal sinuses, lip, and salivary gland) have high incidence of occult cervical node metastases; therefore require treatment to ipsilateral neck either with RT or cervical lymph node

dissection (radical, modified radical or selective), even if nodes are not clinically involved.

Radical RT dosage is 70 Gy in 35 fractions over 7 weeks. Brachytherapy can be used as a definitive treatment for early stage tumours or combined with external beam RT in more advanced lesions in selected tumours (tongue, floor of mouth, tonsil, and nasopharynx) with excellent results.

Loco-Regionally Advanced Disease

Combined modality treatment including surgery, RT, and chemotherapy can produce 5-year survival in 30% to 40% patients with large primary tumours or lymph node metastases. Sequencing of treatment may vary. Chemotherapy may be administered before (neoadjuvant or induction), during (concurrent) or after (adjuvant) RT or surgery.

Induction chemotherapy

Induction chemotherapy followed by definitive RT in chemotherapy-responders is indicated for patients with cancer of the larynx and hypopharynx who wish to preserve their larynx. This strategy allows for tumour reduction and organ preservation in almost half of survivors. Compared to surgery plus RT, this modality results in decreased frequency of subsequent distant metastases. However, survival is not improved.

Intravenous cisplatin 100 mg/m^2 on day 1 and 5-fluorouracil (5-FU) (1,000 mg /m^2 per day) as continuous intravenous infusion for 5 consecutive days (days 1 to 5), repeated every 3 weeks, is the most common regimen. The overall response rate is 85% with a 40% complete remission rate; two-thirds of clinical complete remissions are found to be in pathologic complete remissions in resected specimens. Taxanes (paclitaxel or docetaxel) can be added to PF-based induction therapy to improve survival, minimise toxicity, and increase the rate of organ preservation. Response varies by site, with the larynx and nasopharynx being most responsive and oral cavity the least responsive.

Adjuvant chemotherapy

Adjuvant chemotherapy, given after the patient is rendered disease-free, may benefit selected subset of patients with high risk of local recurrence (positive resection margins, more than 1 positive lymph nodes, extracapsular spread of tumour).

Concurrent chemoradiotherapy

The rationale for simultaneous chemoradiation is based on experimental evidence of synergism between chemotherapy and RT to kill tumour cells. Compared with sequential chemotherapy and RT, concomitant chemotherapy plus RT is associated with increased toxicity, and is considered for patients with good performance status. Meta-analysis of randomised trials in head and neck cancers has shown survival benefit of 8% at 5 years for patients receiving concomitant chemotherapy with 5-FU and RT.

Targeted therapy

Most research in this area is focused on epidermal growth factor receptor (EGFR) inhibitors. Cetuximab (anti-EGFR antibody) in combination with radiation has been approved in treatment of patients with locally advanced head and neck cancers.

Recurrent or Metastatic Disease

These patients are generally treated with palliative chemotherapy; response rates average 30% to 50% with duration of response only 3 months. Patients generally die within 6 months. Drugs like methotrexate, 5-FU, cisplatin, paclitaxel, and docetaxel are used either as single or in combination.

Various treatment options for head and neck cancers are summarised in **Figure 1**.

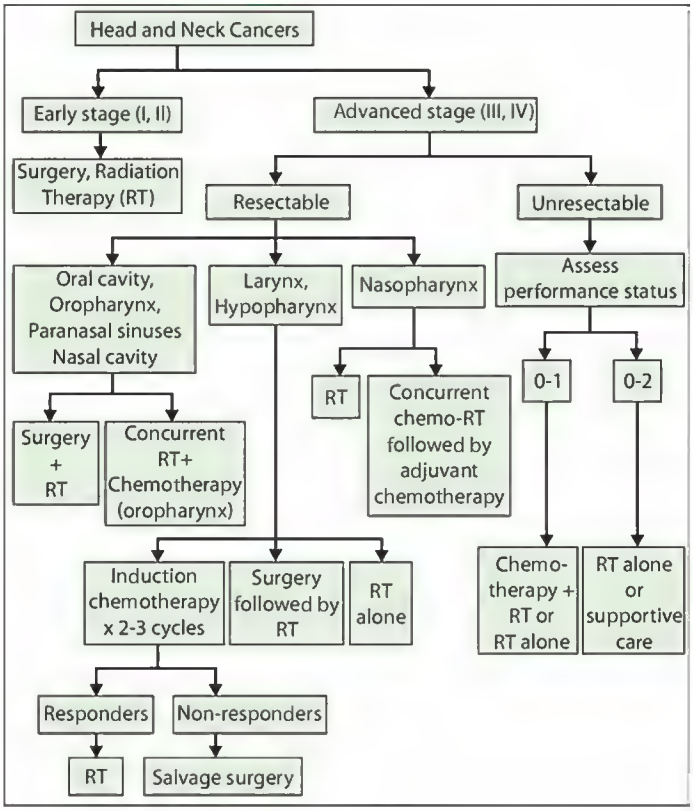

Figure 1: Treatment of squamous cell carcinoma of head and neck.

Adverse Effects of Treatment

Radical surgery results in cosmetic and functional deformity and speech impediment. Acute sequelae of RT include mucositis and dysphagia; chronic sequelae include xerostomia, loss of taste, cataract, mandible necrosis, neck fibrosis, and second malignancies. Chemotherapy complications vary with the regimen but usually include myelosuppression, stomatitis, diarrhoea, nausea, vomiting, and nephrotoxicity (with cisplatin). Post-treatment rehabilitation should be emphasised.

SALIVARY GLAND TUMOURS

The parotid tumours account for 80% of salivary gland neoplasms in adults and about 75% of these are benign. In contrast, nearly half of the tumours arising in submandibular or minor salivary glands are malignant including mucoepidermoid, adenoid cystic or adenocarcinoma. Benign tumours are usually treated with surgery while invasive tumours need both surgery and RT. Malignant tumours may recur regionally; distant metastases may occur as late as 10 to 20 years post-treatment. For metastatic disease, chemotherapy (doxorubicin alone or in combination with cisplatin) is given with palliative intent.

21.7 Breast Cancer

Vinay H Deshmane

INTRODUCTION

The last decade has seen rapid advances in our understanding of breast cancer, facilitated by numerous clinical trials, and an ever expanding knowledge of the molecular changes associated with malignancy. More importantly, these advances have been translated into clinical practice. Tumours can now be classified on the basis of their molecular signatures, which are being used to determine prognosis and treatment. There is an increasing array of drugs available for treatment and newer surgical techniques to enable breast preservation. This increased range of options has resulted in an individualised approach to the treatment of breast cancer.

EPIDEMIOLOGY AND AETIOLOGY

Breast cancer is common in the West where women have a lifetime risk of 1:8. In India, the lifetime risk is lower although the incidence is rising. In 2008, the Indian Cancer Society population based registry recorded 100,000 new cases, and 52,000 deaths due to breast cancer. The lifetime risk in the city of Mumbai has increased from 1:27 a few years ago, to 1:22. The urban-rural divide persists with cervical cancer being the commonest female cancer in rural areas. However, in the cities of Mumbai, Delhi, Chennai, and Bangalore breast cancer has overtaken cervical cancer to become the commonest cancer in women. The cause of this change remains unknown, and has loosely been attributed to a 'Western lifestyle'. However it may be attributed to increasing awareness, access to mammography and an economically increasing middle-class, with access to medical care.

Various factors incriminated to increase the risk of breast cancer are presented in **Table 1**. The other factors are age, sex, lifestyle (Western lifestyle), high fat diet, and increase in body mass index.

Table 1: Risk Factors for Breast Cancer Development

Factors	Relative Risk
BRCA mutation	3.0 to 7.0
Breast density	1.8 to 6.0
ADH on prior biopsy	3.7
Bone density	2.7 to 3.5
Age at first birth	1.9 to 3.5
Mother or sister with breast cancer	2.6
Age at menopause	2.0
Prior benign biopsy	1.7
Postmenopausal BMI	1.7
Age at menarche	1.4
Alcohol	1.4
HRT	1.2 to 1.4
OCP	1.2 to 1.4

BRCA = Breast cancer gene; ADH = Atypical ductal hyperplasia; BMI = Body mass index; HRT = Harmane replacement therapy; OCP = Oral cantraceptive pills.

A past history of a benign breast biopsy may also be associated with an increased risk of breast cancer. In the biopsy, changes in cell morphology and presence of proliferation are pointers to the risk.

PATHOLOGY

The majority of breast cancers start from the ductal epithelium, which extends from the nipple to the terminal duct unit situated in the breast lobule. The major histological subtypes are ductal and lobular carcinoma. The classification is shown in **Table 2**.

All invasive carcinomas with the exception of medullary carcinoma are graded (**Table 2**) using the Nottingham combined histologic grade (Elston-Ellis modification of Scarff-Bloom-Richardson grading system) based on morphological features (tubule formation, nuclear pleomorphism, and mitotic count). The grade of the tumour is determined by, assigning a value of 1 (favourable) to 3 (unfavourable) for each feature, and adding together the scores for all the three categories.

Table 2: Histopathologic Types and Grades

WHO classification of breast cancer	
Non-invasive carcinoma	
Ductal carcinoma *in situ*	
Lobular carcinoma *in situ*	
Invasive carcinoma	
Invasive ductal carcinoma	
Invasive lobular carcinoma	
Mucinous carcinoma	
Medullary carcinoma	
Papillary carcinoma	
Tubular carcinoma	
Adenoid cystic carcinoma	
Secretory (juvenile) carcinoma	
Apocrine carcinoma	
Carcinoma with metaplasia (metaplastic carcinoma)	
Inflammatory carcinoma	
Other (specify)	
Paget's disease of the nipple	
The Nottingham combine histopathologic grade (G)	
GX	Grade cannot be assessed
G1	Low combined histologic grade (favourable)
G2	Intermediate combined histologic grade (moderately favourable)
G3	High combined histologic grade (unfavourable)

More recently a classification based on molecular signatures has been proposed (**Table 3**). Gene expression profiling studies have identified four major subtypes, viz. luminal A, luminal B, HER2, and basal-like. These subtypes reflect clinical features, response to therapy and treatment outcome. Luminal A and B express hormone receptors, account for 70% of the breast cancers and have a good prognosis, although luminal B are usually higher grade and may express human epidermal growth factor receptor

2 (HER2). They respond to hormone treatment (A better than B) and have a variable response to chemotherapy (B better than A). HER2 cancers (15%) have a high HER2 receptor expression and are generally ER/PR negative. They tend to respond to trastuzumab and anthracycline based chemotherapy and are associated with a poor prognosis. Basal-like breast cancers are associated with the worst prognosis. These demonstrate a high expression of basal epithelial genes, basal cytokeratins, and low expression of estrogen receptor, progesterone receptor, and HER2. These constitute 15% of the breast tumours, are often referred to as 'triple negative' tumours, have a poor prognosis and do not respond to either hormonal treatment or trastuzumab. The basal-like phenotype is commonly seen with BRCA-1 associated breast cancers. Platinum-based chemotherapy is being increasingly used to treat this subset of cancers.

Table 3: Molecular Classification of Breast Cancer

Based on gene expression profiles	
Luminal A	
Luminal B	
HER2	
Basal - like	
Based on immunohistochemical markers (ER, PR and HER2)	
Luminal (A and B)	ER/PR +ve; HER2 –ve
HER2	ER/PR –ve; HER2 +ve
Basal-like	ER –ve, PR –ve, HER2 –ve (Also called triple negative)

ER = Oestrogen receptor; PR = Progesterone receptor; HER2 = Human epidermal growth factor receptor 2.

Although classifying breast tumours based on gene expression is of interest, a more practical classification is based on the presence of immunohistochemical markers, viz. oestrogen receptor, progesterone receptor, and HER2. These are used as surrogate markers to reflect the molecular subtypes on gene expression. Luminal (A and B) are ER/PR positive and HER2 negative, HER2 cancers are ER or PR negative and HER2 positive, while basal-like are ER, PR and HER2 negative.

NATURAL HISTORY OF BREAST CANCER

Breast cancers may grow at different rates. However on an average, these are considered to be slow growing. It is estimated that by the time a breast cancer lesion assumes the size of 1 cm it has been in the body for a period of 7 to 10 years. It spreads by direct extension to surrounding tissue, via lymphatics and by the blood stream. The ipsilateral axillary lymph nodes are the commonest site of involvement. Other sites of involvement include the internal mammary lymph nodes especially in medial quadrant tumours and the supraclavicular nodes. Distant organs commonly involved are the lungs, liver, brain, and bones.

CLINICAL FEATURES

The commonest presentation is that of a lump in the breast, frequently situated in the upper outer quadrant of the breast. It may be associated with skin changes, which are subtle to begin with and become more pronounced as the lesion grows. In late disease, the classical appearance of 'peau de orange' is noted. Other symptoms include a vague lumpy area, breast pain, nipple discharge, nipple retraction, nipple eczema, swelling of the breast and a lump in the axilla. On occasion, patients may present with symptoms suggestive of disseminated disease, such as weight loss, bone pains, ascites or headache and vomiting.

DIAGNOSIS

The diagnosis of breast cancer rests on a detailed history and examination. Confirmation is by pathological evaluation. This may be easily achieved by fine needle aspiration cytology (FNAC). FNAC provides a cytological diagnosis but is unable to differentiate between non-invasive and invasive cancer. A core needle biopsy or an open biopsy (incisional/excisional) provides adequate tissue for a definitive histopathological diagnosis.

Imaging modalities, viz. mammography, ultrasonography and magnetic resonance imaging (MRI) provide complementary information. Mammography is a soft tissue X-ray of the breast in two directions (mediolateral and craniocaudal). It can detect microcalcifications, which may be the earliest sign of breast cancer and is the modality of choice for breast cancer screening. However, it is known to miss 10% to 15% of all breast cancers. Ultrasonography is used as an adjunct to mammography. It is especially useful in dense breasts and in young women, where mammography is of limited use. However, it is less sensitive than mammography and not recommended as a screening modality.

Magnetic resonance imaging is the most sensitive technique to detect breast cancer. It is useful in ruling out local recurrence after breast conserving treatment (BCT) and in evaluation of indeterminate masses. It is the preferred modality for screening high-risk women and is used to rule out multicentric disease in patients considered for BCT.

Triple Diagnosis

To minimise mistakes, the concept of 'triple diagnosis' is used in the diagnosis of breast cancer. Based on a review of clinical findings, fine needle aspiration and imaging studies confirmed that the diagnosis of cancer is only made if all three modalities are definitely indicative of the presence of breast cancer. If there is a lack of complete agreement between all the three components, then histological proof (core biopsy/incisional biopsy/excisional biopsy) should be obtained before a definitive diagnosis of breast cancer can be made.

Staging

Following diagnosis, the stage of the disease is determined by investigations, such as serum alkaline phosphatase, liver enzymes, an ultrasound evaluation of the liver, and a chest X-ray. A CT scan of thorax and abdomen and an isotope bone scan are indicated in selected patients. A PET scan may also be performed in individualised cases, however, its routine use is not recommended at the moment. Current recommendations suggest clinical staging with mammography and liver function tests, based on which patients are classified into low risk and high risk for occult metastases and locally advanced breast cancer. Further investigations are advised on an individualised basis.

The Manchester system and the TNM system (Tumour, Node and Metastases) staging system [American Joint Committee on Cancer (AJCC) classification] are used to stage the disease (**Table 4**).

MANAGEMENT

Management of breast cancer is based on the stage of the disease. The overall scheme is determined on whether the disease is early

and localised to the breast and axillary lymph nodes (loco-regional disease/operable cancer), extensive local disease (locally advanced breast cancer [LABC]) or associated with visceral/bony metastases. Treatment is multi-disciplinary and based on a combination of local treatment (surgery and radiotherapy) and systemic treatment (chemo-, hormone, and targeted therapy).

Table 4: Staging of Breast Cancer (Manchester and TNM Classification)

	T		N		M
Manchester Stage	**Tumour Grade**	**Clinical Extent (cm)**	**Node Grade**	**Clinical Extent**	**Distant Metastases**
TIS	Tis	No palpable tumour	N0	No nodal metastases	M0 = no known distant metast-ases

EARLY BREAST CANCER/ OPERABLE BREAST CANCER

The aim of treatment is to cure, control the disease in the breast and axilla, and conserve form and function.

In early disease, surgery with or without adjuvant radiation therapy is adequate for local control of the disease. If the primary tumour size is small there is a choice of surgical procedures, viz. BCT or modified radical mastectomy (MRM). The extent of surgery whether BCT or MRM is based on a detailed discussion of the advantages and disadvantages with the patient. Both approaches result in comparable results in terms of local and systemic control resulting in equal long-term survival. Data from breast conservation trials have confirmed BCT to be safe in selected patients.

Surgery

Modified radical mastectomy consists of removal of the entire breast with lymph nodes in the axilla. The extent of lymph node dissection may vary from complete clearance to less extensive procedures. More recently, the concept of sentinel lymph node biopsy has been introduced. However, this should only be undertaken in specialised centres.

Breast conservative treatment (BCT) consists of a wide excision of the breast lump with negative margins and an axillary dissection (in continuity or through a separate incision). Every patient undergoing BCT is advised adjuvant radiation therapy to the breast, which is usually administered for a period of 6 weeks. Shorter durations of radiation therapy, as well as intraoperative radiation therapy are being evaluated and should be considered experimental at the moment.

Oncoplastic surgery refers to the integration of plastic surgery techniques with excisional surgery. It encompasses minor techniques to maintain aesthetic breast shape and size following lump excisions, to reconstructions following mastectomy.

Radiation Therapy

This is administered in daily fractions to the breast ± regional lymph node basin. The usual dose is 50 Gy in the form of external radiation (with or without a boost to the local tumour bed). Indications for post-operative radiotherapy include all patients undergoing BCT and certain patients undergoing MRM, viz. large primary lesions greater than 5 cm, multiple involved axillary lymph nodes and those with poor prognostic features in the primary lesion, viz. lymphovascular invasion, high-grade lesions.

Systemic Treatment

Systemic therapy is decided on the risk of developing recurrent disease. The risk is calculated on the basis of age, menopausal status, tumour characteristics (size, grade, lymphatic invasion/ vascular invasion, margins of excision), lymph node status (number of positive nodes, extra-nodal spread), hormone receptor status of the primary lesion (oestrogen, ER and progesterone, PgR receptor status) as well as the epidermal growth factor receptor Cerb B2 (Her2 neu) status. Computerised programmes (*Source*: www.adjuvant.com) which can estimate the risk of failure are available to guide clinical decision making.

All patients who have a primary tumour which is greater than 1 cm in size and a tumour grade greater than 1 are advised some form of systemic treatment. Systemic therapy may be in the form of chemotherapy, hormone therapy, targeted therapy or a combination of these. 'Oncotype Dx' and 'Mammaprint' are molecular profiling tests which classify patients into high risk,

intermediate risk, and low risk of recurrence categories with the aim of individualising treatment decisions.

Chemotherapy

Chemotherapy is administered at 3 weekly intervals. It is usually multi-drug and multi-cycle. The common adjuvant regimen used is FEC (5-fluorouracil, epirubicin, and cyclophosphamide). Taxol is increasingly used for aggressive disease. Chemotherapy usually consists of 6 cycles; however, there are alternative regimens that utilise 4 and 8 cycles. Other dose dense and dose intensive regimens are also available.

Hormone Therapy

Hormone therapy is considered in hormone receptor positive tumours. Pre-menopausal women are advised tamoxifen 20 mg per day and post-menopausal women either tamoxifen (20 mg) or one of the aromatase inhibitors, e.g. anastrozole 1 mg per day, letrozole 2.5 mg per day, exemestane 25 mg per day. Hormone therapy is advised for a period of 5 years.

Surgical or medical oophorectomy using [luteinising hormone-releasing hormone (LHRH) agents] provides another avenue of treatment in premenopausal women who are hormone receptor positive. An oophorectomy may be combined with tamoxifen or an aromatase inhibitor to provide 'complete receptor blockade'.

Targeted Therapy

Targeted therapy in the form of monoclonal antibody to the epidermal growth factor receptor (EGFR, trastuzumab) may also be added as adjuvant treatment in patients who overexpress the Cerb B2/HER2 neu receptor. The treatment is recommended for a period of 1 to 2 years at 3 weekly intervals.

During chemotherapy and targeted therapy, it is essential to monitor patients carefully, as there is significant toxicity associated with these agents.

LOCALLY ADVANCED BREAST CANCER

The aim of treatment is to control micrometastatic disease and to downstage the size of the primary lesion to increase cure rates and to decrease the extent of local surgical procedures. This is achieved by systemic treatment. Both chemotherapy and primary hormone treatment are associated with excellent response rates. Following downstaging of the disease, surgery is undertaken to optimise local control. This is followed by further systemic treatment (chemo-/hormonal/targeted therapy) and radiotherapy.

An important development has been the feasibility of breast conservative surgery in patients who respond well to systemic therapy. Numerous studies have demonstrated that it is safe to offer breast conservation to patients whose tumours have adequately decreased in size following primary systemic therapy. However, the option should be carefully discussed with the patient, and if there is any doubt, it is probably better to proceed with a mastectomy.

METASTATIC BREAST CANCER

In the presence of metastasis (visceral or bone involvement) the primary modality of treatment is systemic (chemotherapy or hormonal therapy) as the aim is to control disseminated disease. The accepted practice is to start with systemic chemotherapy. However, recent data indicate that hormonal treatment may be effective in carefully selected post-menopausal women who are strongly hormone receptor positive. Once the metastatic disease is adequately controlled, attention is directed towards control of the disease in the breast. Treatment options include mastectomy or breast conservation in selected cases, viz. small primary lesion presenting with metastases. If the mastectomy is associated with a loss of skin cover, it may be accompanied by reconstructive measures. Radiation therapy is administered to patients with extensive local disease and all patients who undergo breast conservation.

Palliative radiation therapy to sites of bony metastases is useful in controlling the disease. Bisphosphonates, viz. zoledronic acid infusions are also administered at regular intervals for control of skeletal symptoms and to prevent fractures. Surgery may be indicated for stabilisation of pathological fractures or vertebral collapse.

PROGNOSIS

The prognosis of breast cancer does not depend on its chronological age but on its metastatic potential. A range of factors including tumour size grade, receptor status, proliferation markers and oncogene product measurements are assessed. Microarrays are used to prognosticate breast tumours into high, intermediate and low risk, based on their genetic profiles. The best clinical indicators of prognosis are lymph nodal status and tumour size.

Survival ranges from 80% to 90% at 10 years for stage I disease, 60% to 70% for stage II, 40% to 55% for stage III, and 10% to 20% for stage IV disease.

HIGH-RISK STATES AND BREAST CANCER PREVENTION

Women who are carriers of BRCA 1 and 2 mutations, or who have a family history consistent with genetically transmitted breast cancer are considered to be at a higher risk than the general population. Presence of lobular carcinoma *in situ* or atypical hyperplasia in a breast biopsy is also considered as an indicator of a high-risk state.

Assessment of such patients involves a detailed evaluation of the level of risk using certain "risk models" (e.g. Gail, Brcapro, etc.). Based on the level of risk, the patient is counselled. Management options include increased surveillance, medical interventions (viz. anti-oestrogen therapy) or surgical interventions such as a prophylactic oophorectomy or bilateral prophylactic mastectomy.

BREAST CANCER SCREENING AND METHODS FOR EARLY DIAGNOSIS

The main methods for the early diagnosis of breast cancer include screening mammography of the breasts, clinical breast examination, and breast self-examination (BSE).

Current recommendations of the American Cancer Society for early diagnosis include BSE once a month starting at the age of 20, clinical breast examinations about once every 3 years for women in their 20s and 30s and yearly for those over 40 years and yearly mammograms after the age of 40. Magnetic

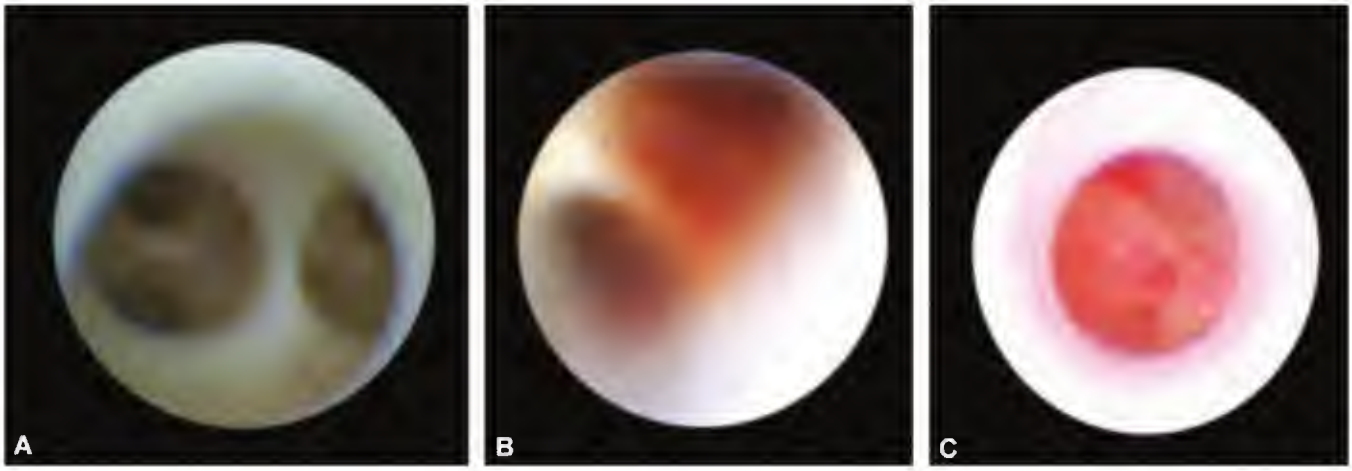

Figure 1: Appearance of ducts on mammary ductoscopy. (A) Normal ductal bifurcation; (B) Intra ductal bleeding; (C) Intraductal growth.

resonance imaging screening is recommended for women with a 20% to 25% or greater life-time risk of breast cancer.

NEWER DEVELOPMENTS: MAMMARY DUCTOSCOPY

Mammary ductoscopy (**Figure 1**) is a new technique in which a microendoscope just a mm in diameter is inserted into breast ducts to visualise early epithelial abnormalities. Ductal washings can be collected and tissue biopsy obtained (much like a bronchoscope). The role of this technique is being evaluated and early data indicate that it is likely to be most useful in assessing patients with nipple discharge. Appearances on ductoscopy of normal ducts, intraductal bleeding and early intraductal growths are shown in **Figure 1**. Lesions identified on ductoscopy can be excised for definitive histological diagnosis, providing an exciting avenue for the early diagnosis of breast cancer.

21.8 Tracheobronchial and Lung Cancers

Kirti M Patel

LUNG CANCER

The term lung cancer is used for tumours arising from the respiratory epithelium (bronchi, bronchioles and alveoli). It is one of the commonest malignant neoplasms all over the world. (**Table 1**). It accounts for more cancer deaths every year than breast, colon and prostate cancer combined. As per records in different registries in India, there is an increase in incidence of lung cancer owing to the widespread use of cigarettes (**Table 2**).

Table 1: Incidence of Common Cancers – World, Developed and Developing Countries

Rank	World	Developed Countries	Developing Countries
Males			
1	Lung	Lung	Lung
2	Stomach	Prostate	Stomach
3	Prostate	Colon/rectum	Liver
4	Colon/rectum	Stomach	Oesophagus
5	Liver	Bladder	Colon/rectum
Females			
1	Breast	Breast	Breast
2	Uterine cervix	Colon/rectum	Uterine cervix
3	Colon/rectum	Lung	Stomach
4	Lung	Stomach	Lung
5	Stomach	Corpus uteri	Colon/rectum

cadmium, polonium, hydrazine and vinyl chloride. Thus, smoking prevention and cessation is better to save many lives than advances in diagnosis or treatment.

Occupational, exposure to asbestos, radon, hydrocarbons, chromium, nickel, and arsenic also increase risk of cancer. The risk in smokers who are exposed to asbestos is increased 90 folds. Other risk factors include recurrent lung inflammation, lung scar, and family history of lung cancer.

Lung cancer occurs principally between the ages of 45 and 65 years. Initially, partial obstruction by tumour, may lead to obstructive emphysema of the lobe or segmental atelectasis. Later,complete obstruction may cause collapse of the lobe predisposing to secondary infection or abscess distal to carcinoma. Pleura may be involved directly or by lymphatic spread. Invasion of chest wall, intercostal nerves or the brachial plexus causes severe pain. The tumour may spread into the mediastinum and invade or compress the pericardium, oesophagus, superior vena cava, trachea, phrenic, or left recurrent laryngeal nerves. Lymphatic spread to supraclavicular and mediastinal lymph nodes is also frequently observed. Metastases commonly occur in liver, bone, brain, adrenals, and skin. A small primary tumour with widespread metastatic deposits is characteristic of small cell type lung cancer (**Figure 1**).

Table 2: Incidence of Lung Cancer at Gujarat Cancer and Research Institute, Ahmedabad

Year	Lung Cancer						Total Cancers		
	Male	Small cell cancer	Non-small cancer	Female	Small cell cancer	Non-small cancer	Male	Female	Total

AETIOLOGY

Lung cancer appears to develop from stem cells that can differentiate along multiple lines (**Table 3**). Smoking is a major cause as 85% to 95% of patients have a history of smoking. The risk is 30 times greater in smokers than non-smokers. Passive smoking also increases the risk by two folds as does smoking cigars or pipes. The risk is related to cumulative dose and duration of smoking (**Table 4**). Following the cessation of smoking the risk steadily declines but never approaches that of non-smokers. Smoking increases the risk of all histologic types of lung cancer. Cigarette smoke contains various carcinogens such as (1) Polycyclic aromatic hydrocarbons, (2) Heterocyclic compounds, (3) N-nitrosamines, (4) Phenolic compounds, (5) Metals and inorganic compounds like nickel,

Table 3: Aetiological Factors in Lung Cancer

Cigarette smoking	Occupational
Particulate phase	Asbestos
Benzpyrene	Radioactivity (uranium mines, radon)
Benzofluoranthenes	Metal works (nickel, chromium, iron oxide)
Dibenzanthracene	Arsenicals (sheep-dip workers)
Nicotine

60	5
90	8
100	13
120	20
>135	33

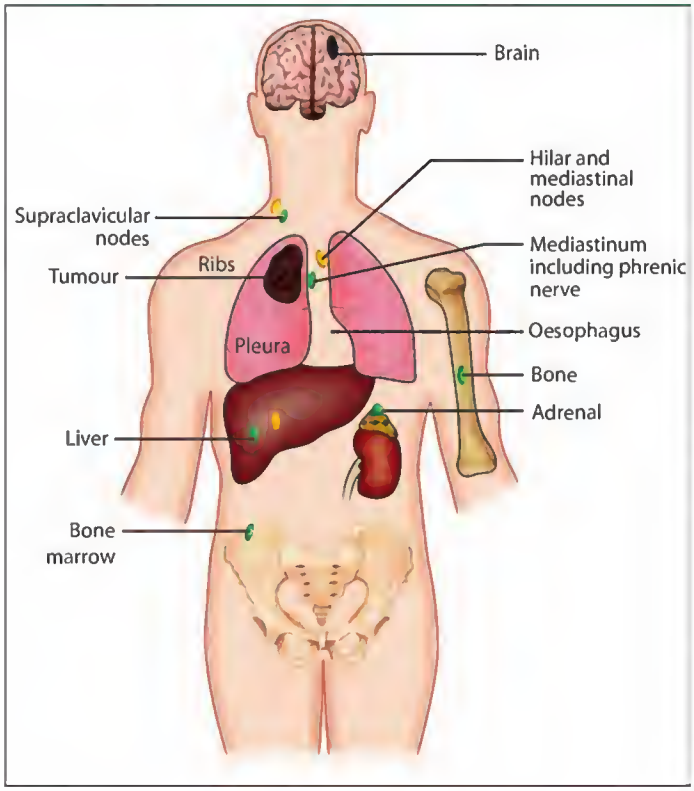

Figure 1: Sites of metastases of lung cancer.

CLASSIFICATION AND PATHOLOGY

The WHO classification of lung tumours is based on progress in the understanding of the biology of these tumours. For therapeutic purpose, it is mainly divided into: Non-small cell lung cancer (NSCLC) which includes squamous (Epidermoid), adenocarcinoma, large cell (large cell anaplastic) (**Table 5**) and small cell lung cancer (SCLC). NSCLC accounts for 80% of total lung cancers. Undifferentiated carcinomas, carcinoids, bronchial gland tumours are rare lung tumours.

Squamous Cell Carcinoma

Represents 30% to 35% of lung cancers. Frequently occurs in smokers and older males. More often central (80%) and relatively slow growing.

Adenocarcinoma

Represents about 40% of the lung cancer cases and often arises in the periphery of the lung parenchyma. It may grow in acinar, papillary, bronchoalveolar or solid growth patterns and produce mucin. It is most common cell type occurring in non-smokers, especially women includes subtypes such as bronchoalveolar adenocarcinoma (BAC).

Bronchoalveolar Carcinoma

It includes only non-invasive tumours where the neoplastic cells spread out along pre-existing alveolar structures (lepidic spread). It may manifest as a solitary peripheral nodule, multifocal disease, or a pneumonic form, with rapid spread from one lobe to another.

Table 5: The Classification of Lung Cancers

Preinvasive lesions
- Squamous dysplasia/carcinoma *in situ*
- Atypical adenomatous hyperplasia

Invasive malignant lesions
- Squamous cell carcinoma (SCC)
- Adenocarcinoma
  - Bronchoalveolar variant
- Large cell carcinoma
- Small cell carcinoma
- Adenosquamous carcinoma
- Carcinoid tumours
- Carcinoma of the salivary gland
  - Mucoepidermoid carcinoma
  - Adenoid cystic carcinoma
- Unclassified

It manifests in mucinous and non-mucinous variants. Mucinous BAC is multifocal and fatal. Non-mucinous BAC arises from type II pneumocytes and epidermal growth factor receptor (EGFR) mutations give rise to bronchoalveolar differentiation. It is most common in non-smoking middle-aged Asian women. EGFR mutations confer sensitivity to EGFR tyrosine kinase inhibitors (TKI).

Large Cell Carcinoma

It is poorly differentiated and represents about 5% to 15% of lung cancers. It may occur in any part of the lung. Tumours are usually large when diagnosed with possibility of brain and mediastinal involvement. It is less responsive to chemotherapy and carries a poor prognosis.

Small Cell Carcinoma

Represents 15% to 20% of all lung cancers with strong association with smoking. More often central or hilar (95%) than peripheral (5%). It is more aggressive than NSCLC, grows rapidly with widespread disease at the time of diagnosis. These tumours are made up of small, round cells with large nuclei that stains blue with haematoxylin and eosin, (H and E).

CLINICAL FEATURES

Lung cancer may present in a number of different ways (**Table 6**). When tumour arises in a large bronchus symptoms occur early, but peripheral bronchus tumours can attain a very large size without producing symptoms. Signs and symptoms are caused by local tumour growth, invasion or obstruction of adjacent structures, growth in the lymphnodes or distant metastasis or as a result of non-metastatic paraneoplastic syndromes. Few asymptomatic patients are identified, usually during routine chest radiograph.

Cough, usually dry and brassy, is the commonest early symptom. Later, it may become productive. A change in the character of the 'regular' cough of smoker should always alert the clinician to the possibility of bronchial carcinoma. Repeated episodes of scanty haemoptysis or blood streaking of sputum is a common symptom, especially in tumours arising in large bronchi. Occasionally, central tumours invade large vessels, causing massive haemoptysis, which may be fatal. Breathlessness may reflect occlusion of large

bronchus, resulting in collapse of a lobe or lung or the development of a large pleural effusion. Stridor may occur when spread of tumour to the subcarinal and paratracheal glands cause compression of the main bronchi or lower end of the trachea or rarely, when the trachea is the site of primary tumour.

Pleural pain usually reflects malignant invasion of the pleura. Involvement of the intercostal nerves or brachial plexus may cause pain in chest or upper limb along the corresponding nerve root distribution. Bronchial carcinoma in the apex of the lung (superior sulcus tumour or Pancoast's syndrome) may cause Horner's syndrome (ipsilateral partial ptosis, exophthalmos, miosis and hypohidrosis) due to involvement of the sympathetic chain at or above the stellate ganglion and pain in the shoulder and inner aspect of the arm caused by involvement of the lower part of brachial plexus. Mediastinal spread may result in dysphagia. Symptoms due to metastasis include focal neurological deficits, seizures, personality change, jaundice, bone pain, or skin nodules. Lassitude, anorexia, and weight loss usually indicate the presence of metastatic spread. Paraneoplastic syndromes may precede pulmonary symptoms (**Table 7**).

Table 6: Symptoms and Signs of Lung Cancer

- **Primary Disease**
  - Central or endobronchial tumour growth
    - Cough
    - Sputum production
    - Haemoptysis
    - Dyspnoea
    - Wheeze (classically unilateral)
    - Stridor
    - Pneumonitis, with fever and productive cough (secondary to obstruction)
  - Peripheral tumour growth
    - Pain, from pleural or chest wall involvement
    - Cough
    - Dyspnoea
    - Pneumonitis
- **Regional involvement (either direct or metastatic spread)**
  - Hoarseness (recurrent laryngeal nerve paralysis)
  - Tracheal obstruction
  - Dysphagia (oesophageal compression)
  - Dyspnoea (pleural effusion, tracheal or bronchial obstruction, pericardial effusion, phrenic nerve palsy, lymphatic infiltration, and superior vena cava obstruction)
  - Horner's syndrome (sympathetic nerve palsy)
- **Metastatic involvement (common sites)**
  - Bone involvement
    - Pain, exacerbated by movement or weight bearing; often worse at night
    - Fracture
  - Liver metastases
    - Right hypochondrial pain
    - Icterus
    - Altered mentation
  - Brain metastases
    - Altered mental status
    - Seizures
    - Motor and sensory deficits

PHYSICAL SIGNS

Physical examination may reveal clubbing of fingers and hypertrophic pulmonary osteoarthropathy, characterised by periostitis of the long bones, most commonly the distal tibia, fibula, radius, and ulna. This causes pain and tenderness in the affected joints and often pitting oedema over the anterior aspect of the shin. Radiographs of the bone show sub-periosteal new bone formation. Supraclavicular lymph nodes may be enlarged.

Signs in the chest are variable. Examination is usually normal unless there is significant bronchial obstruction or the tumour has spread to the pleura or mediastinum. Some show physical signs of collapse, segmental or lobar, due to obstruction of a bronchus. A monophonic or unilateral rhonchi (wheeze) suggests the presence of a fixed bronchial obstruction and presence of a stridor indicates obstruction at or above the level of the main carina. A hoarse voice indicates left recurrent laryngeal nerve palsy, nerve paralysis causes unilateral diaphragmatic palsy and hence dullness to percussion and absent breath sounds at the lung base. Initially superior vena cava syndrome presents as bilateral engorgement of the jugular veins and later as oedema affecting the face, neck and arms.

Table 7: Paraneoplastic Syndromes in Carcinoma of Lung

- **Endocrine**
  - Hypercalcaemia
  - Syndrome of inappropriate ADH secretion (SIADH)
  - Cushing's syndrome
  - Carcinoid syndrome
  - Gynaecomastia
  - Hyperthyroidism
- **Neurological**
  - Encephalopathy
  - Subacute cerebellar degeneration
  - Peripheral neuropathy
  - Autonomic neuropathy
  - Lambert Eaton syndrome
  - Polymyositis
  - Optic neuritis
- **Skeletal**
  - Clubbing
  - Hypertrophic pulmonary osteoarthropathy
- **Haematological**
  - Anaemia
  - Pure red cell aplasia
  - Thrombocytopaenia
  - Thrombocytosis
  - Disseminated intravascular coagulation (DIC)
- **Cutaneous**
  - Hyperkeratosis
  - Dermatomyositis
  - Acanthosis nigricans
  - Hyperpigmentation

INVESTIGATIONS

The diagnosis of lung cancer requires detecting the tumour, establishing its cell type and defining the stage of the malignancy.

RADIOLOGICAL EXAMINATION

Chest Radiograph

The presence of lung cancer is usually suggested by abnormalities, viz. unilateral hilar enlargement, peripheral pulmonary opacity, collapse, pleural effusion, broadening of mediastinum, enlarged cardiac shadow, elevation of hemidiaphragm, and rib destruction (**Figure 2**).

Figure 2: Left-sided apical bronchogenic carcinoma.

CT Scan

In addition to confirming abnormalities seen on a plain chest radiograph, this can detect lesions that cannot be resolved on a chest radiograph and has played an important role in a staging mediastinal lesion. Magnetic resonance imaging (MRI) of chest is generally superior to chest computed tomography (CT) in determining the presence of chest wall or vertebral body invasion and superior sulcus tumours. Bone scan, brain CT, abdominal CT, spinal MRI studies are done to detect abnormalities in bones, brain, liver and adrenal glands and changes in vertebrae and involvement of spinal cord.

Positron emission tomography scan

It is more sensitive than CT scan in identifying mediastinal nodal disease and can identify asymptomatic distant metastatic disease in up to 20% of the patients. The high negative predictive value allows non-invasive staging of mediastinal nodes in early stage disease. However, Positron emission tomography (PET)/CT is more sensitive and accurately stages patients with early stage disease and avoids inappropriate surgery. Some low grade malignant tumours, such as bronchoalveolar carcinoma and carcinoid are frequently false negative on PET scan.

Obtaining Pathologic Proof

The diagnosis of lung cancer must be proved by histology or sputum cytology. Repeated sputum cytology is positive in only 60% to 80% of centrally located neoplasms and 15% to 20% of the peripheral ones. It has been replaced by the flexible fibreoptic bronchoscopy for centrally located tumours. CT-guided biopsy is useful for peripheral located tumours (**Figure 3**).

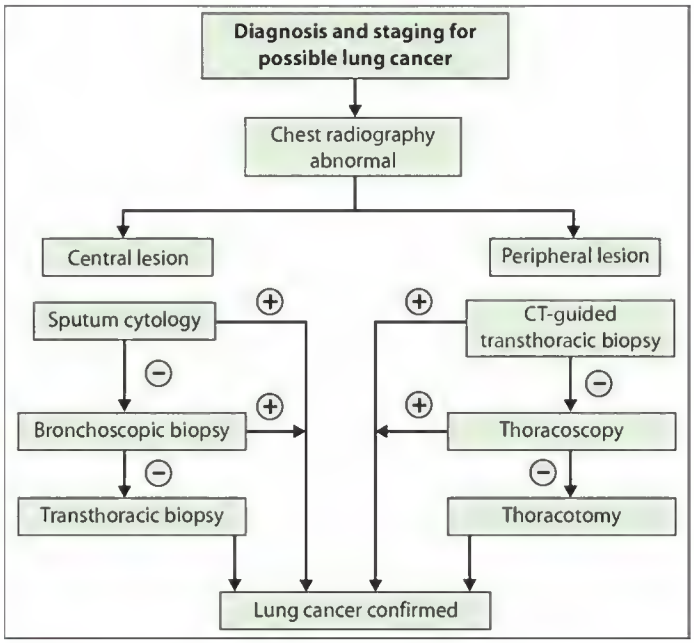

Figure 3: Diagnostic approach for possible lung cancer.

Staging TNM

TNM system is used for NSCLC (**Tables 8 and 9**). Small cell lung cancer (SCLC) is defined as either limited or extensive disease (**Table 10**). Staging evaluation of lung cancer includes history and physical examination, haemogram, biochemistry including electrolytes, liver functions and lactate dehydrogenase, imaging studies of the chest, abdomen, brain and bone scan. Bone marrow aspiration and biopsy is needed in some cases.

Table 8: TNM Staging System for NSCLC

T - Primary Tumour	
T0	No evidence of primary tumour
Tx	Positive cytology but tumour not demonstrable
Tis	Carcinoma *in situ*
T1	Tumour less than 3 cm diameter, no proximal invasion
T2	More than 3 cm but not more than 7 cm, main bronchus ≥ 2 cm from carina, invades visceral pleura, partial atelectasis
T3	Tumour more than 7 cm or of any size with extension into chest wall, diaphragm, mediastinal pleura or within 2 cm of carina, total atelectasis or separate nodules in same lobe
T4	Tumour of any size with invasion of mediastinal organs or vertebral body, carina, trachea, separate nodule in different ipsilateral lobe
N - Regional lymph nodes	
N0	Nodes negative
N1	Ipsilateral hilar, peribronchial nodes
N2	Ipsilateral mediastinal and subcarinal nodes
N3	Contralateral mediastinal or hilar nodes, scalene or supraclavicular nodes
M - Distant metastasis	
M0	No metastasis
M1	Metastasis present Malignant effusion, nodule in contralateral lobe, pleural nodules Distant metastasis

DIFFERENTIAL DIAGNOSIS

Solitary pulmonary nodule on chest radiograph needs to be differentiated from pneumonia, cysts and tuberculosis. Solitary

cavitary lesion on chest radiograph needs to be differentiated from tuberculosis or lung abscess. Differential diagnosis of lung cancer includes metastatic cancer from other organs, lymphoma, or infection.

Table 9: Staging of NSCLC

Stage	TNM Subset
IA	T1a or T1b, N0, M0.
IB	T2a, N0, M0
IIA	T1a or T1b, N1, M0
	T2a, N1, M0
	T2b, N0, M0
IIB	T2b, N1, M0
	T3, N0, M0
IIIA	T1a or T1b, N2, M0
	T2a or T2b, N2, M0
	T3, N1 or N2, M0
	T4, N0 or N1, M0
IIIB	Any T, N3, M0
	T4, N2, M0
IV	Any T any N with M1a or M1b

Table 10: Two Stage Classification for SCLC

Limited Disease (30%)
- Primary tumour confined to one hemithorax
- Can be encompassed in single tolerable radiation field
- Ipsilateral hilar lymph nodes
- Ipsilateral and contralateral supraclavicular lymph nodes
- Ipsilateral and contralateral mediastinal lymph nodes

Extensive Disease (70%)
- Extends beyond ipsilateral hemithorax
- Pleural or pericardial effusion
- Metastasis in the contralateral lung
- Distant metastasis (brain, bone, liver, etc.)

TREATMENT

Treatment varies according to the type of disease, stage and host factors such as age, performance status and the presence of concomitant diseases. Current modalities used in various combinations are surgical resection, radiation therapy and chemotherapy. Radiotherapy and in some cases chemotherapy can relieve distressing symptoms (**Figure 4**).

Surgical Treatment

Anatomic surgical resection (lobectomy, bilobectomy, sleeve lobectomy, or pneumonectomy) with or without regional lymph node resection is considered current standard of care in stage I and II NSCLC who are medically fit to undergo surgery. Cure can only be achieved by surgical resection. Surgical treatment offer 5-year survival rates of >75% in stage I disease and 50% in stage II disease. Post-operative adjuvant therapy is useful to improve the treatment results of these patients. Palliative resections are seldom advisable.

Treatment	Stage							
	IA	IB	IIA	IIB	IIIA	IIIB	IV	Recurrence
Surgery	■	■	■	■				
Radiation Therapy	■	■	■	■	■	■	■	■
Chemoradiation						■		
Palliative chemotherapy						■	■	■
Post op radiation						■		

Figure 4: Treatment in NSCL (Shaded area denotes modality of treatment).

Radiotherapy

Unfortunately in the majority (85%) of cases, surgery is not possible and such patients can be offered only palliative therapy. Definitive radiotherapy is frequently recommended for stage I and II patients for whom surgery is contraindicated. It is also widely used for patients with stage III lesions if the disease is limited to one hemithorax and the ipsilateral supraclavicular lymph nodes. Overall response with radiotherapy is achieved in 35% of the cases. Palliative radiotherapy usually succeeds when given for the relief of haemoptysis, superior vena cava obstruction, bone pain due to osseous metastasis and various symptoms due to metastasis to the brain.

Chemotherapy

The goals of chemotherapy are prolongation of survival and amelioration of symptoms. Agents in NSCLC include cisplatin, carboplatin, paclitaxel, docetaxel, vinorelbine, gemcitabine, irinotecan, pemetrexed, gefitinib, and erlotinib. Ifosfamide, vinblastine, mitomycin C and etoposide are also active but to a lesser degree. Combinations are better than single agents (**Table 11**). Chemotherapy consisting of platinum compounds

Table 11: Chemotherapy for NSCLC

Regimen	Dose	Cycle duration
Carboplatin-Paclitaxel		
Carboplatin	AUC 5 IV, d1	q21d
Paclitaxel	175-225 mg/m² IV, d1	
Carboplatin-Docetaxel		
Carboplatin	AUC 5 IV, d1	q21d
Docetaxel	75 mg/m² IV, d1	
Gemcitabine-Carboplatin		
Gemcitabine	1,000 mg/m² IV, d1, 8	q21d
Carboplatin	AUC 5 IV, d1 only	
Vinorelbine-Cisplatin		
Vinorelbine	30 mg/m² IV, d1, 8	q21d
Cisplatin	80 mg/m² IV, d1 only	
Pemetrexed-Cisplatin		
Pemetrexed	500 mg/m² IV, d1	q 21d
Cisplatin	75 mg/m² IV, d1	
Combination with Targeted Agents		
Bevacizumab-Chemotherapy		
Carboplatin	AUC 6	q 21d
Paclitaxel	200 mg/m² IV, d1	for 6 cycles
Bevacizumab	15 mg/kg IV, d1	q 21d till progression
Cetuximab-Chemotherapy		
Cisplatin	80 mg/m² IV, d1	q 21d
Vinorelbine	25 mg/m² IV, d1	for 6 cycles
Cetuximab	400 mg/m² IV, d1	
	250 mg/m² weekly	till progression
EGFR Tyrosine Kinase Inhibitors		
Gefitinib	250 mg/d oral	till progression
Erlotinib	150 mg/d oral	till progression

AUC = Area under the curve.

plus third generation agents is the current standard of care for patients with advanced NSCLC. The choice of chemotherapy depends upon the performance status, histology, toxicity, convenience of administration, and cost. In a patient beyond 4 courses of platinum containing regimens produces no survival benefit but increases the incidence of side effects. Older patients (>70 years) may be best treated with monotherapy with agents like vinorelbine, gemcitabine, etc.

The drugs with activity against SCLC include cisplatin, carboplatin, cyclophosphamide, doxorubicin, etoposide, ifosfamide, irinotecan, and topotecan. Commonly used combination chemotherapy are summarised in **Table 12**. In limited stage SCLC, concurrent chemotherapy (CCT), and local radiation therapy (thoracic RT) is the standard treatment. In patients with complete response to CCT + RT prophylactic cranial irradiation is recommended to decrease the risk of brain metastasis and to improve survival. In SCLC because of high incidence of second malignancies and local regional and distant recurrence, patients need to have frequent check ups after completion of treatment. In patients with extensive stage disease, combination chemotherapy is superior to single agent. Radiation therapy can be used for palliation of localised symptoms. Results of treatment for lung cancer are summarised in **Table 13**.

Table 12: Chemotherapeutic Regimens in SCL

Regimen	Dose	Duration
EP		
Etoposide Cisplatin	120 mg/m² IV, d1-3 60 mg m/m² IV, d1	Repeated every 4 weeks, for 4 cycles
Etoposide Carboplatin	100 mg/m² IV, d1-3 AUC 6 IV, d 1	Repeated every 4 weeks, for 4 cycles
Etoposide Cisplatin	100 mg/m² IV, d1-3 25 mg/m² IV, d1-3	Repeated every 3 weeks, for 4 cycles
Etoposide Cisplatin	80 mg/m² IV, d1- 3 80 mg/m² IV, d1	Repeated every 3 weeks, for 4 cycles
CI		
Cisplatin Irinotecan	60 mg/m² IV on d1 60 mg/m² IV on d 1,8, 15	Every 4 weeks, for 4 cycles
Carboplatin Irinotecan	AUC-5 IV on d1 50 mg/m² IV on d 1,8,15	Every 4 weeks, for 4 cycles
Relapsed Disease		
CAV		
Cyclophosphamide	1,000 mg/m² IV, d1	Repeated every 3 weeks, for 4 to 6 cycles
Doxorubicin Vincristine	45 mg/m² IV, d1 1 mg/m² IV, d1	
Single Agents		
Paclitaxel	175 mg/m² IV, d1	Every 3 weeks
Docetaxel	75 mg/m² IV, d1	Every 3 weeks
Gemcitabine	1000 mg/m² IV d 1, 8, 15	Every 3 weeks
Topotecan	1.5 mg/m² IV, d 1-5	Every 3 weeks

Targeted Therapy

Increased understanding of molecular abnormalities in lung cancer, has led to development of targeted therapies. Overexpression of the EGFR is one such abnormality, which is

Table 13: Results of Treatment for Lung Cancer

	Treatment	Outcome (5-year survival)
NSCLC		
Stage I	Surgery + chemotherapy	60% to 70%
Stage II	Surgery + chemotherapy	40% to 50%
Stage IIIA	Neoadjuvant chemotherapy	15% to 30%
Stage IIIB or Unresectable disease	Concurrent chemoradiation	10% to 20%
Stage IV	Chemotherapy (3-4 cycles)	<5%
SCLC		
Limited	Concurrent chemoradiation	15% to 25%
Extensive	Chemotherapy	<5%

common in NSCLC. Stimulation of the EGFR pathway leads to increased growth potential, increased ability to metastasise, and increased angiogenesis (new blood vessel formation) in the cancer cells. Cancers overexpressing EGFR have been shown to have increased resistance to therapy, increased metastatic potential, and poorer prognosis.

Gefitinib

It is a EGFR tyrosine kinase inhibitor (TKI) that blocks activation of EGFR pathway. Gefitinib when used as first-line in Asian patients with adenocarcinoma who had never smoked or were former light smokers (none in last 15 years) showed a higher response rate in comparison to carboplatin-paclitaxel (43% *vs* 32%), with similar median survival. Patients who were positive for the EGFR gene mutation had significantly longer progression-free survival.

Erlotinib

A second EGFR-TKI, demonstrated improved response rates and overall survival (6.7 *vs* 4.6 months), compared to placebo in the second- and third-line setting. However, no benefit was seen when erlotinib was combined with chemotherapy. Response rates and survival were better in females, Asians, nonsmokers, particularly those with adenocarcinoma, especially bronchoalveolar cancer.

Cetuximab

It is a monoclonal antibody that binds to the EGFR receptor. It was studied in the first-line setting, in combination with cisplatin-vinorelbine, in patients with NSCLC that expressed EGFR by immunohistochemistry. In responding patients, cetuximab was continued till progression. Patients receiving cetuximab had an increased response rate (36% *vs* 29%), and improved median survival.

Bevacizumab

It is an anti-angiogenesis agent used with standard first-line carboplatin-paclitaxel. It improved median overall survival, and response rate (35% *vs* 15%) compared to chemotherapy alone. It is contraindicated in squamous cell histology, brain metastases, and clinically significant haemoptysis.

NEW IN LUNG CANCER

For Diagnosis

- Development of ras mutations in bronchial epithelium can be detected in the sputum samples as early as one month to four years prior to the clinical diagnosis of lung cancer.

- Detection of p53 protein in sputum samples of patient with bronchial dysplasia and antibodies to p53 in lung cancer.

Prognostic and Predictive Biomarkers

Epidermal growth factor receptor (EGFR) mutation is predictive of treatment benefit from EGFR-TKI therapy. High ERCC1 levels are prognostic of better survival but predictive of poor response to platin-based chemotherapy. K-ras mutation is a poor prognostic factor and predictive of resistance to platinum/vinorelbine chemotherapy or EGFR-TKI therapy. High RRM1 levels are prognostic of better survival but predictive of poor response to gemcitabine-based chemotherapy. Diminished expression of fas, ErbB-1, cyclin A, proliferating cell nuclear antigen (PCNA) are associated with long-term survival.

Therapeutics

1. Gene therapy – replacing defective gene/ protein or decreasing expression of the over expressed ones-studies focused on p53, c-erb B-2 and ras
2. Anti-sense therapy
3. Monoclonal antibody therapy
4. Agents to enhance apoptosis
5. Vaccines targeting MAGE-3, Tol-9 receptor, TGF, and MUC-1
6. Immunotherapy
7. Multiple tyrosine kinase inhibitors, such as sunitinib and sorafenib.

PROGNOSIS

The overall prognosis in bronchial carcinoma is very poor, with around 80% of the patients dying within a year of diagnosis and less than 5% of the patients surviving 5 years after diagnosis (**Table 13**). The best prognosis is with well differentiated squamous cell tumours, which have not metastasised and are amendable to surgical treatment. Efforts directed towards early detection and treatment have failed to reduce lung cancer mortality substantially. Thus, primary prevention through prevention and cessation of smoking remains the single most important measure for combating this frustrating disease.

TRACHEOBRONCHIAL TUMOURS

Tracheal tumours are uncommon, making up less than 1% of all respiratory malignancies. Tumours in the tracheobronchial tree can be classified as primary malignant tumours, secondary malignant tumours, or benign tumours (**Table 14**). The majority of primary malignant tumours originate from the surface epithelium or the salivary gland.

Squamous cell

It is the commonest primary tracheobronchial malignancy. It can be exophytic or infiltrative and involves the posterior wall of the lower two-thirds of the trachea with mediastinal or pulmonary metastasis at diagnosis.

Adenocarcinoma

It is extremely uncommon in the trachea. Both are managed as described in lung cancer.

Table 14: Classification of Tracheobronchial Tumours

Primary malignant tumours
- Surface epithelium
  - Squamous cell carcinoma (SCC) (most common), adenocarcinoma, neuroendocrine tumours (carcinoid tumour, large cell neuroendocrine tumours, small cell carcinoma)
- Salivary glands
  - ACC (second most common), MEC
- Mesenchyme
  - Sarcoma, malignant lymphoma

Secondary malignant tumours
- Direct invasion
  - Thyroid cancer, laryngeal cancer, lung cancer, oesophageal cancer
- Haematogenous metastasis
  - Melanoma, breast cancer, renal cell carcinoma, colon cancer

Benign tumours
- Surface epithelium
  - Squamous cell papilloma, papillomatosis,
- Salivary glands
  - Pleomorphic adenoma, mucous gland adenoma, oncocytoma
- Mesenchyme
  - Hamartoma, leiomyoma, lipoma, fibroma,

Neurogenic tumour

Salivary gland tumours

Arise from the bronchial seromucous glands. The malignant tumours are more common than benign. These are more common in the trachea than in the bronchi due to the preferential location of the commonest glandular tumour, adenoid cystic carcinoma (ACC).

Carcinoid tumours

Pulmonary and bronchial carcinoid tumours account for 1% to 2% of all pulmonary neoplasms. Carcinoid tumours of the tracheobronchial tree are frequently typical and usually involve the main, lobar, or segmental bronchi. They are vascular but have lower uptake on FDG-PET.

Benign tumours

Benign tumours of the tracheobronchial tree are rare, accounting for less than 10% of all airway neoplasms, and usually arise from the mesenchymal tissue. The commonest are hamartomas and squamous cell papillomas. They are well demarcated, round, and less than 2 cm in diameter. They originate in the submucosa, and the overlying epithelium is usually intact and smooth. The affected patients are asymptomatic until 50% to 75% of the luminal diameter is occluded.

Clinical Presentation

Tracheal or the main bronchus tumours cause progressive airway obstruction and present with cough, shortness of breath, or wheeze. Sometimes, tumour growth or mucosal erosion may cause haemoptysis. The diagnosis is usually delayed. Benign tracheal tumours and ACC have a mean symptom duration of 24 months as compared to 12 months for mucoepidermoid carcinoma.

Evaluation

Chest radiographs may demonstrate collapse of a lobe or an entire lung or hyperinflation of the lung distal to a bronchial tumour due to a ball valve effect. Computed tomography (CT) of the chest may demonstrate a tracheal or bronchial mass and invasion of the great vessels but underestimates the extent of submucosal invasion. Patients with malignant tumours are evaluated for metastatic disease that typically includes examinations of the lung, brain, bone, adrenal glands and liver. Endoscopic examination of the airway with rigid bronchoscope provides a diagnosis, and may be used for dilatation of a stricture or for removal of a tumour to relieve symptoms.

Treatment of Tracheobronchial Tumours

Resectable tumours

Local treatment options consist of brochoscopic resection, segmental airway resection, and radiotherapy. Of these techniques, only segmental tracheal or bronchial resection permits complete removal of the tumour.

Bronchoscopic resection

It is a less invasive, restores airway lumen, but does not provide for complete resection or confirmation of resection margins. The primary role is therefore palliative.

Surgical resection

The tumour size, length, and depth influences resectability. The location of tracheal tumours in the mediastinum restricts radical resection. The average length of most resected tracheal tumours measures less than 3 cm, except ACCs which often involve a longer tracheal segment. Due to close margins in mediastinum, adjuvant radiotherapy is now standard therapy. Operative procedures performed for tracheal tumours are laryngotracheal, tracheal, and carinal resection whereas for bronchial tumours, they are main bronchial resections with parenchymal sparing and sleeve lobectomy.

Unresectable tumours

Main criteria are tumour length, regional disease, and distant metastasis. The goals of treatment are to restore a patent airway and to slow progression of disease. Regional radiation or bronchoscopic destruction provide effective local palliation therapy. Local destruction of tumour may be accomplished by the laser, cryosurgery, brachytherapy, photodynamic therapy, or argon beam coagulation. Malignant strictures can be stented.

Prognosis

Benign bronchial tumours have an excellent long-term prognosis and do not recur if completely resected. The malignant bronchial gland tumours have a limited disease-free survival after resection due to distant metastasis and regional disease. Other malignant tracheal tumours are mostly unresectable with poor long-term survival.

See cancer lung in Section 23, Chapter 19.

21.9 Tumours of the Gastrointestinal Tract (Stomach and Oesophagus)

KM Mohandas

INTRODUCTION

Gastrointestinal tract (GIT) is one of the commonest sites for development of cancer. In India, the GIT cancers constitute 15% to 25% of all cancers. Gastrointestinal tract (GIT) cancers are primarily a disease of the elderly population. In the clinics, majority of Indian patients are diagnosed at a younger age because less than 5% of Indian population is above 65 years of age. As the Indian population grows older with increasing life expectancy, the burden of GIT cancers will increase many folds in India. Almost all GIT cancers arise as a result of prolonged exposure to aetiological causes like tobacco, poor diet and infections, like *Helicobacter*, hepatitis and papilloma virus, which are preventable. The stage based on Tumour Nodes and Metastasis (TNM) is the most important prognostic factor for GIT cancers. Surgery is the primary curative treatment for GIT cancers. Patients with the cancer limited to the wall of the GIT have excellent long-term survival following en bloc surgery. Majority of the GIT cancers in India are well advanced at the time of diagnosis. Most patients are suited for palliation only which is possible by surgery, endoscopy, radiotherapy, and chemotherapy. There has been some progress in chemotherapy with and without radiotherapy in improving the outcomes of patients with GIT cancers. A collective effort by Indian physicians can prevent exposure to carcinogens and help in early diagnosis of GIT cancers, and thereby, contribute in the control of GIT cancers in India. Some pointers are listed in **Table 1**. It is important to remember some condition involving stomach and oesophagus which may be mistaken and malignancy may be missed (**Table 2**).

Table 1: Common Precursors of Gastric Cancers (Stomach)

Benign Disease	Malignant Disease
Achalasia or corrosive strictures	Squamous carcinoma of oesophagus
GERD with Barrett's metaplasia	Adenocarcinoma of the oesophagus
Chronic gastritis due to *H. pylori*	Gastric adenocarcinoma and MALT lymphoma

GERD = Gastro-oesophageal reflux disease; MALT = Mucosa-associated lymphoid tissue.

Table 2: Commonly Mistaken Diagnoses for GIT Cancers (Oesophagus and Gastric)

Primary Cancer	Common Mistaken Diagnosis
Oesophageal cancer	Peptic stricture, achalasia, web, impacted foreign body
Gastric cancer	Gastritis, peptic ulcer, pyloric stenosis, thick folds

OESOPHAGEAL CANCER

There are many types of benign and malignant tumours of the oesophagus. Leiomyoma is the commonest benign tumour and has an excellent prognosis following resection. Majority of primary oesophageal cancers are carcinomas. The commonest is squamous carcinoma, followed by adenocarcinoma. Other cancers are very rare and include lymphoma, leiomyosarcoma, and metastatic cancer.

Squamous Carcinoma of Oesophagus

It is one of the common GI cancers. It is the fourth leading cancer in Indians. The incidence rates are higher in China, Puerto Rico, Singapore, South Africa, Switzerland, France, and the Caspian Littoral area of Iran. Squamous carcinoma is aetiologically associated with tobacco chewing and smoking, alcohol abuse, human papilloma virus infection, corrosive strictures, sclerotherapy, Plummer-Vinson syndrome, irradiation of the mediastinum, achalasia, and previous squamous carcinoma of the head and neck region. Tylosis and squamous cell papilloma is precursor lesion for squamous carcinoma. Adenocarcinoma is more common in Western populations and occurs mainly in the distal oesophagus. As the incidence of squamous carcinoma is declining, the incidence of adenocarcinoma is rising. Adenocarcinomas of the oesophagus are difficult to differentiate from the adenocarcinoma of the proximal stomach when in an advanced stage. Adenocarcinoma of the oesophagus develops in Barrett's oesophagus. Barrett's oesophagus develops following long-standing gastro-oesophageal reflux disease (GERD). Other less common cancers of the oesophagus include variants of squamous carcinoma such as spindle cell carcinoma, adeno-squamous carcinoma, oat cell carcinoma, carcinoid tumour, sarcoma, and primary malignant melanoma. Several other cancers are known to metastasise to the oesophagus. The cancer can arise anywhere in the oesophagus and develop as a stricture, protruding mass, or an ulcerated plaque.

Symptoms and Signs

The incidence of oesophageal cancer peaks after 70 years of age. Oesophageal cancer presents with progressive dysphagia over several weeks and months often with progressive weight loss and weakness. Dysphagia begins with difficulty in swallowing solids, then progresses to semisolids, liquids, and finally saliva. Chest pain and back pain is ominous sign, suggestive of local spread of the cancer (**Table 3**). Hoarseness due to compression of the recurrent laryngeal nerve and Horner's syndrome due to compression of sympathetic nerves may occur. Compression of nerves elsewhere may cause spinal pain, hiccups, or paralysis of the diaphragm. Malignant effusions and pulmonary metastasis produces dyspnoea. Progressive tumour growth produces odynophagia, vomiting, haematemesis, melaena and iron-deficiency anaemia, aspiration, cough, lung abscess, and pneumonia. Superior vena cava syndrome, malignant ascites, oesophago-respiratory fistula, and bone pain suggests very advanced disease. Oesophagus is drained all along its length by a rich lymphatic plexus resulting

in early metastasis into internal jugular, cervical, supraclavicular, mediastinal, and coeliac lymph nodes. Blood-borne metastasises to bone, lung, liver and other distant sites (e.g. brain, adrenal glands, kidneys, and peritoneum) are not uncommon.

Table 3: Warning Signs of Digestive Cancer

Gut specific
Difficulty in swallowing solid foods or medicines
Fullness after meals and/or early satiety
Vomiting of undigested foods
New abdominal pain
Jaundice
Bleeding per rectum
Non-specific
Nausea, anorexia, weight loss
Depression, insomnia
Venous thrombosis

Investigations

Fibreoptic endoscopy is the investigation of choice as it enables biopsy and cytological sampling necessary to confirm diagnosis. The combined yield of biopsy and brush cytology is over 95%. Endoscopy is also useful for placing feeding tubes and palliating dysphagia by dilation and stenting. Barium swallow can demonstrate the location and the degree of stenosis, length of stenotic tumour, deviation of luminal axis, and the presence of regurgitation or tracheo-oesophageal fistula. Over 98% of upper oesophageal cancers are squamous carcinoma. Ten to twenty-five per cent of lower oesophageal cancer and 80% of gastro-oesophageal junction cancers are adenocarcinomas. A multi-detector computed tomography (MDCT) of the chest and upper abdomen is the essential for staging oesophageal cancer. Multi-detector computed tomography (MDCT) detects infiltration of the tumour to mediastinal structures, enlarged lymph nodes, metastasis to distant organs, and malignant effusions. It is useful for precise planning of the radiation fields. MRI does not offer additional advantage over CT. An endoscopic ultrasound (EUS) is needed in all patients being considered for surgery for detailed loco-regional staging of the cancer and adjacent lymph nodes.

Prognosis and Treatment

The prognosis of advanced oesophageal cancer is poor and less than 10% of patients diagnosed after the onset of dysphagia survive over 5 years. For early oesophageal cancer, a 5-year survival may be as high as 80%. The site and type of cancer, stage, co-morbidity, and the patient's preferences influence the optimal treatment modality. Most localised oesophageal cancer is treated with curative intent using surgical resection or radiotherapy. Adenocarcinoma occurring in the distal oesophagus is most often treated with distal oesophagectomy and radiation is used as the primary treatment of upper oesophageal cancers. Recent studies support the use of pre-operative chemoradiotherapy and peri-operative chemotherapy which is also useful for locally advanced cancers. For patients having more advanced cancer with metastasis, recurrent cancer or severe co-morbid illness palliative treatments such as oesophageal dilation, prosthesis (stent) placement, internal radiotherapy, and laser photocoagulation are used. Chemotherapy has limited role in the palliation of advanced oesophageal cancer.

Objectives of pre-treatment assessment include (i) confirmation of diagnosis by histology, (ii) determine the extent of the disease, (iii) exclusion of extra-mural extension of the tumour, (iv) exclusion of distant metastasis, (v) to establish the resectability of tumour, and (vi) to assess operative risk of the patient.

Surgical therapy of oesophageal cancer is associated with 5% to 15% mortality rates and a 10% to 20% of 5-year survival. Surgery must be undertaken in high volume centres to reduce mortality. Complication rates, operative mortality rates, and 5-year survival are mainly dependent on the patient selection. En bloc resection of tumour with lymph nodes is more risky in elderly patients, those with cardiac ejection fraction less than 40%, and forced expiratory volume in one second of less than 1.5L. The 2-year survival is poor in patients with cancer extending beyond the oesophageal wall or metastasis to lymph nodes. Nevertheless, surgery is still one of the most effective forms of therapy and permits over 80% of patients eat a soft or solid diet.

The choice of surgery is determined by the location, size and stage of the tumour, the experience of the surgeon, and the intent of treatment. In curative resection, the entire tumour with clear proximal and distal margins of normal oesophagus and all the involved lymph nodes are removed en bloc. The defect of the oesophagus is repaired by creation of a gastric tube and oesophagogastric anastomosis, or with small-bowel or colonic interposition. Complications of surgery include septicaemia, pneumonia, anastomotic leaks and strictures, bilious gastro-oesophageal reflux, and dumping syndrome.

External beam radiotherapy (EBRT) is an effective primary therapy for patients who are at high risk for surgery or have advanced disease. External beam radiotherapy (EBRT) is contraindicated in patients with tracheo-oesophageal fistula. Rarely patients with aortic involvement by tumour may experience massive haemorrhage following EBRT. Occasionally, oedema caused by EBRT may worsen oesophageal obstruction, dysphagia, and odynophagia. Temporary oesophageal dilation or placement of a feeding tube may be required to provide enteral nutrition. Radiotherapy may also produce nausea, vomiting, anorexia, fatigue, oesophagitis, odynophagia, stricture, radiation pneumonitis, radiation pericarditis, myocarditis, and transverse myelitis. Chemotherapy is combined with EBRT to enhance the tumour response.

Chemotherapy is primarily used along with surgery or radiotherapy to improve response rates and survival rates. Several drugs have moderate anti-neoplastic activity against squamous and adenocarcinoma. These include 5-fluorouracil (5-FU), capecitabine, gemcitabine, mitomycin, cisplatin, oxaliplatin, carboplatin, bleomycin, methotrexate, and paclitaxel. Shrinkage rates of tumour vary from 10% to 70% depending on the morphology, size and stage of primary tumours and the combination of drugs used. Cisplatin is the most commonly used drug in combination with 5-FU, methotrexate, and less commonly bleomycin. Multi-modality therapy (surgery, radiotherapy, and chemotherapy in the same treatment plan) is used to control both local disease and distant metastases. Chemotherapy given peri-operatively with or without external radiation therapy is superior to surgery or radiation therapy alone in patients with loco-regional cancer. Chemotherapy or radiotherapy given alone after surgery has little benefits.

Pre-operative radiotherapy alone or in combination with chemotherapy is effective in reducing tumour bulk, increasing resectability, and improving survival of complete responders. There is little evidence to support the use of post-operative radiotherapy in prolonging survival compared with surgery alone. Combined modality radiotherapy with 5-FU and cisplatin might result in prolonged disease-free and overall survival in patients with unresected oesophageal cancer. Benefit occurs in patients with adenomatous or squamous cell cancer and is superior to that achieved with radiotherapy alone. Patients with locally advanced adenocarcinoma of the lower end of the oesophagus benefit from peri-operative chemotherapy and post-operative chemoradiotherapy.

Oesophageal dilation is a palliative therapy for maintaining the swallowing at any time during the course of illness. The dilation is very safe, and the balloon dilators passed under direct endoscopic vision or over a guide wire enhance the safety. The effect of dilation is temporary, and needs to be repeated every 6 to 8 weeks. Oesophageal stents are placed across the malignant strictures to restore the oesophageal lumen for longer periods and to close tracheo-oesophageal fistulas. Currently available, expandable metallic and plastic stents have increased the ease and safety of stent insertion. Endoscopic laser therapy with Nd: YAG is used to vaporise the tumour and establish the lumen. Laser treatment however is palliative, needs to be repeated and expensive. The complication rate for laser therapy is similar to that of stent placement. Photodynamic therapy is another treatment designed to destroy tumour cells without damaging surrounding normal tissues. Photo-activation of the dye absorbed by the cancer cells causes self-destruction from cytotoxic oxygen singlet within the tumour cells. Laser therapy and photodynamic therapy (PDT) are expensive for routine use in India.

Prevention and Screening

Barrett's oesophagus, the precursor of adenocarcinoma, rarely regresses with medical therapy and anti-reflux surgery. Endoscopic surveillance of malignant transformation is often recommended at 3- to 12-month intervals depending on the degree of metaplasia, but its cost-effectiveness is controversial. PDT and endoscopic mucosal resection (EMR) are useful means to ablate Barrett's oesophagus with dysplasia. Newer endoscopic techniques like narrow band imaging, confocal microscopy, and fluorescence endoscopy are under investigation for screening. Routine uses of anti-oxidants and vitamin supplements do not reduce mortality.

STOMACH CANCER

Ninety-five per cent of stomach tumours are adenocarcinomas. Less common cancers are lymphomas (which may be localised primarily in the stomach) and leiomyosarcomas. The incidence of stomach cancer is very high in Japan, Chile, and Iceland. In the USA, gastric cancer is most common in Northerners, the poor, and the African-American populations. In India, the incidence of stomach cancer has decreased to about 2 to 8 per 100,000, making it the seventh most common cause of death from cancer. The incidence of stomach cancer peaks after 70 years of age, and hence, is associated with several co-morbid illnesses.

Aetiology and Pathogenesis

Gastric adenocarcinoma is hypothesised to arise through a series of events starting with chronic gastritis, atrophy and hypochlorhydria, metaplasia, dysplasia, and carcinoma in situ. Benign peptic ulcers of the stomach do not turn malignant, and in very few patients where it had occurred probably had undetected cancer at the outset. *Helicobacter pylori* is responsible for gastric adenocarcinoma and mucosa-associated lymphoid tissue tumours of the stomach. Gastric polyps are likely to be malignant if the polyps is more than 2 cm in diameter, has villous histopathology or when multiple polyps are present at a time. The incidence of stomach cancer is lower in patients with duodenal ulcer.

Pathology

Gastric adenocarcinomas are classified on the depth of infiltration of the tumour. Adenocarcinoma limited to the mucosa and submucosa is termed early gastric cancer irrespective of their nodal metastatic status. The Japanese Society for Gastroenterological Endoscopy has proposed a classification for early gastric cancer that is widely used. Identification is based on gross morphology: type I—protruded; type II—superficial (elevated, flat, or depressed); type III—excavated. Early gastric cancer is most often detected by mass screening programmes and is amenable for EMR. Patients with early gastric cancer have excellent long-term prognosis. When the tumour infiltrates the muscularis propria, the gastric cancers are labelled as advanced. Advanced cancers are grossly classified as protruding, ulcerated, infiltrating, and combined types. Protruding tumours have the best prognosis. Tumour size does not predict the risk of co-existing metastasis. The smallest tumour can metastasise to distant sites at the time of diagnosis. Extensive tumour infiltration of the stomach wall with fibrous reaction results in 'leather bottle' stomach (linitis plastica). Most gastric cancers occur in the antrum and pyloric region; the incidence of proximal tumours is increasing.

Symptoms and Signs

Satiety (fullness or distension) after a meal occurs if the cancer obstructs the pyloric region. Pain is suggestive of ulceration or deep infiltration. Proximal stomach cancers cause dysphagia from obstruction to the oesophagogastric junction. Infiltrative cancer may be confused with oesophageal cancer or achalasia. Linitis plastica is suggested by early satiety, a never-changing shape of the stomach on barium studies and thickened gastric wall on MDCT. Loss of weight and weakness results from dietary restriction. Massive haematemesis or melaena is uncommon except in gastrointestinal stromal tumours and lymphomas, but anaemia may develop due to occult blood loss. Sometimes, the first symptom or sign is from a metastasis with the primary tumour in the stomach remaining silent. More advanced cancer causes severe weight loss, palpable mass, or enlarged neck nodes develop. Ultimately, tumour spread leads to enlarged liver, pelvic deposits, abdominal distension from ascites, jaundice, skin nodules, and even pathological fractures.

Diagnosis and Staging

Differential diagnosis commonly involves several benign disorders such as peptic ulcer, chronic gastritis, and rarely infections like tuberculosis. Endoscopy allows direct inspection and multiple biopsies sampling suspicious mucosa and needle aspiration of submucous tumours and when combined with brush cytology has a yield of over 98%. Cytology on gastric washings increases the yield. Rarely, special techniques (e.g. lift and cut technique or EMR) may be required. Conventional barium

Table 4: Treatment Summary of GIT Cancers

Cancer Site	Stage at Diagnosis by Imaging (Preferably a MDCT)		
	Localised	**Loco-regional**	**Metastatic**
Oesophagus radiation	Surgery Chemoradiation	Chemoradiation Followed by surgery or surgery alone	Intra-luminal Stenting Laser ablation
Stomach	EMR Radical surgery	Radical surgery and chemotherapy	Chemotherapy Bypass Stenting

EMR = Endoscopic mucosal resection.

X-rays are unreliable. A double-contrast barium examination is preferred over conventional barium examinations.

Staging of gastric cancer is necessary for treatment planning and includes MDCT, EUS to exclude pancreatic infiltration and peritoneal infiltration and a laparoscopy before performing surgery. The role of PET scan is under evaluation.

Treatment

The treatment options are depicted in **Table 4**. Surgery is the primary treatment of gastric cancer. Complete excision of the tumours with combined excision of the tumour with all the draining lymph nodes is needed for achieving cure. Presence of residual microscopic tumour as shown by involved surgical margins and many lymph nodes suggests incurable disease. The controversy on the role of extended lymph node dissection compared to standard resection is unresolved. Role of palliative surgery for debulking tumours or creating bypass-like gastrojejunostomy should be individualised based on the tumour site, extent, stage and patient's co-morbidity. Several endoscopic techniques such as placement of stents combined with chemotherapy have helped to avoid palliative surgery.

The role of chemotherapy and radiotherapy has been increasing in the overall management of gastric cancer. There has been progress in surgical adjuvant therapy of stomach cancer. Neoadjuvant peri-operative chemotherapy given along with surgery is useful in increasing cure rates for stomach cancer. Similarly, post-operative adjuvant chemoradiotherapy given after complete surgical resection improves survival rates. Palliative chemotherapy has achieved some success in improving survival and quality of life of patients with incurable gastric cancer. Combined chemotherapy and radiotherapy is used to cure gastric lymphoma without surgery. Targeted chemotherapy using imatinib is used for non-resectable gastric malignancy.

21.10 Colorectal Cancer

K Govind Babu

Colorectal region is that part of the large bowel extending from the ileocaecal valve to the anus. Colorectal cancer is a significant contributor to the morbidity and mortality in the developed countries. With rapid urbanisation and change in dietary habits, it is seen more frequently in the developing countries as well.

In the United States of America, it is the fourth most common cancer. In India, the age standardised incidence is 4.6 to 6 per 100,000.

AETIOPATHOGENESIS

The aetiology of colorectal cancer is complex involving several factors including the environment and genetics. This interplay brings about the metamorphosis of the normal mucosa through premalignant adenomas to overt malignancy over several years. Family history confers an increased risk. Involvement of first degree relatives increases the risk two-fold. Epidemiological studies suggest a dominant inheritance for cancer. Genetic polymorphisms are seen for glutathione S-transferases, methylenetetrahydrofolate reductase and N-acetyltransferases. The variation of these in different populations may explain the geographic variation in colorectal cancer.

Colorectal cancers develop by a series of steps influenced by inherited factors and the environment, from an early adenoma to a metastatic disease, associated with activation of oncogenes and inactivation of tumour suppressor genes, Kinzler and Vogelstein at Johns Hopkins have put forth a model to explain these events, referred to as the 'Vogelgram' of colorectal cancer.

Genetic Factors

There exists an inherited predisposition to colorectal cancers. The well studied are hereditary non-polyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP). HNPCC is associated with dysfunction in many deoxyribonucleic acid (DNA) repair genes, such as MSH2, MLH1, PMS1 and PMS2. Most cases of colorectal cancers do not have an inherited component and are termed as 'sporadic'. These result from a series of genetic events as shown in **Figure 1**.

The familial adenomatous polyposis (FAP) syndrome has inactivation of the APC gene in over 80% of sporadic cases. It is estimated that it takes at least seven somatic mutations and a few decades for these sporadic cases to evolve. The other rare syndromes accounting for about 1% of adult and paediatric colorectal cancers are the haemartomatous polyposis syndromes, of these are the Peutz-Jeghers syndrome, Cowden's syndrome.

Environmental Factors

Many environmental factors have been implicated in colorectal cancers.

Diet

It is important as global epidemiologic studies have shown that these are more prevalent in the more developed nations. It has also been seen that the first generation migrants from less developed nations acquire the increased risk who have diet low in fibre content.

Two major components having a bearing are: (i) the total fibre and fat soluble fibre contents. It is hypothesised to dilute faecal carcinogens, decrease the colon transit time and generate a favourable luminal environment, and (ii) the other factor is the association of animal fat and colorectal cancer has also been reported in several studies. It has also been found that saturated fatty acids increase the risk, intake of red meat is also associated with increased risk as also ingestion of fried, barbequed, and processed meats. Alcohol and cigarette consumption also increase the risk.

Vegetables and fruits have been shown to have a protective effect. This is thought to be due to antioxidants and plant phenols.

Physical inactivity

It is associated with more of colonic than rectal cancer. Some data exists to show beneficial effects of coffee and tea.

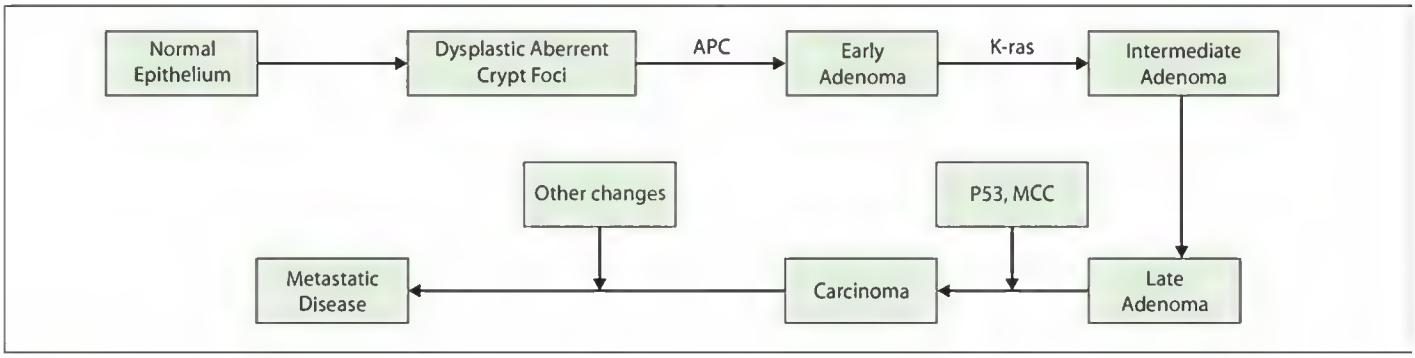

Figure 1: Molecular model of colorectal carcinogens.

APC = Adenomatous polyposis coli gene on 5q chromosome; K-ras = Mutated in 50% of colorectal cancers; DCC = Deleted in colorectal cancer, is a tumour suppressor gene; P53 = Tumour suppressor gene on 17p chromosome; MCC = Mutated in colon cancer, gene on 5q.

PATHOLOGY

Most primary tumours of the large bowel are adenocarcinomas, other cancers in this region are lymphomas, stromal tumours. The anatomic and histopathology of the tumours have a prognostic significance. The annular circumferential lesions have a shorter survival than those that involve only a portion of bowel wall. Those with a polypoidal lesion survive twice as long as those with infiltrating lesion. Tumours of the ascending colon seem to fare better than those with involvement of descending colon. The histological features that have a prognostic significance include tumour grade, vascular lymphatic and perineural infiltration and the presence or absence of inflammatory infiltrates. Poorly differentiated signet ring and mucinous tumours fare far worse than well-differentiated tumours.

CLINICAL FEATURES

Symptoms can help in anatomic localisation of the tumours. Those in the ascending colon present with abdominal pain, bleeding, weight loss rather than with obstruction that is more common in the descending colon along with altered bowel habits.

Physical examination may reveal anaemia, emaciation, and palpable mass in the abdomen. Rectal examination may show bright red blood in left colonic tumours or altered blood in right colonic tumours. If at presentation it has metastasis then findings will depend on the sites of metastasis—jaundice if the liver is involved, pleural effusion if lung and pleura are involved, pathological fractures in case of bony involvement is seen, etc.

The patient evaluation should include a detailed history, family history, and physical examination. Laboratory evaluation should cover haematology, liver function and renal function tests. The carcinoembryonic antigen (CEA) increases in about half the patients and is useful in monitoring the patient's response to therapy.

DIAGNOSIS

Colonoscopy and biopsy are the most common procedures to establish a pathologic diagnosis. A pan-body computed tomography (CT) can be done if metastasis is suspected. Stool occult blood testing, that was popular in the past remains an unreliable test. The advances in molecular biology have opened avenues to do DNA analysis on stool and study genetic alterations including analysis of genes like ras and its mutations. This could, in the future, be a very effective screening tool for detecting colorectal cancers.

Once the diagnosis is made, staging the disease is imperative for appropriate treatment.

It was in 1932 that the Dukes pathologic staging was introduced. It was essentially based on the depth of involvement of the bowel wall, lymph node involvement, and distant metastases. This system has undergone several modifications and is used for its ease. But the present day staging system is the TNM of the International Union Against Cancer (UICC) based on this system we have stage 0, I, II, III, and IV.

The staging of colorectal cancer is important for giving proper therapy and prognostication. In addition to staging, histological features also have a prognostic importance. A 5-year survival for a well-differentiated and moderately differentiated type is 57% and 54%, respectively while poorly differentiated one has a low survival rate of 35%.

MANAGEMENT

The management of colorectal cancers is a multi-modality approach that is tailored to the stage of the disease and involves surgery, radiation, chemotherapy, and biotherapy.

Colonoscopy is the first procedure that picks up the lesion. Small polypoidal lesions can be removed during this procedure and sometimes may be curative, larger lesions have to be biopsied to have a histological diagnosis.

Surgery

Surgery plays an important role in the management of colorectal cancers for invasive cancers of stage I, II, and III. The type and extent of surgery is decided by the size and anatomic location of the tumour. The resection of the colon is based on the understanding of the blood supply of the different parts. The surgical management also depends on the complication of the tumour such as obstruction perforation. Laparoscopic surgery is fast replacing conventional surgery as experience is improving and in the long run may be more cost-effective.

Radiation

Radiotherapy is not indicated for colon cancers in stage T1 and T2. No radiation is required in rectal cancers with good surgical clearance. Local recurrences are a problem in advanced rectal cancers and here radiation is employed to reduce them.

Pre-operative chemoradiotherapy protocols have led to sphincter preservation in distal rectal cancers and this is an important advancement in maintaining quality of life of these patients.

Systemic Therapy

This include chemotherapy and also the use of biological agents, one of the oldest drugs which continues to be an important agent is the fluoropyrimidine, 5-fluorouracil (5-FU).

Several advances have occurred leading to fine tuning of systemic therapy. Some of these are: role of adjuvant therapy for locally advanced disease, effective scheduling of 5-FU dose and administration, the incorporation of newer drugs, identification of tumour characteristics to predict response.

Adjuvant Chemotherapy

Patients of high risk stage II (T4 N0 M0) and stage III are candidates for adjuvant chemotherapy although high-risk stage II is controversial, it needs to be individualised, however is useful in those presenting with obstruction or perforation.

The drugs used are 5-FU and folinic acid for 6 months. The earlier regime of 5-FU and levamisole for 1 year is no more used today.

The more recent regimen incorporate oxaliplatin into them and are popularly referred to as FOLFOX regimes with several modifications, the most widely used is the FOLFOX regime. Irinotecan is another drug used sometimes in place of oxaliplatin. Trials have been done incorporating both oxaliplatin and irinotecan with 5-FU but have not shown any advantage except adding to toxicity.

The arrival of oral fluoropyrimidines—capecitabine and legofer are good alternatives to injectable 5-FU.

Investigational approaches include portal vein infusion with 5-FU, intraperitoneal chemotherapy with 5-FU, edrecolomab—a monoclonal antibody, vaccines, and active specific immunotherapy.

Follow-up after curative treatment includes physical examination and CEA levels every 3 months, yearly CT of chest, abdomen and pelvis for 3 years and a colonoscopy every 2 to 3 years. A rising CEA with a normal CT could warrant a positron-emission tomography.

Chemotherapy for Advanced Disease

Unresectable metastatic colorectal cancers are not curable. The goals here are symptom control and improving quality of life, and to lengthen progression-free and overall survival.

Patients with good performance status, good organ reserves, no significant co-morbidities and/or well motivated are the ones who would derive substantial advantages with aggressive treatment protocols while the other group should get less intensive protocols or supportive care only. Chemo-immunotherapy has made tremendous progress in the treatment of metastatic colorectal cancers. The median overall survival has increased from 4 months with best supportive care to nearly 24 months now. This could increase further with newer molecules being added to the armamentarium every day.

The backbone of most protocols still remains 5-FU and folinic acid. The activity of 5-FU has been effectively modified by using it as a protracted infusion, the response rates increasing by nearly 10% over bolus 5-FU agents that have got incorporated into the regimes include interferon, ralitrexed, irinotecan, oxaliplatin and monoclonal antibodies such as bevacizumab and cetuximab.

CONCLUSIONS

The understanding of the molecular pathology of colorectal cancers parallel with the development of chemotherapy and biological agents have brought about a vast change in the management of colorectal cancers. Cures in the adjuvant setting and meaningful prolongation of survival in metastatic colorectal cancer is now a reality.

21.11 Genitourinary Cancers

Sudeep Gupta

INTRODUCTION

Genitourinary malignancies constitute some of the most common cancers worldwide and in India. From an oncologist's point of view, these can vary from being the most gratifying (germ cell tumours of testis and ovary) to the most frustrating tumours to treat. Some of these tumours can be detected early with the help of screening (cervical cancer) or awareness programmes (penile cancer). The decisions regarding management require active patient participation and understanding since there can be difficulties in social adjustment and loss of sexual and reproductive functions. The aim of this chapter is to briefly introduce the subject to students and highlight the significance of clinical features and basic investigations to identify these malignancies in an unselected patient population followed by a brief discussion of the salient therapeutic options. The ovarian, uterine, and cervical cancers are discussed in detail in the next chapter on 'gynaecological malignancies.'

RENAL CELL CARCINOMA

Renal cell carcinoma (RCC) is the third most common and the most lethal of all genitourinary malignancies. It accounts for 5% of all malignancies in India. The peak incidence of RCC is in the 7th decade.

Aetiology

The exact cause remains unclear. Smoking, obesity, analgesic abuse, cadmium, and end stage renal diseases are recognised risk factors for RCC. Endogenous genetic risk factors include hereditary familial forms of kidney cancer, such as the von Hippel-Lindau (VHL) disease, familial hereditary papillary renal cell carcinoma (HPRCC), hereditary leiomyoma RCC (HLRCC), the Birt-Hogg-Dube Syndrome (BHD), and tuberous sclerosis (TS). The von Hippel-Lindau tumour suppressor gene is mutated in more than 50% of sporadic cases of clear cell RCC.

Pathology

Renal cell carcinoma originates from the renal tubular epithelium. RCC has a number of distinct subtypes, each with a unique genetic basis and tumour biology. RCC is now classified into conventional clear cell constituting about 70% of renal cancers, papillary, chromophobe, oncocytic, and collecting duct carcinoma. Tumour spread occurs by direct extension into the peri-renal tissue or renal veins or by haematogenous metastasis and lymphatic dissemination. About 25% to 30% of patients have evidence of metastatic disease at presentation.

Clinical Features

Currently, more than 50% of patients with RCC are detected incidentally due to increased use of non-invasive imaging to evaluate a variety of non-specific symptoms. Incidentally detected RCC is generally smaller and of lower stage than symptomatic RCC. The classic triad of flank pain, gross haematuria, and palpable abdominal mass is now rare (6% to 10%), but when present, signifies an advanced stage of the disease. Patients with metastatic disease may present with symptoms, such as bone pains, chronic cough, etc. Paraneoplastic syndromes are seen in about 20% to 30% of patients with symptomatic RCC, such as hypertension due to increased renin secretion. According to the 2002 revision of the American Joint Committee on Cancer (AJCC)/Union for International Cancer Centre (UICC), TNM system is the currently accepted staging system for RCC.

Investigations and Work-Up

Contrast enhanced computed tomography (CECT) of chest, abdomen, and pelvis is the most important investigation for the assessment of a renal mass. A solid mass with significant heterogenous post contrast enhancement (due to characteristic high vascularity), which is less than that of the normal renal parenchyma is virtually diagnostic of RCC. Fine needle aspiration cytology/biopsy is rarely indicated when a renal abscess or infected cyst is suspected and when RCC must be differentiated from metastatic malignant disease or renal lymphoma.

Management

Surgery is the mainstay of treatment of localised RCC. Radical nephrectomy is the gold standard for patients with localised RCC and has a cure rate of 70% to 90%. The principles of radical nephrectomy include early ligation of renal vessels, removal of kidney and ipsilateral adrenal gland surrounded by the Gerota's fascia and regional lymphadenectomy from the crus of the diaphragm to the bifurcation of aorta or inferior vena cava. Presently, there is no role for adjuvant treatment after radical or partial nephrectomy.

Approximately one-third of patients with RCC present with metastatic disease and another 40% to 50% will develop metastasis some time during their natural history. The majority of these patients will die of disease within 12 to 24 months, if left untreated. RCC is somewhat unique amongst genitourinary cancers in being completely resistant to conventional chemotherapy drugs. Until recently the only available treatments for metastatic RCC were immunotherapeutic agents interferon alpha and interleukin-2. The response rates were less than 10% and there was considerable toxicity from these agents. Recently, a better understanding of the molecular perturbations in RCC has led to the development of a number of targeted agents with robust therapeutic effects in this disease.

The following drugs are currently in use for metastatic RCC:

1. Sunitinib

This is a small molecule drug that inhibits the tyrosine kinase inhibitor of vascular endothelial growth factor (VEGF) receptor; platelet derived growth factor, cKIT and FLT-3. It is

recommended as a first-line therapy in metastatic conventional clear cell RCC.

2. Bevacizumab

A monoclonal antibody against VEGF and is used in combination with interferon.

3. Everolimus and temsirolimus

These are inhibitors of the mammalian target of rapamycin (m-TOR) and recommended in poor risk patients and those who progress after other drugs.

4. Sorafenib

This is a small molecule oral multikinase inhibitor. It is recommended as second-line therapy.

Prognosis

The estimated 5-year survival rates for RCC range from 80% to 90% in low-risk non-metastatic patients to 10% in patients with metastatic RCC.

URINARY BLADDER CANCER

Bladder cancer is the commonest urological malignancy in India and the second most common genitourinary malignant disease in the world. Males are commonly affected (M:F= 2.4:1) and this malignancy occurs mostly in the elderly with median age at presentation of about 60 to 70 years.

Aetiology and Risk Factors

Cigarette smoking is the single most important environmental aetiological factor. Other risk factors include chemical exposure to aromatic amines, aniline dyes in industries, analgesic abuse, and schistosoma infestation in certain regions of the world.

Pathology

Carcinoma of bladder is a heterogeneous disease which presents as superficial, muscle invasive, or metastatic disease. Morphologically, the majority (70%) are exophytic papillary tumours confined to mucosa (Ta) or invade submucosa (T1). About 50% to 70% of superficial tumours recur and 5% to 20% of them progress to invasive disease. Histopathologically, the majority of bladder cancers are transitional cell carcinomas (90% to 95%). Low-grade tumours have high local recurrence rate but usually do not invade muscularis. High-grade superficial tumours have high propensity to transform to invasive tumours. All invasive tumours are high grade.

Clinical Features

Patients usually present with painless haematuria (80% to 90%) or with unexplained urinary frequency or irritative voiding symptoms. Lower urinary irritative and obstructive symptoms may be the sole presenting symptoms in the absence of haematuria. The currently accepted staging classification of primary bladder cancer is as follows:

Ta : Non-invasive papillary carcinoma
T1 : Invasion of lamina propria
T2 : Invasion of muscularis propria
T3 : Invasion of perivesical tissues
T4 : Invasion of adjacent organs or pelvic/abdominal wall

Investigations

Cystoscopic examination of the bladder and pathological evaluation of the resected lesion form the cornerstone of diagnosis. Transurethral resection of the bladder tumour (TURBT) is the most important test for judging the depth of tumour penetration. Inclusion of muscle in biopsy is essential. An important component of the work-up is examination under anaesthesia after TURBT to evaluate the presence of residual induration and mass. CECT of chest, abdomen and pelvis and urine cytology are the other investigations that are done at initial evaluation and follow-up.

Management

Treatment of non-muscle invasive disease

TURBT is the standard of care for superficial bladder cancers. The goal of TURBT in Ta/T1 bladder tumours is to make correct diagnosis and remove all visible lesions. These tumours are classified as low or high risk based on tumour grade, size, number, and invasion of lamina propria. Based on their risk stratification patients receive either intravesical chemotherapy or Bacillus-Calmette Guerin. They are followed up with serial cystoscopies after treatment to monitor for recurrence.

Treatment of muscle-invasive disease

Radical cystectomy is the preferred treatment for invasive bladder cancers in patients whose medical condition allows a major surgical procedure. Pelvic lymphadenectomy is routinely performed as a part of radical cystectomy for bladder cancers. Such patients may also benefit from neoadjuvant chemotherapy using either the MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin) or gemcitabine-cisplatin combinations. Bladder conservation can be done in selected patients with multi-modality treatment involving neoadjuvant chemotherapy followed by concurrent chemoradiation.

Chemotherapy for metastatic bladder cancer

The common sites of metastatic spread include lymph nodes, lung, liver, and bones. Chemotherapy is the standard therapy for patients with metastatic bladder cancer in good performance status. The gemcitabine-cisplatin combination is often used.

TESTICULAR CANCER

Testicular cancer constitutes about 1% of all malignancies in males in India. Germ cell tumours (GCT) comprise of 95% of malignant tumours arising from testis. These tumours predominantly affect young males. Testicular tumours in elderly males are usually lymphoma or seminoma.

Aetiology and Risk Factors

Numerous studies have established cryptorchidism as a major risk factor for the development of testicular cancer with the relative risk being 2.5 to 17 folds. Importantly this risk also extends to the contralateral normally descended testis indicating that the propensity for cancers is due to the abnormal gonadal development rather than malposition. The putative protective effect of orchiopexy is controversial and never well established. Patients with Klinefelter syndrome are also at increased risk for mediastinal GCT.

Pathology

Testicular GCT is considered by many to represent the malignant counterpart of normal embryonic components. It is classified into two major subgroups: seminoma and non-seminoma. Seminomas comprise about 40% of all germ-cell neoplasms and

are considered to have spermatocyte as the normal counterpart. Non-seminomatous GCT include embryonal carcinoma, endodermal sinus or yolk-sac tumour, choriocarcinoma, teratomas (mature, immature and with malignant transformation), and mixed tumours with more than one component. The most common genetic abnormality in GCT is an isochromosome of the short arm of chromosome 12. These tumours spread by lymphatics to retroperitoneal lymph nodes and haematogenously to lung, liver, and other sites. Pure seminomas are associated with raised lactate dehydrogenase (LDH), β–beta-hCG (less than 5 times) but never α-fetoprotein(AFP). Non-seminomatous GCT are often associated with raised β-hCG, LDH, and AFP which constitute valuable tumour markers that are useful in the diagnosis and follow-up. The most marked increase in β-hCG is seen in choriocarcinomas and the most marked increase in AFP is seen in endodermal sinus tumours.

Clinical Features

A testicular tumour usually presents as a painless scrotal swelling, heaviness, tenderness, and loss of testicular sensation. Involvement of retroperitoneal lymph nodes may produce back pain or abdominal swelling. Widely disseminated parenchymal disease in lungs, liver, bone, and brain is uncommon but, if present, may produce systemic symptoms. The currently accepted staging for testicular cancer is the TNM system that incorporates tumour markers in addition to the usual information on tumour, nodes, and metastases.

Stage I : Tumour confined to the testis/spermatic cord or scrotum with or without elevated markers

Stage II : Involvement of regional (retroperitoneal) lymph nodes

Stage III : Presence of distant metastasis to either non-regional lymph nodes/lung or other sites

In addition to the staging, metastatic GCT are classified into low, intermediate and high risk categories based on the histology (seminoma *versus* non-seminoma), location of the primary (gonadal *versus* extra-gonadal), location of the metastases (pulmonary *versus* non-pulmonary), and tumour marker levels. This International Prognostic Risk Stratification is important since treatment strategy is based on the risk category and it is accurately prognostic.

Investigations

The diagnosis of testicular cancer is based on clinical suspicion. High resolution bilateral trans-scrotal ultrasound can reliably differentiate a solid testicular mass from hydrocoele and paratesticular masses and is a useful initial diagnostic evaluation. In suspected case of testicular cancer, biopsy should not be performed. Serum tumour markers (AFP, β-hCG, LDH) and CECT scan of chest, abdomen and pelvis are required for staging and risk stratification.

Management

High inguinal orchiectomy is the initial procedure that is both diagnostic and therapeutic. Routine retroperitoneal lymphadenectomy in clinically and radiologically negative patients is controversial and not universally practiced. Tumour markers should be repeated after surgery. Subsequent treatment is planned according to histology, tumour marker levels, and metastasis.

Seminoma

Localised disease is curable with orchiectomy and either low-dose adjuvant radiotherapy to para-aortic nodes or single-dose carboplatin (dosed to an area under curve of 7) in more than 95% of patients. In view of the low toxicity of single cycle of carboplatin, this has become the standard of care in many institutions. Patients with non-bulky stage II disease are treated with radiation to retroperitoneal and ipsilateral pelvic lymph nodes, which results in risk of relapse less than 5%. An acceptable alternative is combination chemotherapy with the BEP (bleomycin, etoposide and cisplatin) or EP (etoposide and cisplatin) regimens. Patients with bulky stage II or stage III disease are treated with chemotherapy that results in cure rate of more than 90%. Post-chemotherapy retroperitoneal lymphadenectomy can prevent subsequent relapse in selected patients.

Non-seminomatous germ cell tumour

In patients with stage I and non-bulky stage II non-seminomatous GCT, 2 to 3 cycles of BEP or 4 cycles of EP result in cure rate of more than 95%. Some centres advocate prophylactic retroperitoneal lymph node dissection (RPLND) in patients with stage I disease to obviate the need for chemotherapy. In patients with bulky stage II and good risk stage III disease, the treatment of choice is BEP chemotherapy given up to 2 cycles beyond marker normalisation, which is usually a total of 3 cycles. Any residual masses post-chemotherapy should be surgically removed since these can harbour mature teratoma. Cure rates of more than 80% can be expected in this group of patients. In patients with intermediate and high risk metastatic non-seminomatous GCT, 4 cycles of the BEP regimen is considered a standard treatment, but this will be inadequate in up to half of these patients. These patients require second-line chemotherapy with more complex and toxic regimens. Surgical consolidation of residual post-chemotherapy masses is a critical component of a successful therapeutic strategy in these patients.

Prognosis

Testicular tumours are one of the most curable cancers even in the presence of metastatic disease. Localised tumours have long-term survival of more than 95%. Good risk metastatic tumours have 80% to 90% survival compared to 50% in high risk metastatic tumours.

PROSTATE CANCER

Prostate cancer is the most common non-cutaneous cancer among males in the West. The age adjusted incidence rate in urban Indian population is about 6 to 8 per 100,000 compared to 60 to 120 in the Western populations. This disparity is fuelled, at least partly, by the widespread adoption of prostrate specific antigen (PSA) screening in the latter regions. The natural history of clinically localised disease is variable, with lower-grade tumours having a more indolent course, while some high-grade lesions progress rapidly to metastatic disease. The indications for screening are controversial as it may result in treatment of those tumours that may never manifest in individual's life time. The United States Preventive Services Task Force specifically recommends against routine PSA screening in the population.

Aetiology and Risk Factors

Androgens are a major driving force for normal prostate development and are also implicated in its carcinogenesis. There is a high incidence of clinically occult cancers in autopsy series of older men dying of unrelated causes indicating that most cancers are not responsible for morbidity and mortality. Apart from increasing age, other risk factors for prostate cancer include high body mass index, Western lifestyle, and African-American ancestry.

Pathology

A large number of cancers arise from prostatic acinus and are adenocarcinomas. They are now universally graded according to the Gleason system that essentially scores the dominant and the next most common pattern along a scale of 1 (well differentiated) to 5 (poorly differentiated). The final score is obtained by adding the two scores, e.g. 4 + 3 = 7.

Clinical Features

Many patients are diagnosed because of incidental digital rectal examination and PSA estimation. Some patients present with haematuria, obstructive or irritative urinary complaints. Metastatic symptoms include weight loss and loss of appetite, bone pain or features of cord compression. Prostate cancer has a marked propensity to metastasise to bones, especially those in the axial skeleton. The classical bone metastasis from prostate cancer are osteoblastic. Other sites of metastasis include lymph nodes, lung, liver and brain. The most commonly used staging systems in clinical use are the TNM and the American Urological Association staging. It is useful to think of prostate cancer as organ (prostate) confined, locally advanced (involvement of seminal vesicle or regional nodes), and metastatic.

Investigations

The appropriate tests include trans-rectal ultrasound (TRUS), serum PSA, conventional MRI or MRI with endorectal coil, CECT of abdomen and pelvis, radionuclide bone scanning, and chest radiograph. TRUS-guided biopsies of involved and uninvolved peripheral regions are essential for establishing the diagnosis.

Management

The appropriate options for the management of localised low-stage cancers include watchful waiting, radical prostatectomy and external beam or interstitial radiation therapy. The first option is generally chosen for unfit patients. There is no conclusive evidence of the superiority of surgery over radiation, but the pattern of morbidity is different. Patients with high-risk cancers are candidates for adjuvant androgen deprivation therapy usually in the form of an luteinising hormone releasing hormone (LHRH) agonist like goserelin. In patients with locally advanced cancers, neoadjuvant hormonal therapy using androgen deprivation followed by local radiation is a common treatment approach. The hormonal manipulation is continued for up to 3 years in this group of patients. In patients with metastatic cancer, the initial treatment of choice is androgen deprivation therapy, either by bilateral orchidectomy or use of LHRH agonists. The initial addition of anti-androgen drugs like bicalutamide or flutamide to androgen deprivation ('total androgen blockade') has not been proven to be more efficacious compared to androgen deprivation alone. The anti-androgen drugs and ketoconazole are an option after disease progression on androgen deprivation. In patients with androgen independent tumours, the therapeutic options include withdrawal of anti-androgen drugs and chemotherapeutic agents like docetaxel, estramustine and mitoxantrone. Bisphosphonates like zoledronic acid have been shown to reduce the skeletal morbidity and symptoms in patients with bone metastasis. Recently, newer drugs like abiraterone (an androgen biosynthesis inhibitor) and cabazitaxel (a chemotherapeutic agent) have been approved for advanced prostatic cancer.

CARCINOMA OF PENIS

It is an uncommon malignancy in Western countries, but in India and other developing countries it is not so uncommon. In some parts of Asia, Africa and South America, its incidence is as high as 10% of all cancers as compared to 3% in developed countries. In recent times, there has been some decrease in its incidence, which may be attributed to better personnel hygiene and health awareness.

Aetiology

Penile cancer has been very strongly associated with poor local hygiene and phimosis. In various studies phimosis was associated with penile cancer in more than 50% of cancers. The accumulation of smegma under the prepuce leading to irritation and secondary bacterial infection has been proposed to be the mechanism of cancer development. Neonatal circumcision as practised by Jewish community has been found to virtually eliminate the risk of cancer of penis. Penile cancer has been strongly associated with phimosis as it is found in more than half of the patients in most large series. Circumcision in childhood or after puberty does not have benefit comparable to neonatal circumcision.

Infection with human papillomavirus (HPV) particularly HPV 16, exposure to multiple sexual partners, as well as use of tobacco products has been found to be associated with penile cancer. Thus, avoidance of tobacco products, neonatal circumcision, and maintaining penile hygiene represent important preventive strategies against penile cancer.

Pathology

The most common histology of penile cancer is squamous cell carcinoma, which constitutes more than 95% of all penile cancers, while others may include melanoma, basal cell carcinoma, lymphoma, and sarcomas. The squamous cell carcinomas are graded using Broders' classification. Low-grade tumours (grade I and II), which are typically confined to prepuce and glans penis, constitute nearly 80% of penile cancers. On the other hand, most lesions involving shaft of the penis are high-grade (grade III). Thus, grade and stage are often correlated. Lymph node metastasis depends upon the vascular invasion in the surgical specimen. The exuberant variant of squamous cell carcinoma known as verrucous carcinoma has a very low potential for lymph node metastasis and therefore has a good prognosis.

Penile cancers are associated with various pre-malignant stages which allow clinicians the opportunity for early diagnosis and cure. The various pre-malignant lesions are leucoplakia, balanitis xerotica obliterans, Buschke löwenstein tumour.

Clinical Features

Local signs and symptoms of erythema or induration to a frankly ulcerated, fungating, foul-smelling mass is the common presenting feature, while pain is not usually prominent. The prepuce and glans are most commonly involved and it is usually associated with a tight phimosis. In late stages of cancer, the shaft of penis get involved leading to its destruction. Urethral involvement is late and it usually results in urethral erosion leading to multiple urethral fistulas. In India and other developing countries, it has been found that the 50% of patient's delay taking medical advice by up to 1 year.

Diagnosis and Staging

The work-up includes thorough genital and inguinal nodes examination to evaluate the local and regional extent of disease. The most important prognostic marker in penile cancer is local lymph node involvement. The most common metastatic sites are bone, lung, and liver. The TNM classification is used to stage the primary tumour and the extent of nodal metastasis.

In early stage, local disease, no radiologic imaging is required while in obese patients, a CECT pelvis may be done to evaluate the inguinal nodes status and in few aggressive cancers, a contrast-enhanced MRI may be required.

Management

Surgical therapy

The management of penile cancer is mainly surgical and in selected cases, radiotherapy is done. The treatment of the primary lesion includes a 2 cm proximal margin of resection to avoid local recurrence and is the standard of care. Leaving the patient with inadequate penile length for hygienic upright micturition and sexual intercourse should be avoided. The partial or total penectomy is done depending upon the primary cancer stage.

In advanced stages (T4), various operative procedures include emasculation hemipelvectomy, or even hemicorpectomy.

Radiotherapy

It is effective in a select group of patients. It is attractive from a cosmesis point of view but has significant disadvantages in the form of tumour recurrence rate. Radiation therapy permits preservation of the penis, thereby obviating the psychosocial and physical morbidity caused by partial or total penectomy. External-beam and brachytherapy techniques have been used for treatment of the primary cancer. Circumcision is usually recommended before the radiation therapy to prevent post radiation secondary phimosis and it also helps in better evaluation of tumour extent. Although radiation has been shown to control early (T1 and T2) lesions with a 65% to 80% success rate, treatment of more advanced T-stage penile cancers is fraught with local recurrences (20% to 40%) and significant risk of tumour progression to nodal and systemic disease with loss of the window of curability.

21.12 Gynaecological Malignancies

PP Bapsy, Ankit Jain

Gynaecological malignancies constitute 15% of all cancers in women and remain a major problem throughout the world. In India, cancer of the cervix uteri is the most common cancer in women.

CARCINOMA CERVIX

Cervical cancer is the second most common malignancy in women worldwide, and remains a leading cause of cancer deaths in women from developing countries. It had bimodal age peaks, the first being in the third decade and the second in the sixth decade with median age at 51.4 years. It is one of the cancers which showed a marked change in epidemiological trend that was attributed to mass screening with Papanicolaou tests (Pap smears). Due to inadequacy of screening and social attitudes cancer cervix in developing countries is diagnosed at an advanced stage.

Aetiology

Early epidemiological data demonstrated a direct causal relationship between cervical cancer and sexual activity. Major risk factors observed includes; sexual intercourse at a young age, multiple sexual partners, promiscuous male partners, and history of sexually transmitted diseases.

However, the search for a potential sexually transmitted carcinogen had been unsuccessful until breakthroughs in molecular biology enabled scientists to detect a viral genome in cervical cells. Strong evidence now implicates human papilloma viruses (HPV) as a prime suspect. Approximately 95% of the cervical cancers are associated with HPV. The high-risk HPV includes types 16, 18, 31 and 33. The disease is aggressive in HPV-positive individuals. Three main factors have been postulated to influence the progression of low-grade squamous intra-epithelial neoplasia (SIL) to high-grade SIL. These include the type and duration of viral infection and high-risk HPV type.

Natural History

The squamo-columnar junction of the cervix is the most common site for continuous metaplastic changes and most cancers arise from this zone. The mean age of women with cervical intra-epithelial neoplasia (CIN) is 15.6 years younger than women with invasive cancer; suggesting a slow progression of CIN to carcinoma *in situ* (with an intact basement membrane) and invasive cancer (invasion beyond the basement membrane). It may later penetrate the cervical stroma and invade lympho-vascular channels.

Cervical cancer usually follows a relatively orderly pattern of metastatic progression. Spread may occur by direct invasion into cervical stroma, corpus vagina and parametrium, lymphatic permeation and metastasis which in turn is taken into consideration for staging. Although cervical cancer can spread to all pelvic nodes, the obturator nodes are most frequently involved. Haematogenous spread occurs most commonly to lung, liver and bone, less common sites are bowel, adrenal glands, spleen and brain.

Pathology

The various pathological types of cervical cancer are listed in **Table 1**.

Table 1: Histological Types of Carcinoma Cervix

Squamous cell cancer
Anaplastic small cell cancer
Neuro-endocrine differentiation
Adenocarcinoma
Others-mixed Müllerian
Adenosarcoma
Leiomyosarcomas
Lymphoma
Melanoma
Metastatic-breast, colon

Clinical Features

Abnormal vaginal bleeding (post-coital, inter-menstrual, post-menstrual or post-menopausal) is the commonest symptom. In sexually inactive women, the disease is asymptomatic until late stage. Malodorous discharge may arise due to invasion of bladder or bowel which occurs very late in the course of the disease. Examination usually reveals exophytic, endophytic, ulcerative, or polypoid lesions. It should include palpation of groin nodes, liver, and supraclavicular areas to exclude metastasis.

Diagnosis

Early diagnosis can be extremely difficult due to asymptomatic nature of early disease, origin of some tumours in the endo-cervical canal, and false-negative Pap smears.

Colposcopy

Colposcopy is the examination of epithelium of the cervix, genital tract, and ano-genital area using magnified illumination after application of specific solution (3% to 5% acetic acid, Lugol's iodine) to detect abnormal appearances consistent with neoplasia or to affirm normality. The characteristic appearances arise from magnification and illumination of underlying capillaries and abnormal Pap smear.

Biopsy

Obvious tumour growth should undergo punch biopsy for histological confirmation. A cervix that appears unusually firm or expanded should be subjected to a biopsy and endocervical curettage (ECC).

Once the diagnosis is established, imaging studies are performed for staging purposes. A routine chest radiograph

should be obtained to help rule out pulmonary metastasis. Computed tomography (CT) of the abdomen and pelvis is performed to look for metastasis in the liver, lymph nodes, or other organs and to help rule out hydronephrosis/hydroureter. Trans-vaginal ultrasound (TVS) is recommended wherever CT is not performed. Cytoscopy is usually reserved to confirm the abnormal findings in the CT/TVS. Magnetic resonance imaging (MRI) delineates better than CT, hence it is likely to be a more useful imaging study to decide on operability.

Screening

Screening for cervical cancer is one of the most prevalent and successful public health measures for the prevention of cancer. False-negative rate for Pap smear is 10% to 18% and a negative Pap smear should not be relied on in symptomatic patients. Sensitivity ranges from 50% to 98%. A simple flow-chart of the management of abnormal Pap smear is shown in **Figure 1**.

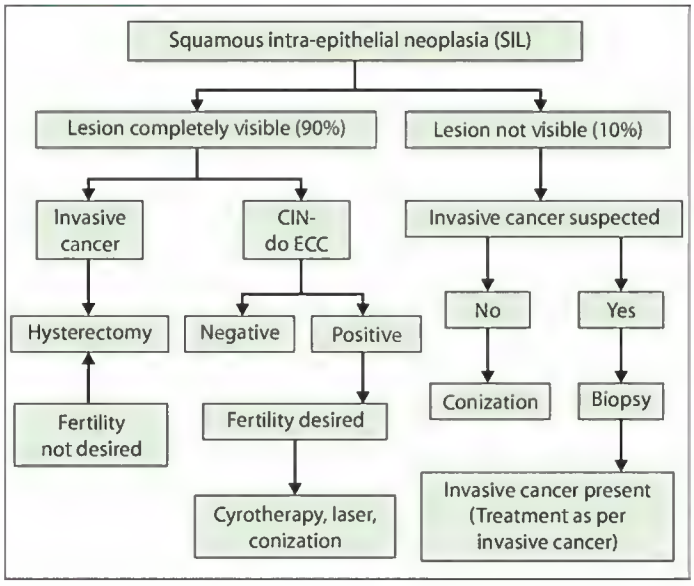

Figure 1: Management of abnormal Pap smear.

CIN = Cervical intra-epithelial neoplasia; ECC = Endocervical curettage.

American Cancer Society screening suggests Pap test and pelvic exam yearly for all women who have reached 18 years of age. After three normal tests, Pap tests can be carried out less often at the discretion of the physician. The recent WHO guideline recommends at least one Pap smear in the lifetime of women in developing countries. Indian Council of Medical Research recommends at least one Pap smear before the age of 40 years.

Staging

The International Federation of Gynecology and Obstetrics (FIGO) or TNM staging system is followed all over the world. The comparison of the staging systems with 5-year survival is shown in **Table 2**.

Prognostic Factors

The FIGO stage of the cervical cancer is the most important prognostic factor (**Table 2**). Other prognostic factors include patient's age, performance status, and biological markers like aneuploidy and S phase fraction.

Table 2: FIGO Staging of Cervical Cancer with 5 years Overall Survival (OS)

TNM	Cervix Uteri	FIGO	5 Years Survival
Tis	*In situ*	0	100%
T1	Confirmed to uterus		I
T1a	Diagnosed only by microscopy	IA	>95%
T1b	Clinically visible or microscopic lesion, ≤ 4cm	IB	IB 80 to 90%
T2	Beyond uterus but not pelvic wall or lower third vagina		II
T2a	No parametrium	IIA	80%
T2B	Parametrium	IIB	65 to 75%
T3	Lower third vagina/pelvic wall hydronephrosis		III
T3A	Lower third vagina	IIIA	40 to 50%
T3b	Pelvic wall / hydronephrosis	IIIB	30 to 40%
T4	Mucosa of bladder /rectum; beyond true pelvis	IVA	10 to 15%
M1	Distant metastasis	IVB	0%

Treatment

Stage IA: The treatment of choice for stage 1A disease is surgery—total hysterectomy; radical hysterectomy and conization are accepted procedures. Intra-cavitary radiation is an option for selected patients.

Stage IB or IIA: For patients with stage IB or IIA disease, treatment options are either combined external beam radiation (presently) concurrent chemo-radiation with cisplatin given at 40mg/m^2 per week during the course of radiation therapy with brachytherapy or radical hysterectomy with bilateral pelvic lymphadenectomy. Most retrospective studies have shown equivalent survival rates for both procedures, although such studies usually are flawed due to patient selection bias and other compounding factors. However, a recent randomised study showed identical overall and disease free survival rates.

Stage IIB/III/IV A: Concurrent chemo-radiation is the treatment of choice.

Stage IV B: Usually treated with irradiation to palliate central disease or distant metastasis. Chemotherapy with cisplatin, 5-FU, ifosfamide, paclitaxel, irinotecan, gemcitabine may be tried, but responses are ill-sustained and survival benefit is minimal.

Recurrence

Recurrence following surgery is treated with radiotherapy. It is often used individually to control bleeding, pelvic pain, or urinary or partial large bowel obstructions from pelvic disease. Palliation with chemotherapy is an alternative if initial modality of treatment is radiation.

UTERINE CANCER

Endometrial cancer is the fourth most common cancer in women, following breast, lung, and colorectal cancer, in that order. However, in developing countries, it is much less common than carcinoma of the cervix. The median age of persons with this malignancy is early in the 7th decade of life, although most patients are aged 50 to 59 years. Approximately

5% cases of endometrial carcinoma can be in women younger than 40 years of age.

Aetiology

Multiple epidemiological risk factors have been identified which include obesity (10-fold increase), nulliparity (2-fold) and late menopause (aged >52 years), all secondary to the unopposed oestrogen action. In recent times, tamoxifen, one of the most widely used anticancer drug has been suggested to cause an increased incidence of carcinoma body uterus. Other factors include smoking, sedentary lifestyle, and some genetic syndromes.

Natural History

Endometrial cancer may originate in a diffuse multi-focal pattern. Early tumour growth is characterised by an exophytic and spreading pattern. Later tumour growth is characterised by myometrial invasion and growth towards the cervix. Four routes of spread occur beyond the uterus. Direct/local spread accounts for the majority of local extension beyond the uterus. Lymphatic spread to pelvic, para aortic, and, rarely, inguinal lymph nodes.

Haematological spread is responsible for metastases to the lungs, liver, bone, and brain (rare). Peritoneal/trans-tubal spread results in intraperitoneal implants, particularly with uterine papillary serous carcinoma (UPSC), similar to the pattern observed in ovarian cancer.

Pathology

Sixty per cent of endometrial carcinomas are adenocarcinomas. Other histological subtypes include adenosquamous, clear cell and papillary serous carcinomas. Sarcomas make up about 4% of the uterine corpus malignancies, including carcinosarcomas or mixed homologous Müllerian tumours (48% to 50%), leiomysarcomas (38% to 40%) and endometrial sarcomas containing histological components foreign to the uterus, such as rhabdomysarcomas, osteosarcomas, and chondrosarcomas.

Clinical Features

The most common symptom in up to 90% of women is post-menopausal bleeding. Most women recognise the need for prompt evaluation, although only 10% to 20% of the women with post-menopausal vaginal bleeding have a gynaecological malignancy. Because of this prompt evaluation, 70% to 75% of the women are diagnosed with surgical stage I disease. Because bleeding usually occurs from the endometrium, pelvic examination findings may be entirely normal, with no gross evidence of disease on the cervix and with a normal-sized uterus.

Screening

Currently, no screening tests for cancer of the uterus are recommended for asymptomatic women.

Diagnosis

Besides routine haematological tests, there is no specific marker for the carcinoma body uterus. The histological confirmation is obtained by endometrial sampling.

Imaging

Trans-vaginal ultrasound (TVS) is the commonest investigation employed. Chest radiographs are useful in the work-up to exclude distant metastases. Computed tomography and/or MRI are typically not necessary in the work-up of endometrial cancer or uterine sarcomas because the first-line therapy for the vast majority of these patients includes exploratory surgery. Local extension and metastatic disease, requiring comprehensive staging, can be predicted using clinical evidence, including obvious cervical disease and high tumour grade on the endometrial biopsy specimen.

Staging

The commonly used FIGO staging is represented in **Table 3**.

Table 3: FIGO Staging System for Uterine Cancer

Stage IA:	Tumour limited to endometrium
Stage IB:	Invasion to less than one half the myometrium
Stage IC:	Invasion to more than one half myometrium
Stage IIA:	Endo-cervical glandular involvement only
Stage IIB:	Cervical stromal invasion
Stage IIIA:	Tumour invades serosa and/or adnexa and/or positive peritoneal cytology
Stage IIIB:	Vaginal metastasis
Stage IIIC:	Metastasis to pelvic and/or para-aortic lymph nodes
Stage IVA:	Tumour invasion of bladder and/or bowel mucosa
Stage IVB:	Distant metastases including intra-abdominal and/or inguinal lymph nodes
According to the degree of histological differentiation they are graded into:	
Class G1:	Non-squamous or non-morular solid pattern of 5% or less
Class G1:	Non-squamous or non-morular solid pattern of 6% to 50%
Class G1:	Non-squamous or non-morular solid pattern of more than 50%

Treatment

Surgery is the treatment of choice and whenever feasible the patients should undergo either simple or modified radical hysterectomy. Radiation therapy, chemotherapy and hormonal therapy play a minor role in the treatment of uterine cancers. Of these only radiotherapy has some place in primary therapy for early endometrial cancer and uterine sarcomas. It is (total dose to tumour of up to 80 Gy) the treatment of choice for those patients who are poor surgical candidates. It is used in adjuvant setting in cases of node-positive disease and positive surgical margins. It can also be used with palliative intent in stage IVA.

Role of hormone therapy is limited and medroxyprogesterone acetate. Megestrol therapy is efficacious for those low-grade tumours that are oestrogen and/progesterone receptor-positive in adjuvant and palliative settings.

If advanced disease is not amenable to localised/whole abdominal radiotherapy or hormonal therapy, chemotherapy is initiated. Doxorubicin, cisplatin, and taxanes are the most effective agents used. Combination of the two agents increases the progression-free interval, with a complete remission in about 10% to 15% of the cases and a partial response in 25%.

Survival

Overall 5-year survival rates for all grades and histological subtypes are 87%, 72%, 51%, and 9% for surgical stage I, II, III, and IV disease, respectively.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic neoplasia (GTN) can be benign or malignant. Histologically, it is classified into a hydatidiform mole, an invasive mole (chorioadenoma destruens), choriocarcinoma, and a placental site trophoblastic tumour (PSTT). Three per cent of patients with hydatidiform mole develop choriocarcinoma. The incidence is 1500 times more after molar pregnancy than normal term delivery. Choriocarcinoma is twice as common in antecedent hydatidiform mole (29% to 83%) followed by ectopic pregnancy (11% to 42%) and live-births (5% to 34%).

Pathology

Histologically, hydatidiform moles look like placental tissue, but oedema of the villi demonstrates varying sizes. During the proliferation of the trophoblast there is no/or scarce development of foetal blood vessels. Therefore, tumour relies on vessels of the tissue it invades. The syncytio-trophoblast is largely responsible for secretion of β-human chorionic gonadotrophin (β-hCG). Choriocarcinoma are aneuploid and can be heterozygous, depending on the type of pregnancy from which the choriocarcinoma arose. If a hydatidiform mole preceded the choriocarcinoma, the chromosomes are of paternal origin. Maternal and paternal chromosomes are present if a term pregnancy preceded the choriocarcinoma.

Clinical Features

Majority of the patients present within a year of an apparently normal pregnancy or non-molar abortion. Vaginal bleeding or blood-stained discharge may be associated with or without abdominal pain and mass. Extra-uterine masses and ovarian involvement are common. One-third of the patients may present with features due to distant pulmonary or brain metastasis. Occasionally thyrotoxicosis is present with very high levels of hCG because of cross-reaction between alpha subunit of hCG and TSH. Common sites for metastasis are lungs (80%), vagina (30%), pelvis (20%) and brain (10%). Bowel metastasis (<5%) may present with haemorrhage, intra-peritoneally or within the lumen of the bowel.

Investigations

Besides routine haematology and biochemical parameters, β-hCG is mandatory in all the patients. It is a peptide with half-life of 24 to 36 hours and the most sensitive and specific marker for trophoblastic tumours. It gives an indication of tumour volume. Serial measurements are used to monitor progress of disease and response to therapy.

Imaging

Chest radiograph and ultrasound of abdomen and pelvis are mandatory in all cases. Computed tomography of the brain is indicated in symptomatic cases.

Staging

The official International FIGO staging of gestational trophoblastic disease is: stage I—confined to the uterus, II—limited to genital structures, III—lung metastases, IV—other metastases.

Prognosis

Revised WHO scoring system is followed to determine the prognosis (**Table 4**).

Table 4: WHO Scoring System

Prognostic factor	0	1	2	4
Age	<35	>35		
Pregnancy	Mole	Abortion	Term	
Interval	<4 mo	4 to 6 mo	7 to 12 mo	>12 mo
Serum β-hCG	<1,000	<10,000	<1,00,000	>1,00,000
Site of Metastases	Lung	Spleen kidney	Gastroin-testinal	Liver, brain
Size of largest tumour			3 to 5 cm	>5 cm
Number of metastases		1 to 4	4 to 8	>8 cm
Prior chemotherapy			Single agent	Multiple

Total score: 0 to 4, low risk; 5 to 7, intermediate risk; >8, high risk for death.

Treatment

A scheme for management of gestational trophoblastic disease is shown in **Figure 2**. The brief protocol is represented in **Table 5**.

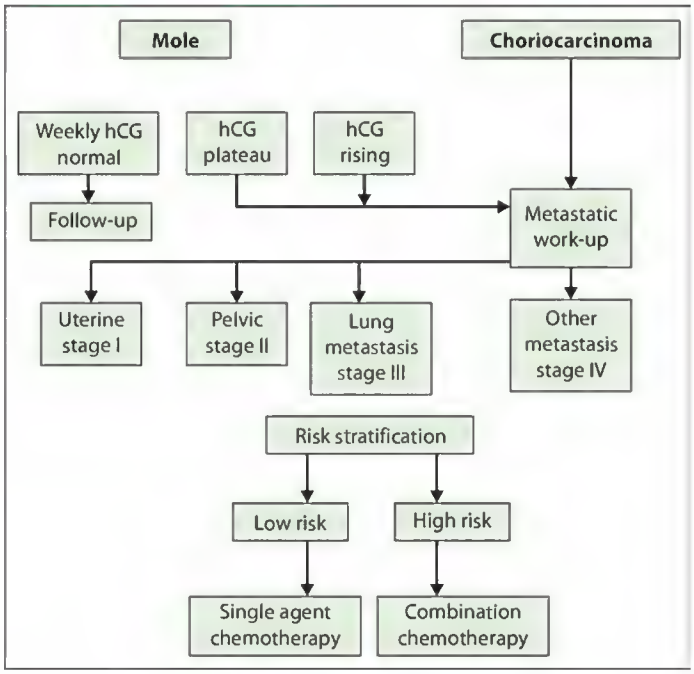

Figure 2: Management of gestational trophoblastic disease.

Hydatidifom mole is treated by suction and evacuation. Hysterectomy is reserved for resistant cases, persistent β-hCG elevation, and choriocarcinoma in excised tissue, metastatic disease, and bleeding or placental site gonadal trophoblastic tumours. β-hCG levels should be done weekly during treatment and chemotherapy should be administered for two cycles after the normal β-hCG level

Patients should be under close follow-up with monitoring of β-hCG levels done weekly for the first six weeks and month if any affected or rise in β-hCG levels denotes resistant disease and warrants change of chemotherapy regimen.

Survival

Low-risk patients have a complete cure. Patients with medium risk have a 98% long-term survival. Prognosis disease treated with combination chemotherapy have 93% survival if they have

Table 5: The Brief Protocols for Gestational Trophoblastic Disease

Patient's Characteristics	Regimen	Schedule and Doses	Regimen	Repeated
Non-metastatic or low risk metastatic	MTX ACT-D	Methotrexate Leucovorin Actinomycin	1 mg/kg IM days 1,3,5,7 0.1 mg/kg IM days 2,4,6,8 10 to 13 µg/kg IV x 5 days	Every 2 weeks Every 12 days

not received prior chemotherapy. Long-term survival is 74% for patients who received prior chemotherapy. Relapse after successful therapy does not indicate fatal outcome, even in high-risk group. Complete remission is possible in these patients with chemotherapy with or without surgery.

Follow-Up

Because of the potential to recur, patients should be followed up with β-hCG estimations. Patients are advised contraception for a year after completion of chemotherapy because raised β-hCG levels due to pregnancy may mask relapse and follow-up is then discontinued during pregnancy and then continued 3 weeks after delivery.

OVARIAN CANCER

Ovarian cancer is the most common cause of cancer death from gynaecologic tumours in the United States. Early disease causes minimal, non-specific, or no-symptoms making at least 70% of patients to present in an advanced stage.

Therefore, it is described as 'silent killer'; however, recent improvements in identification of the women at high risk for ovarian cancer, as well as improved imaging techniques, increase the likelihood of early detection. Many histological types exist, though more than 90% are epithelial tumours. The remaining are either stromal or germ cell tumours.

Pathophysiology

The commonly observed risk factors are increasing age and fertility. One common thing associated with all these factors is increased ovulation (which in turn causes rapid proliferation, and aberrant repair might generate a malignant clone). Most theories hypothesise that ovarian cancer begins with the de-differentiation of the cells overlying the ovary, which will be incorporated into it during ovulation and then proliferate. Ovarian cancer arises from coelomic epithelium. The other cancers arising from coelomic epithelium are fallopian tube carcinoma and primary peritoneal carcinoma.

Genetic factors might also play an important role in an estimated 10% of the patients. It has site-specific inheritance pattern and the patients are relatively young (30 to 50 years). Other risk factors include breast carcinoma (BRCA mutation - 60% risk of having ovarian cancer).

Pathology

The major pathological variants are described in **Table 6**. The most common histological type of epithelial ovarian cancer is serous type.

Table 6: Classification of Ovarian Neoplasms

Tumours of epithelial origin	Serous, mucinous, endometroid, clear cell
Germ cell tumours	Dysgerminomas, carcinoma, endodermal sinus tumour (yolk sac), teratomas-immature (embryonal)
Stromal tumours	Gonadoblastoma, Sertoli-Leydig cell, tumours, sex cord
Mesenchymal tumours	
Metastatic	Krukenberg
Miscellaneous	Fibromas, lymphoma

There is a small subgroup of patients who can present with borderline ovarian tumours also called as epithelial ovarian cancer with low malignant potential. These tumours present at younger age and surgery is the main stay of treatment.

Mode of Spread

Ovarian carcinoma can spread by local extension, lymphatic invasion, intra-peritoneal implantation (most common and recognised characteristic), haematogenous dissemination, and trans-diaphragmatic passage.

Clinical Features

The signs and symptoms of ovarian cancer are non-specific. Most patients present with symptoms of several months duration. Symptoms include abdominal/pelvic pain, vaginal bleeding, bloating, abdominal distension, irregular menses, or change in bowel habits. Majority of the patients present in advanced stage (III or IV). Palpable abdominal mass and ascites are the commonly described presenting features.

Diagnosis

Routine pre-operative tests include complete blood count (CBC), chemistry panel (including liver function tests), and a cancer antigen 125 assay (CA-125).

Cancer antigen-125

It is quite sensitive and all the women in reproductive age with complex cyst of more than 8 cm should undergo CA-125 monitoring. If the titres are rising, it is almost diagnostic of ovarian cancer. It is also useful to monitor the response to therapy. It should be remembered that it may be within normal limits in 50% of women with early ovarian cancer. If a patient presents with a raised CA-125 prior to surgery it should be used for follow-up after treatment. However, this is controversial, as treatment for biochemical relapse and for clinical relapse does not alter the natural history of disease.

Other markers

Include α-fetoprotein, β-hCG, and LDH whenever germ cell tumour is one of the differential diagnoses especially in younger women.

Imaging

Transvaginal USG (TVS) is recommended whenever there is dilemma. However, routine imaging is not required in all patients in whom ovarian cancer is highly suspected pelvic and abdominal CT scan is warranted in all cases prior to therapy to monitor the response. Chest radiographs are considered routine but CT scan of the chest is seldom indicated.

Staging

Ovarian cancer is surgically staged and the FIGO system is shown in **Table 7**.

Table 7: FIGO Staging System for Ovarian Cancer

Stage I: Growth limited to the ovaries

- Ia : Growth limited to one ovary, no ascites, no tumour on external surface, capsule intact
- Ib : Growth limited to both ovaries, no ascites, no tumour on external surface, capsule intact
- Ic : Tumour either stage Ia or Ib but with tumour on surface of one or both ovaries, ruptured capsule, ascites with malignant cells or positive peritoneal washings

Stage II: Growth involving one or both ovaries, with pelvic extension

- IIa : Extension and/or metastasis to the uterus or tubes
- IIb : Extension to other pelvic tissues
- IIc : Stage IIa or IIb but with tumour on surface of one or both ovaries, ruptured capsule, ascites with malignant cells from positive peritoneal washings

Stage III: Tumour involving one or both ovaries, with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; superficial liver metastases equal stage III

- IIIa : Tumour grossly limited to pelvis, negative lymph nodes but histological proof of microscopic disease on abdominal peritoneal surfaces
- IIIb : Confirmed implants outside of pelvis in the abdominal peritoneal surface; no implant exceed 2 cm in diameter and lymph nodes are negative
- IIIc : Abdominal implants larger than 2 cm in diameter and/or positive lymph nodes

Stage IV: Distant metastasis, pleural effusion must have a positive cytology to be classified as stage IV; parenchymal liver metastasis equals stage IV

Prognostic Factors

Stage at presentation and volume of the disease after surgery are the most important risk factors. Patients with limited disease are classified as having low risk for recurrence if they have grade 1 or 2 disease, no tumour on external surface of the ovary, negative peritoneal cytology, no ascites, and tumour growth confined to the ovaries. They will be labelled as high risk if they have any of the above features. The other factors include CA-125 levels, age, performance status, and histological subtype (mucinous and clear cell having poor prognosis).

Treatment

Surgery and chemotherapy are the main modalities with radiation having a minimal role.

Surgical care

The standard care for ovarian cancer includes a primary staging and cyto-reductive or de-bulking surgical exploration (primary and secondary look). The staging procedure should include peritoneal cytology, multiple peritoneal biopsies, omentectomy and pelvic and para-aortic lymph node sampling.

Chemotherapy

For post-operative treatment, chemotherapy is indicated in all patients with ovarian cancer except those surgical-pathological stage I disease with low-risk characteristics. The single most active agent is platinum analogue (cisplatin and carboplatin) followed by taxanes. Other agents include alkylating agents (Cyclophosphamide, Ifosfamide, Melphalan) anthracyclines (Liposomal Doxorubicin, Adriamycin), gemcitabine, etoposide and topotecan. The present standard of therapy is a combination of taxanes with platinum analogues (T + P) showing maximum benefit compared to any other regimen.

Stage I: Total abdominal hysterectomy (TAH) with bilateral salpingo-oophorectomy (BSO) is the treatment of choice. Intra-peritoneal cisplatin or P32/pelvic radiation are rarely used in view of their higher toxicity, recurrence rates and availability of better and safer surgical alternatives.

Stage II/III: Options include aggressive primary cytoreductive surgery followed by chemotherapy (T + P) or neo-adjuvant chemotherapy followed by surgery. This choice is case to case dependent.

Stage IV: At present the intent is palliation and any of the above mentioned agents can be used. Single agent sequential is better in terms of quality of life of the patient compared to combination chemotherapy and the survival results are almost same. Other investigational agents are angiogenesis inhibitors and small molecular tyrosine inhibitors whose efficacy is yet to be proven.

Prognosis

Prognosis remain poor with 5-year survival rates for stage I, II, III, IV of 73%, 45%, 21%, and 5% respectively. Though in the early stages of treatment, a survival advantage was seen with the advent of taxanes and platinum-based chemotherapy, the situation in high-risk patients is far from satisfactory.

Prevention

Oral contraceptives (for general population) and prophylactic oophorectomy (for genetically predisposed patients) have been

tried as primary prevention modalities with the latter showing promising results. Secondary prevention, including routine pelvic examination, CA-125 levels and TVS, does not alter the cancer related mortality.

SEX CORD STROMAL TUMOURS

Commonest in the category is granulosa cell tumour, followed by Sertoli-Leydig cell tumours. They have excellent prognosis as they present in early stage (owing to hormonal effects like precocious puberty, virilisation, post-menopausal bleeding). Surgery is the treatment of choice (unilateral salpingo-oophorectomy in reproductive and pre-menarche females and TAH with BSO in menopausal women). Chemotherapy has a minimal role and whenever tried it is either with BEP (bleomycin, etoposide and cisplatin) or CAP (cyclophosphamide, adriamycin and cisplatin).

Other agents have minimal response rates. It can be tried prior to surgery to down stage or as a palliative treatment in stage IV disease. Hormonal agents like progestins also palliate symptoms in some patients and few reports suggest that they may prevent relapses in high-risk patients.

GERM CELL TUMOURS

These are uncommon in elderly and usually present in young women with an early stage disease. Most of the tumours are dysgerminomas. They are bilateral and often spread to retroperitoneal lymph nodes, they are highly radio and chemo sensitive, and either modality can be used in adjuvant setting for early stage disease after surgery. The remainder are predominantly unilateral with haematogenous metastases on occasions. Fertility can be preserved in vast majority of the patients with conservative surgical approaches and post-operative chemotherapy (BEP- the commonest regimen). Except for stage 1A, chemotherapy is indicated for all patients. Most patients have excellent prognosis even in advanced stages of disease.

VAGINAL CANCER

Primary cancer of the vagina constitutes 1% to 2% of the malignant neoplasms of the female genital tract; cure rates of even advanced cases should now be comparable with those of cervical cancer due to improved techniques of radiation therapy.

Eighty-four per cent of carcinomas involving the vagina are secondary, usually from cervix (32%), endometrium (18%), colon and rectum (9%) or vulva (6%). Endometrial carcinoma and choriocarcinoma commonly metastasise to the vagina, whereas tumours from bladder or rectum invade the vagina directly.

Radical surgery has been the mainstay of treatment. Radiotherapy may be effective in selected patients. The overall prognosis for patients with vaginal melanoma is poor because most cases present with deeply penetrating lesions at the time of diagnosis.

VULVA CANCER

Vulva cancers are usually squamous cell carcinomas diagnosed after the age of 60 years. The clinical presentation is usually a mass lesion which is treated with surgical excision. Pelvic node dissection and radiotherapy are used in advanced stages. Mitomycin C, bleomycin, cisplatin, and 5-FU are active but there is no definitive role for chemotherapy. Other cutaneous neoplasm like melanoma can also occur in this region. Paget's disease of the vulva can often present as a red inflamed pruritic mass.

FALLOPIAN TUBE MALIGNANCIES

These are the rarest of all gynaecological malignancies that are present in an early stage with symptoms pertaining to obstruction (pain) or mass (lump on abdomen). Majority of them are adenocarcinomas. The staging system, treatment and prognosis are very similar to carcinoma ovary.

21.13 Soft Tissue Sarcomas

Avinash Deo

INTRODUCTION

Sarcomas are mesenchymal tumours. These are divided into two groups: (i) bone sarcomas, and (ii) soft tissue sarcomas (STS). Soft tissue sarcomas are sarcomas of muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Soft tissue sarcomas are the commonest sarcomas. The group is heterogeneous in terms of histology and biological behaviour.

AETIOLOGY

The aetiology of most STS is unknown. Genetic factors, radiation, lymphoedema, and exposure to chemicals have been associated with STS. They do not appear to arise from the mature cell types they resemble. This is evident from the occurrence of sarcomas in areas where normal counterparts are absent, e.g. synovial sarcoma in the head and neck, and occurrence of sarcomas without a normal counterpart, e.g. peripheral neuroectodermal tumour.

Conditions with Predisposition to Soft Tissue Sarcomas

Soft tissue sarcomas have been associated with retinoblastoma, Li Fraumani syndrome, neurofibromatosis, Gardner's syndrome, naevoid basal cell carcinoma syndrome and tuberous sclerosis, which are conditions associated with mutations in tumour suppressor genes. Many of these sarcomas occur in radiated field, e.g. occurrence of head and neck STS in survivors of retinoblastoma.

Radiation

Radiation is probably the most convincing documented aetiological agent for STS. The sarcomas associated with radiation (in decreasing frequency) are osteosarcoma, malignant fibrous histiocytoma (MFH), and angiosarcoma or lymphangiosarcoma. Radiation-associated sarcomas have a reputation for originating close to the penumbra of radiotherapy fields. These have a poor prognosis.

Lymphoedema

Angiosarcomas have been associated with lymphoedema following breast cancer surgery and filarial lymphoedema has been associated with lymphangiosarcoma.

Chemicals

Phenoxyacetic acids, dioxin, and agent orange have been associated with STS. The association has not been convincingly documented. Thorotrast, vinyl chloride, and arsenic have been associated with angiosarcomas of the liver.

GENETICS

Cytogenetic anomalies are seen in a high proportion of STS particularly the high grade tumours. However, these are not consistent. Two anomalies worth mentioning are: (a) t(11;22)-(q24;q12) in Ewing's sarcoma/peripheral neuroectodermal tumour, and (b) t(X;18)(p11;q11) seen in synovial sarcomas. These are useful for the diagnosis. Other anomalies include t(11;22) (p13;q12) in desmoplastic round cell tumour; t(12;22) (q13;q12) in malignant melanoma of soft tissue; and t(2;13) (q35;q14) in alveolar rhabdomyosarcoma.

PATHOLOGIC CLASSIFICATION (TABLE 1)

The pathologist has a major contributory role in the management of STS, as therapy for STS depends on the size, grade, and resection margins of the tumour. Clinical trials of therapy of STS have clubbed subtypes. Though subtypes have a bearing on prognosis and behaviour, these are not important for the treatment planning, more because of lack of information than for any other reason. Soft tissue tumours may be benign or malignant. Some of the tumours have a borderline behaviour. The ratio of benign to malignant tumour is 100:1. Confusion between malignant and benign types may occur on small biopsies. It is important that the pathologist be provided with an adequate sample. Grade is determined from the cellularity, differentiation, pleomorphism, amount of necrosis, and number of mitoses in the tumour. There is a significant amount of discordance between experts about the diagnosis of sarcoma and its grade. Immunohistochemistry is a useful tool for the diagnosis of STS. The most useful immunohistochemical markers are the intermediate filaments (e.g. vimentin, keratin, desmin, leucocyte common antigen, S-100 protein). Cytogenetics and fluorescence *in situ* hybridisation (FISH) are also being used.

Table 1: Histopathological Types of Soft Tissue Sarcoma

Alveolar soft part sarcoma
Angiosarcoma
Dermatofibrosarcoma protuberans
Epithelioid sarcoma
Extra-skeletal chondrosarcoma
Extra-skeletal osteosarcoma
Fibrosarcoma
Gastrointestinal stromal tumour (GIST)
Leiomyosarcoma
Liposarcoma
Malignant fibrous histiocytoma
Malignant hemangiopericytoma
Malignant mesenchymoma
Malignant schwannoma
Malignant peripheral nerve sheath tumour
Peripheral neuroectodermal tumours
Rhabdomyosarcoma
Synovial sarcoma
Sarcoma, not otherwise specified (NOS)

Soft tissue sarcomas are commonest in the lower extremity (30%) followed by viscera (19%), retroperitoneal or intra-abdominal (15%), upper extremity (13%), and trunk (10%). Malignant fibrous histiocytoma is the most common histologic type (40%) followed by liposarcoma (25%). The metastatic

behaviour of sarcomas depends on grade, size, and site of origin. Metastasis are more common as the size and grade increases. Low grade tumours less than 5 cm seldom metastasise. The site of metastasis depends on the site of primary tumour. The extremity lesions metastasise to the lungs while the retroperitoneal or visceral lesions commonly metastasise to the liver.

CLINICAL FEATURES

Soft tissue sarcomas (STS) usually present as a large, often painless mass. The histological type varies with the site (**Table 2**). The distal extremity sarcomas are noticed earlier by the patient and hence present at an earlier stage. Sarcomas of the retroperitoneum grow to a large size before they are noticed, and hence, present at an advanced stage. This is also true to an extent about sarcomas of the proximal lower extremity. Sarcomas may present with pressure symptoms, e.g. neurovascular symptoms in extremity and retroperitoneal sarcomas (involvement of lumbar plexus).

Weight loss is uncommon. Factors associated with a poor prognosis include age older than 60 years, tumours larger than 5 cm or high-grade histology. Positive margins are associated with an increased risk of local relapse. The features of common sarcomas are listed in **Table 3**.

Table 2: Soft Tissue Sarcoma by Anatomical Site

Site	Common Tumours
Head and neck	Rhabdomyosarcoma, angiosarcoma
Chest wall	Liposarcoma, myogenic sarcomas
Gastrointestinal	Leiomyosarcoma, gastrointestinal stromal tumour (GIST)
Genitourinary	Leiomyosarcoma, rhabdomyosarcoma (tests), malignant mixed müllerian, endodermal sinus tumour (both uterus)
Retroperitoneum	Liposarcoma, leiomyosarcoma
Extremity	Malignant fibrous histiocytoma, liposarcoma, synovial sarcoma, fibrosarcoma

INVESTIGATIONS

Imaging Studies

The aim of imaging studies is to evaluate operability. This includes defining the extent of local disease, involvement of neurovascular bundles and other critical structures, and evaluation for metastasis. The imaging modalities include magnetic resonance imaging (MRI) and computed tomography (CT). Magnetic resonance imaging is preferred for extremities, while CT for retro-peritoneum and for evaluation of lungs for metastasis. Positron emission tomography is upcoming and useful for prediction of response to chemotherapy.

Biopsy

Biopsy is necessary for confirming the grade, histological type, and evaluation of margins in a resected specimen. It may be an open biopsy or a needle biopsy. Both the techniques are acceptable. Tissue may also be used for immunohisto-chemistry, electron microscopy, cytogenetics and FISH, in addition. Fine needle aspiration cytology (FNAC) is not appropriate for the diagnosis of STS and it may be used for the confirmation of recurrences. Frozen section is accurate for the diagnosis of malignancy but not for histological subtyping and grading.

Table 3: Features of Common Sarcomas

Tumour	Clinical Features	Remarks
Malignant fibrous histiocytoma	Commonest extremity STS; subtypes described but not found to be distinct on gene profiling Peak incidence in the 7th decade	Complex karyotype genes involved not known
Liposarcoma	Peak incidence from 50 to 65 years Commonest sites are thigh and retroperitoneum Three common types: well-differentiated or undifferentiated, myxoid or round cell and pleomorphic	Undifferentiated liposarcoma is characterised by ring or giant marker chromosomes on cytogenetic analysis
Fibrosarcoma	Usually in the 4th to 6th decade as a painful, deep-seated mass Thigh and trunk are the most common sites	—
Leiomyosarcomas	More than half are located in retroperitoneal or intra-abdominal sites Present insidiously, and reach a large size	—
Angiosarcomas	Lymphangiosarcoma occur in areas with lymphoedema Haemangiosarcomas are usually located in the skin or superficial soft tissue	—
Synovial sarcoma	Young adults, typically found in the para-articular areas of the tendon sheaths and joints, may also be encountered in regions without apparent relationship to synovial structures Higher risk of lymph node metastasis	t(X;18)(p11;q11)SYT-SSX1, SYT-SSX2 exhibits more favourable responses to chemotherapy than most other histologic subtypes
Malignant peripheral nerve sheath tumour	Oedema of the extremeties difficulty in movement of the limb having the tumour and soreness localised to the lymph Biopsy, MRI and CT scan are helpful	Treatment is similar to other sarcomas and is based on the age and type of tumour and vascularity

STAGING

American Joint Committee on Cancer (AJCC) staging system for STS is given in **Table 4**.

TREATMENT

Soft tissue sarcomas can be grouped into four groups for treatment, viz. (i) low-grade tumours (stage I); (ii) high-grade tumours (stage II and III); (iii) unresectable disease; and (iv) metastatic and recurrent disease. The aim of therapy is three-fold; to get local control, to get systemic control, and to get functional preservation.

Table 4: American Joint Committee on Cancer Staging of Soft Tissue Sarcomas

Tumour grade
GX : Grade cannot be assessed
G1 : Well differentiated
G2 : Moderately differentiated
G3 : Poorly differentiated
G4 : Poorly differentiated or undifferentiated

Primary tumour
TX : Primary tumour cannot be assessed
T0 : No evidence of primary tumour
T1 : Tumour 5 cm or less in greatest dimension
T1a : Superficial tumour
T1b : Deep tumour
T2 : Tumour 5 cm or larger in greatest dimension
T2a : Superficial tumour
T2b : Deep tumour

Nodes
NX : Regional lymph nodes cannot be assessed
N0 : No regional lymph node metastasis
N1 : Regional lymph node metastasis

Metastasis
MX : Distant metastasis cannot be assessed
M0 : No distant metastasis
M1 : Distant metastasis

Stage I: Low-grade tumour
G1, any T, N0, M0
G2, any T, N0, M0

Stage II: All small high-grade tumours; superficial large high-grade tumours
G3 or G4, any T1, N0, M0
G3, any T2, N0, M0

Stage III: Large deep high-grade tumours
G3 or G4, any T2, N0, M0

Stage IV: Presence of lymph node or distal metastasis
Any G, any T, N1, M0
Any G, any T, N0, M1

Management of Low-Grade Tumours

Low-grade small tumours tend to be locally aggressive and rarely metastasise. Surgical excision with a 1 cm tumour free margin is adequate for low-grade tumours less than 5 cm. In case the tumour is greater than 5 cm or the margins are less than 1 cm, radiation may be considered.

Management of High-Grade Tumours

The options available for high-grade localised tumours include surgery, radiation (pre-operative, intra-operative, and post-operative) and chemotherapy. Pre-operative radiotherapy is associated with a higher incidence of wound complications but requires a lower dose and a lower volume. Post-operative therapy is free of wound complications but the dose and the volume are higher. A higher treatment dose and volume may be associated with greater risk of radiation associated long-term functional compromise. Intra-operative radiation may be administered as external beam, or brachytherapy. The issue of the best modality to radiate a STS has not yet been resolved. The data on chemotherapy is equivocal but the trials have been small, lack the power to detect small difference and were all conducted without the use of granulocyte-colony stimulating factor (G-CSF) support. The consensus is that the effect of chemotherapy if at all is moderate and the need of chemotherapy needs to be decided on a case to case basis. Doxorubicin and dacarbazine with or without ifosfamide should be used. The dose of chemotherapy can be increased by the use of G-CSF with the hope to get a better outcome.

Unresectable Disease

The tumour size may be reduced by administration of pre-operative chemotherapy or radiotherapy and resection attempted if possible.

Stage IV Disease

If the regional nodes are involved, or if there is a low volume metastasis to a single organ, resection with post-operative chemotherapy and radiation is an option. If this is not possible, palliative therapy should be considered.

Special Situations

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) respond to imatinib which should be used in case of residual disease following surgery or in patients with recurrence.

Uterine and ovarian sarcomas

Ovarian and uterine sarcomas are treated with surgery, radiation and chemotherapy. Endodermal sinus tumour is sensitive to hormonal therapy (progestins, tamoxifen and gonadotrophin releasing hormone analogues).

Retroperitoneal tumours

Retroperitoneal tumours are large and the intra-abdominal structures put a limitation on the amount of radiotherapy that can be administered. These are usually treated with a multi-modality approach involving surgery, chemotherapy and radiation. The outcome of these tumours is poor compared to other STS.

21.14 Cancer of Unknown Primary Site

Hemant Malhotra

INTRODUCTION

Cancer of unknown primary site (CUPS) or occult primary malignancy (OPM) represents a group of heterogeneous tumours that share a unique clinical feature: "early" apparent metastatic disease with no identifiable site of origin at the time of presentation. Thus, OPM patients present with usually widespread metastatic disease for which no primary site can be detected after a good medical history, detailed clinical examination, and extensive investigations. The primary site may either have a slow growth or may possibly become involute and, therefore, unlikely to manifest itself. About 3% of all cancer patients suffer from cancer of unknown primary origin.

The majority of CUPS/OPM are adenocarcinomas or undifferentiated tumours; less commonly, squamous cell carcinoma (SCC), melanoma, sarcoma, and neuroendocrine tumours can also present with a primary site of origin that cannot be determined. In approximately 15% to 25% of patients, the primary site cannot be identified even at post-mortem examination.

The prognosis for patients with OPM is poor. In the pre 2000 era, as a group, the response rates were 8% to 39% (mean 20%). The complete response rates were less than 1% and the mean survival was approximately 6 months (range 4 to 15 months in various studies) survival beyond 2 years was rare. With the availability of newer chemotherapeutic drugs (paclitaxel, docetaxel, gemcitabine, irinotecan) and newer targeted agents (gefitinib, erlotinib, bevacizumab), the one year overall survival has increased to 35% (range 25% to 50%) and about 13% (range 5% to 18%) of patients are alive at 2 years.

Large studies have shown that carcinoma of the lung and pancreas are the most common primary carcinomas that initially present as OPM. Other common malignancies such as colorectal, breast, and prostate cancers infrequently present as OPM. With the advent of two new advanced diagnostic modalities, one radiological and the other molecular, in the last decade, the number of patients with true OPM is decreasing. The positron emission tomography (PET) and molecular profiling of the tumour by DNA microarray technology, are extremely useful additions in the diagnostic armamentarium for this group of cancers.

HISTOLOGICAL CLASSIFICATION

According to routine light microscopy, cancers of unknown primary origin are divided into 4 major subtypes.

1. Adenocarcinomas well to moderately differentiated
2. Poorly differentiated carcinomas and adenocarcinomas
3. Squamous cell carcinomas
4. Undifferentiated neoplasms

The majority of the cases are adenocarcinomas, with poorly differentiated tumours being the next most frequent pathology (**Table 1**). Squamous cell carcinoma is a special minor subtype involving mainly the cervical nodes, and undifferentiated neoplasms are frequently re-classified to major histologic categories (i.e. carcinoma, lymphoma, melanoma, and sarcoma) because of the improvements in histopathology techniques. As regard to the organ of origin of the tumour, the majority of primaries are from either lung or pancreas (**Figures 1 and 2**). Clinical characteristics of the major OPM histologic types are depicted in **Table 2**.

Table 1: Proportions of Reported Histological Diagnoses in OPM

Author	Number of OPM Patients	Adeno-carcinoma (%)	Undifferentiated to Poorly Differentiated Carcinoma (%)	Squamous Cell Carcinoma (%)	Other* (%)
Muir	26,050	47.7	22.0	19.5	8.8
Holmes	686	28.0	16.0	10.0	46.0
Abbruzzese	657	58.2	29.4	5.8	6.7
Le Chevalier	302	45.0	27.5	15.0	12.5
Buda	332	65.0	14.0	21.0	

**includes undifferentiated neoplasm, other specified and unknown histotypes.*

CLINICAL FEATURES

Epidemiology—Demographics

Occult primary malignancy (OPM) comprises approximately 3% of human cancer. The average annual age-adjusted incidence is 7 to 12 cases per 100,000 population per year and as a cause of death, it is reported to be the fourth most common among cancer-related deaths in developed countries. Demographics of OPM patients generally mirror those of the general cancer population, with a mean age of 59 years at diagnosis (range 20 to 89 years) and a marginally higher frequency in males. Squamous cell carcinomas are twice as frequent in males as in females, while there is a compensatory shift in the frequency of adenocarcinomas. In children, OPM represents less than 1% of diagnosed solid tumours.

Natural History

Early dissemination, clinical absence of primary tumour, unpredictable metastatic pattern, and aggressiveness constitute the fundamental characteristics of these tumours. Several studies report that autopsy has failed to identify the primary site in 15% to 25% of OPM cases. Between the identified occult primaries, lung and pancreas constitute the majority, while other common malignancies represent smaller proportions (**Figures 1 and 2**).

The clinical presentation in cases of OPM depends on the predominant site of metastatic involvement. Regarding the organ sites affected, most patients (60%) have more than two sites affected at presentation, with lymph nodes being the most frequently involved. Liver, lung, bones, and pleura constitute common metastatic sites, whereas relatively high frequencies of odd localisations of metastases have been observed. General deterioration and weight loss are the most common symptoms, while digestive and respiratory symptoms, liver enlargement,

Table 2: Clinical Characteristics of the Major Occult Primary Malignancies Histologic Types

	Mean Age (Range)	Major Sites Involved	Specific Clinical Characteristics	Main Treatment Effectiveness	5-year Survival Rate (%)
Adenocarcinoma (well-to-moderately differentiated)	58	Liver, lung, bones	The most frequent type in adults; poor prognosis	Chemotherapy palliative	4
		Axillary lymph nodes only (subtype)	Females; relatively good prognosis	Loco-regional effective	60
		Peritoneum only (subtype)	Females; relatively good prognosis; response to chemotherapy and survival similar to ovarian cancer	Platinum-based chemotherapy effective	12
Poorly-differentiated carcinomas	37 (17 to 70)	Lymph nodes of midline distribution, lung	Rapid tumour growth, favourable response to chemotherapy	Platinum-based chemotherapy effective (57% ORR)*	13 to 16
Squamous cell carcinoma	60	Cervical lymph nodes	Male:female ratio of 6:1	Loco-regional or platinum-based chemotherapy effective	30
Embryonal malignancies	8 (1 to 17)	Bone marrow, bone lesions, lymph nodes, lung	Predominated type in childhood	Carboplatin-doxorubicin-ifosfamide-based chemo-therapy regimens effective	17

ORR = Overall response rate.

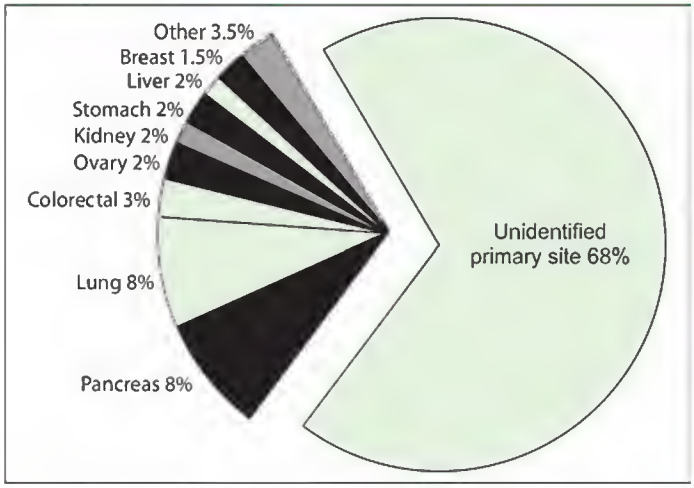

Figure 1: Distribution of identified primary tumour sites reported among 2,114 cases with OPM.

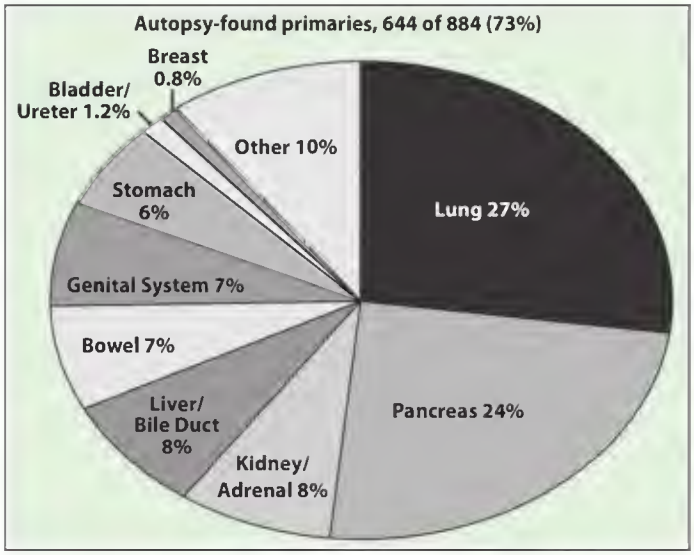

Figure 2: Distribution of identified primary tumour sites reported among 884 cases with occult primary malignancy at autopsy.

ascites, skin nodules, and bone pains suggest the sites of predominant metastatic involvement.

PROGNOSIS

The overall prognosis in patients with OPM is poor, with a mean survival of 5 to 10 months. Fewer than 25% of patients survive up to one year, but survival differs among clinicohistological subgroups (**Table 2**). Significant prognostic factors recognised in OPM are: histopathology, organs involved, tumour burden, gender, and performance status (**Table 3**). The prognostic significance of histological type can be attributed to the chemosensitivity of the underlying occult primary in each category. In poorly-differentiated carcinomas, several chemosensitive tumours may be included, whereas adenocarcinomas usually represent chemotherapy-resistant primaries.

Table 3: Prognostic Factors in Occult Primary Malignancy

	Favourable Factors	Unfavourable Factors
Pathology	Poorly differentiated carcinoma Squamous cell carcinoma Neuroendocrine carcinoma	Adenocarcinoma
Organs involved	Lymph nodes (except supraclavicular)	Liver, lung, bones
Tumour burden		≥three sites
Gender	Female	Male
Performance status	0 to 1	>1
Alkaline phosphatase	≤1.25 N	1.25 N

Lymph node metastatic topography deserves separate mention, since several distinct subgroups of prognostic significance have been recognised. Cervical nodes with squamous cell cancer, axillary nodes with adenocarcinomas in females, and lymph nodes with undifferentiated carcinomas constitute presentations of a favourable prognosis. Supraclavicular lymph node involvement has been defined as a bad prognostic factor.

DIAGNOSIS

Pursuing the Anatomical Location or Searching for Clues to Treatable Tumours?

The search for the identification of the occult primary has always challenged clinicians. The argument in favour of pursuing the anatomical location of the primary is the belief that localising the primary might result in a more specific and effective treatment. In a minority of OPM patients, a primary site of origin can indeed be identified after extensive diagnostic evaluation, but exhaustive investigations have been criticised because of a low yield and a lack of influence on patients' prognosis. Such a strategy has never been found to have any therapeutic implications or to be of survival benefit to the patient. On the contrary, it costs the patient a longer hospital stay, with the experience of painful and distressing investigations and the health care system an unacceptable cost-effectiveness ratio.

Regarding the identification of treatable subgroups, a careful consideration of the clinical presentation of the disease with an optimal re-evaluation of the biopsy specimen provides the best clue. Immunohistochemistry and, in exceptional cases, molecular genetic and cytogenetic studies may help the diagnosis. This way, the well-recognised clinico-pathological subsets of treatable and potentially curable tumours can easily be identified, and any histological misclassifications can be clarified.

Proposed Diagnostic Strategy

As a rule, a reasonable diagnostic approach to OPM patients is to avoid excessive diagnostic procedures without compromising clinically useful diagnostic efficacy.

Based on the initial clinical presentation and pathology report, the diagnostic strategy for a probable OPM should be divided into the standard and optional diagnostic procedures (**Table 4**).

Table 4: Investigations for the Diagnosis of OPM

Standard diagnostic investigations	
Pathology	Histopathologic review of the biopsy material with the use of immunohistochemistry
Laboratory tests	Full blood count, routine biochemistry, faecal occult blood testing, urine test
Imaging studies	Chest radiograph, CT of abdomen and pelvis, PET
Optional or symptoms/signs-oriented investigations	
Imaging studies	CT of head and neck region in cervical node metastasis
	Mammography for axillary lymph node metastasis
Endoscopies	ENT pan-endoscopy, bronchoscopy, proctoscopy, colposcopy
Surgery	Mastectomy in axillary cases, cytoreductive laparotomy for peritoneal carcinomatosis

The standard diagnostic procedure for the majority of these patients is proposed to include the histopathologic review of biopsy material with the use of immunohistochemistry, full blood count, routine biochemistry, faecal occult blood testing, urine testing, chest radiograph, and computed tomography (CT) of abdomen and pelvis. It must be emphasised that immunohistochemistry staining for common leucocyte antigen, CEA, cytokeratin, and vimentin is considered today a routine pathology procedure for these tumours. For the subgroups of the cervical node; epidermoid carcinomas and the axillary adenocarcinomas in females, more specific initial investigational procedures are advisable; those include ear-nose-throat panendoscopy and head and neck CT in cases of cervical lymph nodes and mammography in axillary lymph node metastases in women. Other recommended optional investigations are the high specificity α-fetoprotein (AFP), β-human chorionic gonadotrophin (β-hCG), and prostate-specific antigen (PSA) serum tumour markers in men to exclude extra-gonadal germ cell tumour or prostate cancer, and symptoms or signs oriented endoscopies. Surgical diagnostic procedures have not gained a wide acceptance.

Evaluation of Diagnostic Methods

Physical examination

The physical examination must always be a thorough one and should include head and neck, thyroid, and rectal examination. In women, breast and pelvis; in men, prostate and testicles examination should never be overlooked.

Imaging studies

Although chest radiography has always been a prerequisite for the diagnosis of OPM, its usefulness in the differential diagnosis between primary and secondary disease in lungs has been disputed.

CT is considered today as one of the most valuable imaging tests in OPM cases. It has a clearly proven impact on OPM diagnosis, offering an additional diagnostic accuracy of 20% in cases previously characterised as OPM. CT also helps in the evaluation of tumour mass and provides guidance to biopsy procedure.

In the past 5 years, F-18 fluorodeoxyglucose (FDG) PET/CT has become one of the more frequent imaging modalities in the management of patients with cancer of unknown primary origin. FDG-PET/CT detects more sites of metastasis than other modalities, and in 20% to 40% of cases it discloses the site of the primary tumour. Its exact role is yet to be defined because of a lack of prospective clinical trials comparing the performance of PET/CT with conventional anatomic imaging modalities.

Endoscopy

Endoscopies should always be symptoms or signs oriented investigational procedures in OPM cases.

Surgery

Surgery as a diagnostic procedure has a definite role in biopsy sampling. In cases of women with adenocarcinomas of the peritoneum, cytoreductive laparotomy has a therapeutic rather than a diagnostic benefit.

Pathology

Histopathology is the cornerstone in the diagnostic procedure of OPM. A good biopsy specimen is of great importance, especially in cases of poorly differentiated tumours, and for the application of special pathology techniques that can improve the diagnosis of chemosensitive tumours which are subject to mis-diagnosis. The contribution of light microscopy and specialised pathological studies in the diagnosis of OPM is depicted in **Figure 3**.

Immunohistochemistry is the most useful diagnostic tool and the central axis of the initial basic investigation, especially in

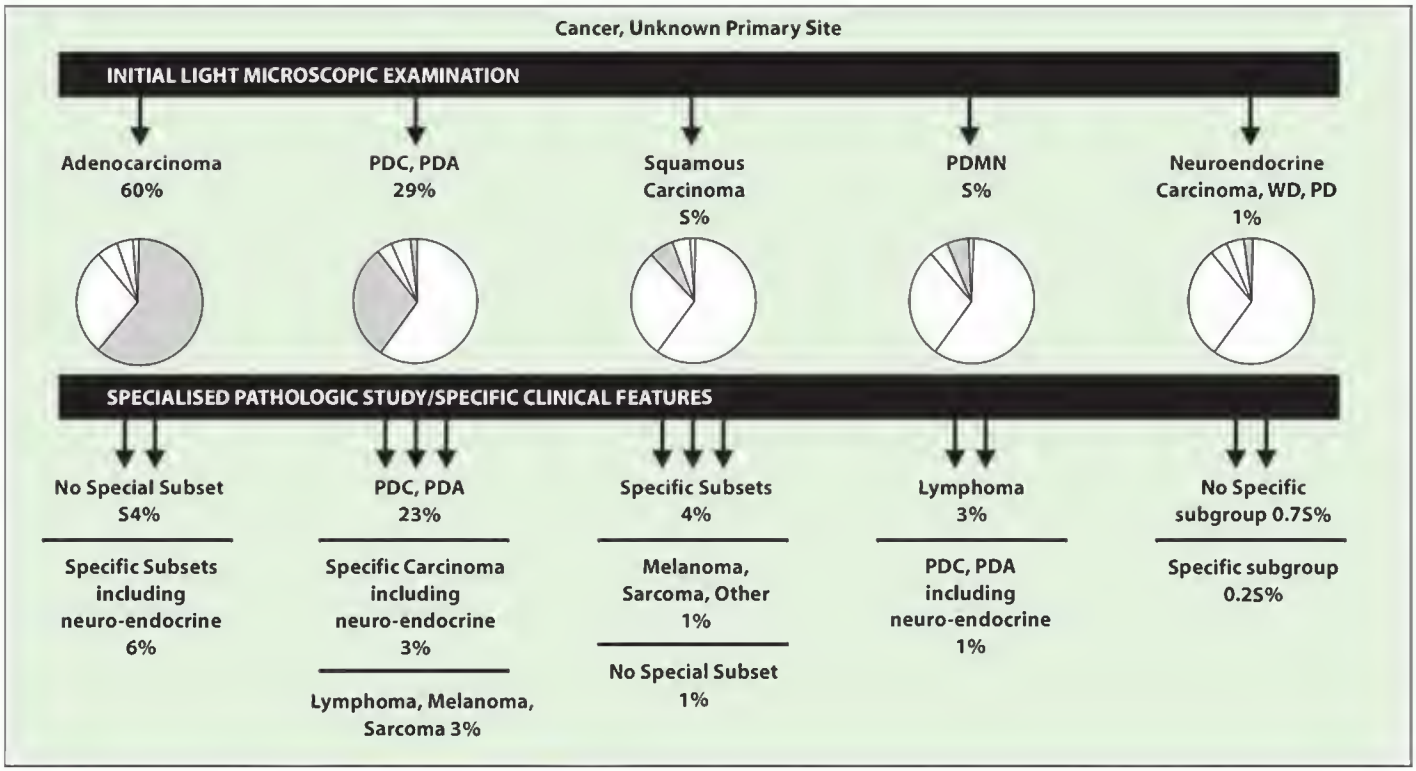

Figure 3: Rale and diagnastic yield af variaus pathalagical tests in OPM.

PDC = Paarly differentiated carcinama; PDA = Poarly differentiated adenacarcinama; PDMN = Paarly differentiated malignant neaplasm; WD = Well differentiated; PD = Poarly differentiated.

cases of poorly differentiated carcinomas. Immunoperoxidase staining has now become widely available and can be reliably applied on routinely fixed paraffin-embedded biopsy materials. Immunocytochemistry can also be applied on cytological preparations in cases of malignant perfusions. Today, with the help of a wide range of immunohistochemistry markers, the misdiagnosis of other malignancies, such as lymphomas, extragonadal germ cell tumours, malignant melanomas, and undifferentiated sarcomas as OPM is rather rare.

Advanced diagnostic tests

Electron microscopy can be a useful diagnostic tool in 15% of undifferentiated OPM not otherwise identified by light microscopy, offering an additional diagnostic accuracy in one-third of these cases. It is a well-reputed diagnostic method for the poorly differentiated neuroendocrine tumours and amelanotic melanomas recognising core granules, electron-dense secretory granules, and premelanosomes. It can also contribute to the diagnosis of undifferentiated squamous cell carcinoma (desmosomes attached to tonofilaments), adenocarcinomas (acinar spaces, tight junctions, and microacini) and sarcomas (myofibrils, dilated rough endoplasmic reticulum, extracellular osteoid). Disadvantages of electron microscopy are the special handling procedure, the experienced personnel, and the expensive equipment required.

Molecular genetic and cytogenetic studies can offer today additional diagnostic information toward the identification of special tumour types that have specific genetic markers. Fluorescence *in situ* hybridisation (FISH) using the chromosomal marker i(12p), which is highly non-random for germ cell tumours, has been proven an excellent diagnostic tool in atypical extragonadal germ cell tumours presenting as undifferentiated OPM. Genetic analysis can also contribute to the diagnosis of a number of tumours with specific chromosomal aberrations, usually seen in soft tissue sarcomas and lymphomas. Nasopharyngeal undifferentiated carcinomas can be distinguished from undifferentiated epidermoid tumours by detection of Epstein-Barr virus genome with polymerase chain reaction analysis.

Serum tumour markers

Males should always have the high-specificity tumour markers β-hCG, AFP, and PSA tested to exclude treatable extragonadal germ cell tumours and prostate cancer amenable to endocrine treatment. In children, testing for urinary catecholamines can produce valuable diagnostic clues, as high urine levels are diagnostic of neuroblastoma (**Figure 2**).

TREATMENT

A reasonable treatment approach for OPM patients is to individualise the treatment, taking into consideration the most appropriate modality for each case, whether loco-regional, systemic, curative, palliative, or supportive.

Loco-Regional Treatment

Being by definition a metastatic disease, OPM leaves only limited room for loco-regional treatment practices, radiotherapy, and surgery.

Loco-regional treatment of curative orientation should be considered in cases of isolated axillary node metastases in females and squamous cell metastases in cervical nodes, especially in $< N_2$ stages. For higher stages (N_3), combination modality treatment with radio-chemotherapy is proposed as a more reasonable approach, offering a better response rate

and survival. Loco-regional radiation therapy has a role in palliation.

Systemic Treatment

Although curative in few cases of OPM, chemotherapy constitutes the mainstream of treatment practices for the majority of patients with this systemic metastatic disease.

Potentially Curable OPM Subgroups

The better-defined, potentially curable sub-population is young adults, primarily males, with poorly differentiated carcinomas having as dominant tumour sites the mediastinum, retroperitoneum, lungs, or peripheral lymph nodes. In these patients, a 16% actuarial 10-year survival has been achieved.

Another well-documented subset of patients with favourable response to platinum-based chemotherapy and improved prognosis is women with peritoneal carcinomatosis. Cure is also possible for the rare cases of children with OPM, if treated with chemotherapy regimens effective against embryonal malignancies.

An indicative synopsis of effective treatment approaches in patients with OPM is presented in **Table 2**.

Adenocarcinomas: Supportive, Palliative, or Investigational Treatment Approach?

Unfortunately, the favourable subsets of OPM constitute a minority. The large majority of adenocarcinomas of unknown primary origin (AOPM) still remain resistant to clinically established chemotherapy. The regimens used so far have been empirical and of palliative orientation and the observed responses in most retrospective studies were moderate, with no definite impact on survival. Quality of life is a major point in these cases and should be taken very seriously into consideration because of the poor performance status and prognosis of these patients.

Future Treatment Perspectives

With the availability of newer chemotherapeutic drugs like the taxels (paclitaxel and docetaxel), gemcitabine, vinorelbine, irinotecan and oxaliplatin and targeted agents like bevacizumab, gefitinib and erlotinib, there have been significantly more response and 1- and 2-year survivals in these patients. Two versus three drugs combinations are being evaluated in clinical trials.

Biological Profile of the Tumour

The search for genetic damage has taken a central role in cancer research in the last decade. A unique biological profile is also suggested by the observations that show an extremely high overexpression of several tumour markers and oncoproteins in these tumours (**Figure 4**).

More and more research is now focused on molecular profiling of patients with OPM (**Figure 5**). Commercially available DNA microarray chips can now be used for molecular profiling and exact characterisation of the tumour such that tumour-specific chemotherapy can be offered rather than empiric therapy. Gene expression microarray (GEM) analysis has demonstrated that molecular signatures

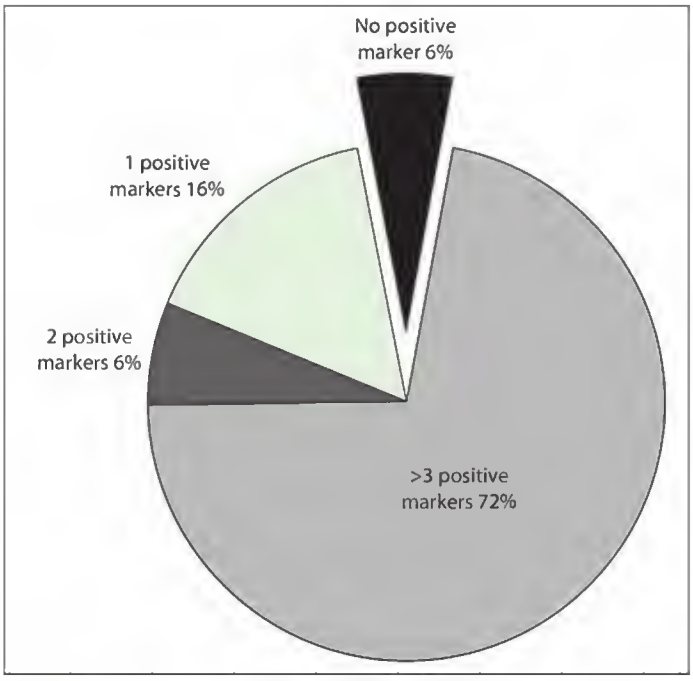

Figure 4: Multiple over-expression of 6 serum tumour markers (CEA, CA 19-9, CA 15-3, CA 125, HCG, AFP) evaluated in 58 OPM cases.

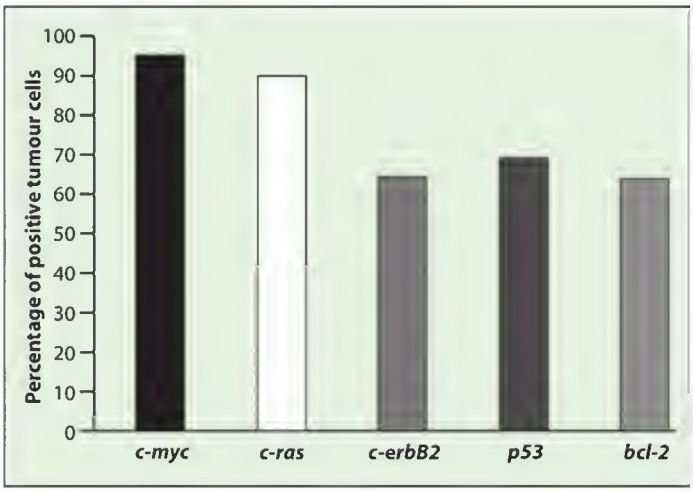

Figure 5: Immunohistochemical detection of oncoproteins in OPM (c-myc, c-erbB-2 and ras were studied in 26 cases, p53 and bcl-2 in 47 OPM cases).

can aid in tumour classification and propose foster primaries. The improved diagnosis by the GEM method possibly influences the management in 50% to 60% of cases. Genomic profiling and cancer classification tools represent a promising analytical approach to assist with the management of OPM patients. It is proposed that molecular profiling diagnosis be considered when the primary clinical algorithm has failed to provide a diagnosis.

CONCLUSIONS

The heterogeneous-in-origin tumours that present clinically as OPM share common clinical features of early metastatic dissemination from an occult primary. A limited diagnostic evaluation toward the detection of the primary tumour and a thorough clinicopathological evaluation for clues to identify the

well-recognised, treatable subgroups are recommended. As a significant therapeutic improvement has not been achieved for the majority of patients with metastatic adenocarcinomas, innovative treatment approaches with the introduction of new classes of drugs into trials are warranted. Findings suggestive of a unique biological profile of OPM have recently been evidenced and justify further research for the genetic and biologic identity of these aggressive tumours that express an absolute metastatic phenotype.

21.15 Paraneoplastic Syndromes

Senthil Rajappa, D Raghunadharao

INTRODUCTION

Paraneoplastic syndromes or non-metastatic manifestations refer to the signs and symptoms produced by the tumour at sites distant from the primary or metastasis. These syndromes occur in 2% to 20% of all malignancies. However, this may be an under estimation considering the fact that there is under-reporting of these syndromes. No race or sex predilection is reported. Cancers and their related paraneoplastic syndromes may affect people of all ages. These syndromes may be the presenting feature of a malignancy and may help in identifying a possible primary. The signs and symptoms of paraneoplastic syndromes may result from several mechanisms. These are most commonly due to release of physiologically active substances like cytokines, enzymes and hormones, production of antibodies against antigens, which are shared by the tumour and normal tissues or interference with metabolic or synthetic pathways. Increased understanding of the molecular mechanisms of paraneoplastic syndromes may help in an early diagnosis, design of therapies, monitor responses and predict outcomes. Paraneoplastic syndromes may affect almost all organ systems of the body.

CLINICAL SIGNIFICANCE OF PARANEOPLASTIC SYNDROMES

Certain paraneoplastic syndromes are typically associated with certain malignancies, and hence, may help in identifying the primary, e.g. opsoclonus-myoclonus syndrome in neuroblastoma.

Certain paraneoplastic syndromes secrete proteins which may be used as tumour markers to track disease responses and progression, e.g. α-fetoprotein in testicular cancers.

In some situations, the underlying disease may not be treated but the symptoms of the paraneoplastic syndromes may need attention, e.g. metastatic carcinoid tumours.

Paraneoplastic syndromes may confer poor prognosis in certain malignancies, e.g. hyponatraemia in small cell lung cancer (SCLC).

Paraneoplastic syndromes may sometimes precede and can help identify an early relapse, e.g. α-fetoprotein in germ cell tumours.

Many paraneoplastic syndromes may run a clinical course independent of the malignancy, e.g. immune-mediated neurologic syndromes.

ENDOCRINE PARANEOPLASTIC SYNDROMES

Endocrine paraneoplastic syndromes result from the production of peptide hormones or cytokines, which are referred to as 'ectopic' hormones by the tumour. These syndromes include hypercalcaemia of malignancy, Cushing's syndrome, syndrome of inappropriate anti-diuretic hormone secretion (SIADH), hypoglycaemia, oncogenic osteomalacia, as well as production of growth hormone, gonadotrophins, calcitonin, prolactin and thyrotrophic substance.

Hypercalcaemia of Malignancy

Hypercalcaemia is a major metabolic abnormality and an oncological emergency that can occur in 10% of all individuals diagnosed with cancer. The most common cause of hypercalcaemia of malignancy is multiple myeloma (33%) followed by breast and bronchogenic carcinoma. Hypercalcaemia can be classified as that resulting from bone destruction, i.e. osteolysis or humoral hypercalcaemia of malignancy (HHM). Parathyroid hormone-related protein (PTHrP) produces endocrine and paracrine effects and is responsible for HHM. Factors released by or in response to bone metastasis namely receptor activator of nuclear factor kb ligand (RANKL), tumour necrosis factor-alpha (TNF-α) and IL-1 can cause paracrine effects. However, both may result in bone resorption resulting in hypercalcaemia. Determining the stage of the disease and the antineoplastic options are paramount to manage the hypercalcaemia.

Hypercalcaemia may present with renal, gastrointestinal (GI) , neurologic or cardiac manifestations. Patients who are symptomatic should be treated irrespective of the absolute level of calcium. A corrected serum calcium level of 11 to 12 mg% is referred to as mild hypercalcaemia, 12 to 14 mg% as moderate and more than 14 mg% as severe hypercalcaemia.

Therapies for hypercalcaemia are directed at either increasing the renal excretion of calcium or by inhibiting osteoclast activity. Hydration and diuresis although helpful, must be administered with caution in order to prevent fluid logging and pulmonary oedema. Specific measures like bisphosphonates (zoledronic acid) and steroids especially in haematologic malignancies need to be instituted. Calcitonin or gallium nitrate are reserved for those patients who do not respond to the above measures. Anti-tumour therapy should be employed early for best results.

Ectopic Adrenocorticotrophic Hormone Syndrome

This syndrome was first reported by Brown in a patient with SCLC. Some tumours have overaction of *c-fos* oncogene due to loss of a tumour suppressor gene leading to increased production of propiomelanocortin (POMC), which is a precursor of adrenocorticotrophic hormone (ACTH) and many other proteins in the steroid hormone synthesis cascade. Ectopic ACTH syndrome production is most commonly associated with SCLC. Myopathy, muscle wasting, hyperpigmentation and hypokalaemia are more common in ectopic ACTH production compared to Cushing's syndrome. Additional abnormalities include glucose intolerance and metabolic alkalosis.

Distinguishing between pituitary adenoma, ectopic ACTH production and primary adrenal disorders is the primary focus of the diagnostic work-up. Laboratory evaluation reveals

excessive cortisol production by 24-hour free cortisol measurement and lack of suppression after administration of dexamethasone. The levels of ACTH are unaltered by metyrapone and corticotrophin releasing hormone (CRH) stimulation tests unlike a pituitary adenoma. Specific treatment is directed at the underlying tumour.

Syndrome of Inappropriate Anti-Diuretic Hormone Secretion

Hyponatraemia can occur in 10% to 30% of patients with SCLC. SIADH occurs as a result of overproduction of anti-diuretic hormone (ADH) or ADH-like substance by the tumour. Drugs like vincristine, cisplatin and cyclophosphamide may also cause SIADH. The cardinal features of SIADH are water intoxication and hyponatraemia including decreased serum osmolality, euvolaemia, inappropriate elevation of urine osmolality with elevated urine sodium with normal renal, thyroid and adrenal function. Many patients are asymptomatic. Those with sodium level of <125 mEq/L and developing hyponatraemia rapidly are more likely to be symptomatic.

Water restriction (500 to 1000 mL per day) is the most important measure in treating SIADH. Hypertonic saline and diuretics are reserved for patients who have life-threatening convulsions or coma. It is important to raise the sodium level gradually. Demeclocycline is used for patients where fluid restriction and treatment of the malignancy are ineffective.

Paraneoplastic Gonadotrophin Secretion

β-Human chorionic gonadotrophin is the most commonly elevated in testicular cancer, hydatiform mole and choriocarcinoma. Rarely other cancers like breast, lung, gastric and renal cell carcinoma can produce elevated β-hCG. The usual manifestations are gynaecomastia in men and oligomenorrhoea in women. Due to the sharing of the alpha subunit between thyroid stimulating hormone (TSH) and hCG, there may be manifestations of hyperthyroidism. β-hCG also helps in monitoring response to therapy.

Other Endocrine Syndromes

Oncogenic osteomalacia is characterised by osteomalacia, hypophosphataemia, hyperphosphaturia, normocalcaemia, normal parathyroid hormone (PTH) levels and decreased vitamin D levels as a result of a phosphaturic substance or decreased conversion of 1,25 dihydroxy vitamin D. It is associated with mesenchymal tumours, like haemangiomas and haemangiopericytoma.

Calcitonin may be produced in excess by SCLC, carcinoids, and breast cancer. Hypoglycaemia is associated with an insulinoma. It may also be associated with a variety of unusual mesenchymal tumours and GI cancers, which are typically large and involve the liver. It arises due to the production of insulin-like growth factor (IGF 1 and 2).

NEUROLOGIC PARANEOPLASTIC SYNDROMES

Most neurological paraneoplastic syndromes (**Table 1**) begin acutely or subacutely and progress over weeks to months before stabilisation. It usually precedes the diagnosis of cancer. Syndromes that have a relentless or fluctuating course are less likely to be paraneoplastic.

Due to the rare occurrence of these syndromes exact incidence is unknown except in certain situations. *Myasthenia gravis* is associated with 10% to 15% of cases of thymoma, Lambert-Eaton myasthenic syndrome (LEMS) in 3% of SCLC and peripheral neuropathy in 10% of monoclonal gammopathies and 50% of osteosclerotic myeloma.

Table 1: Paraneoplastic Neurological Syndromes

Syndromes of the central nervous system
Encephalomyelitis
Limbic encephalitis
Brainstem encephalitis
Subacute cerebellar degeneration
Opsoclonus-myoclonus
Optic neuritis
Cancer-associated retinopathy
Melanoma-associated retinopathy
Stiff person syndrome
Necrotising myelopathy
Syndromes of the peripheral nervous system
Subacute sensory neuronopathy
Acute sensorimotor neuropathy
Guillain-Barré syndrome
Brachial neuritis
Subacute/chronic sensorimotor neuropathies
Neuropathy and paraproteinaemia
Neuropathy with vasculitis
Autonomic neuropathies
Chronic gastrointestinal pseudo-obstruction
Acute pandysautonomia
Syndromes of the neuromuscular junction and muscle
Myasthenia gravis
Lambert-Eaton myasthenic syndrome (LEMS)
Dermatomyositis
Acute necrotising myopathy

The nervous system can be involved in one of the three ways:

1. Paraneoplastic disorder may damage a non-neural organ/tissue with secondary effects on the nervous system, e.g. hypercalcaemia from tumour-related production of PTHrP can lead to encephalopathy.
2. Paraneoplastic disorder affecting non-neural organ or tissue may lead to structural damage to nervous system, e.g. hypercoagulability may lead to cerebral infarction due to venous or arterial thrombi.
3. It may directly affect the nervous system without involvement of the other organs, e.g. encephalomyelitis, LEMS or *Myasthenia gravis*.

Tumours express antigens are normally present exclusively in the nervous system. These shared antigens are referred to as onconeural antigens and can be isolated in most paraneoplastic neural syndromes. When the tumour cells undergo apoptosis and are phagocytosed by dendritic cells, the onconeural antigen is recognised by the immune system. This results in the production of cross-reacting antibodies leading to an immune attack, which in rare cases may even obliterate tumour.

These syndromes are associated with evidence of inflammation on the cerebrospinal fluid (CSF) analysis as evidenced by pleocytosis and presence of oligoclonal bands, which represent the antibodies. Neuro-imaging is rarely contributory and helps to exclude metastasis. Many patients have serum and CSF antibodies, e.g. anti-Yo, anti-Hu, anti-Ri. Some classical syndromes like paraneoplastic encephalomyelitis and certain

antibodies can be typical of certain malignancies while many may be non-specific. Although immune-mediated mechanisms have been implicated in most neurologic paraneoplastic syndromes, plasmapheresis, immunoglobulins and immunosuppressive therapy are rarely beneficial.

Encephalomyelitis

Encephalomyelitis is a general term used for paraneoplastic syndromes with intense inflammatory response, perivascular lymphocytic cuffing affecting the brain and spinal cord. This includes paraneoplastic cerebellar degeneration, limbic encephalitis and transverse myelitis. There is no known treatment and the disorder runs a subacute course. Limbic encephalitis is characterised by subacute onset of behavioural and mental changes. It is associated with small cell lung, breast and uterine cancers. Paraneoplastic cerebellar degeneration is characterised by acute or subacute onset of cerebellar dysfunction and widespread loss of Purkinje fibre layer. It is associated with small cell lung and breast cancer and Hodgkin's disease.

Paraneoplastic opsoclonus is manifested by high amplitude, involuntary, chaotic, conjugate, saccadic eye movements often associated with myoclonus and ataxia. It occurs in 2% of childhood neuroblastomas. Unlike in adults, opsoclonus-myoclonus in children responds to corticosteroids although some residual neurological defects may persist.

Subacute Neuronopathy

Subacute neuronopathy may be sensory or motor. Subacute sensory neuronopathy is characterised by loss of sensations in the extremities. It is more common in women and is associated with SCLC. Subacute motor neuronopathy is associated with Hodgkin's disease and presents with progressive lower extremity weakness. Unlike other neurologic syndromes, it is commonly diagnosed after the malignancy and runs a chronic non-debilitating course. Anti-neuronal antibody (anti-Hu) directed against the nucleoprotein of the dorsal root ganglia have been isolated. There is no effective treatment for either disorder.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is a disorder of the myoneural junction characterised by proximal muscle weakness. Of the 60% of patients with underlying cancer, two-thirds have SCLC. LEMS is caused by antibody to the voltage-gated calcium channel leading to decreased acetylcholine release into the myoneural junction. Unlike Myasthenia gravis, bulbar involvement is uncommon but can be associated with dysautonomia in 50%. Repetitive nerve stimulation shows decrement of the compound muscle action potential at low stimulation rate and increase at high stimulation rates.

In contrast to other syndromes, LEMS responds to plasmapheresis, intravenous immunoglobulins, immunosuppression and treatment of underlying cancer. Drugs like 3,4-diaminopyridine that increase neurotransmitter release can be used as maintenance therapy.

Peripheral Neuropathy

Peripheral neuropathy occurs in 5% of patients and can be sensory, motor or mixed type. It is reported in lymphomas, plasma cell dyscrasia and cancer of the lung, breast and colon. The demyelinating type may occur acutely as in Guillain-Barré syndrome or have a more chronic course. Axonal neuropathy is more commonly associated with lung cancer and responds to the treatment of the underlying malignancy.

HAEMATOLOGIC PARANEOPLASTIC SYNDROMES

Anaemia

Anaemia is one of the most frequently encountered abnormality in cancer patients with a multitude of causes. These include bone marrow involvement, blood loss, nutritional deficiencies, infections, myelofibrosis and treatment-induced. Although iron stores are adequate, there is impaired iron utilisation. The exact mechanism of this under utilisation of iron is unknown but some studies have shown low levels of erythropoietin. Treatment of the malignancy or erythropoietin supplementation may reverse the anaemia.

Pure red cell aplasia (PRCA) is a rare syndrome with selective loss of red cell precursors. Thymomas have been found in 50% of PRCA and thymectomy results in reversal in 25% to 30% of cases. PRCA can also be associated with lung and breast cancers and haematological malignancies.

Antibody-mediated haemolytic anaemia is frequently associated with β-cell neoplasms like chronic lymocytic leukaemia (CLL) and lymphomas. Microangiopathic haemolysis is an uncommon complication of cancer most commonly seen in mucin-producing adenocarcinomas, especially gastric cancer.

Erythrocytosis

Inappropriate production of erythropoietin by tumours like renal cell carcinoma, hepatoma, adrenocortical tumours, uterine tumours and haemangioblastoma may lead to polycythaemia. Other possible causes include tumour-derived peptides, androgenic hormones or other peptides with erythropoietic effects.

Granulocytosis

Marked granulocytosis or leukaemoid reaction commonly accompanies breast, lung, gastric cancers, lymphomas and brain tumours. The mechanism is supposed to be the release of colony stimulating factors (G-CSF, GM-CSF, IL-3 and IL-1). Leukaemoid reaction may be confused with chronic myeloid leukaemia at times.

Coagulopathy

Coagulopathy associated with malignancy may result in thrombosis or bleeding. These haemostatic abnormalities are an important cause of death in cancer patients. Cancers associated with DIC are acute promyelocytic leukaemia, pancreatic, gastric, lung, breast and colon cancers with mucin secreting tumours of the GI tract being the most frequent. The pathogenesis of the prothrombotic state in cancer is complex and probably, multifactorial. Prothrombotic factors in malignancy include the tumour production of procoagulants [i.e. tissue factor (TF) and cancer procoagulant (CP)], inflammatory cytokines, and the interaction between tumour cells, blood (i.e. monocytes/macrophages, platelets) and endothelial cells. Other mechanisms of thrombus promotion include some general responses of the host to the tumour (i.e. acute phase, inflammation, angiogenesis), decreased levels of inhibitors of coagulation, and impaired fibrinolysis. In addition, the prothrombotic tendency of cancer patients is enhanced by anti-cancer therapy, indwelling central venous catheter, and by haemodynamic compromise (i.e. stasis).

Non-bacterial thrombotic endocarditis is associated with numerous cancers, most commonly GI and lung. It is

characterised by the deposition of fibrin and platelets on the leaflets of the left heart valves. These fibrin vegetations lead to arterial embolisation, infarction, and sudden death.

RENAL PARANEOPLASTIC SYNDROMES

Although renal manifestations of systemic cancer may result from direct infiltration, metabolic complications and drug-induced renal damage, some syndromes are specific and paraneoplastic in nature.

Glomerular Disorders

Membranous nephropathy characterised by nephritic range of proteinuria, hypertension and microscopic haematuria is associated with cancers of the stomach, lung and colon. It usually occurs during or after the diagnosis of malignancy. Immune complexes are thought to play a role in membranous nephropathy as evidenced by subepithelial deposits on immunofluorescence and electron microscopy. The antigens may be foetal antigens or tumour-associated antigens, which lead to the production of cross-reacting autoantibodies. The nephrotic syndrome responds to the treatment of malignancy. Other glomerulopathies include focal and segmental glomerulosclerosis in CLL, immunoglobulin (Ig) A nephropathy in lung cancer and rarely, rapidly progressing glomerulonephritis with lymphoma.

Microvascular Lesions

Haemolytic uraemic syndrome has been reported with giant haemangiomas, acute promyelocytic leukaemia, gastric and pancreatic cancers or treatment with mitomycin C. Renal vasculitis with cryoglobulinaemia has been rarely reported.

CUTANEOUS PARANEOPLASTIC SYNDROMES

A wide range of cutaneous syndromes may be associated with internal malignancy. The appearance of skin lesions may be of extreme value in detection and management of cancer because skin is readily accessible for examination and biopsies. Secretion of cytokines like keratinocyte growth factors, interleukins, insulin like growth factor and triggering of an immune response to antigens expressed in the tumour and skin are thought to be responsible for cutaneous syndromes. These lead to increased proliferation, improper differentiation and hyperkeratosis of skin leading to the various manifestations.

Acanthosis Nigricans

It is characterised by hyperpigmented, grey brown, velvety-soft thickening of the skin on the nape of the neck, axilla, palms, soles, perineal and intertriginous areas and may be associated with pruritus. Acanthosis associated with tumour is of sudden onset and progressive and 50% to 65% are associated with gastric-carcinoma. Other malignancies include breast cancer, lymphoma, and squamous cell cancers. Successful treatment of the underlying malignancy may not lead to alleviation of symptoms.

Dermatomyositis

Dermatomyositis is an inflammatory proximal myopathy associated with characteristic skin changes. The rash accompanies or precedes the onset of myopathy. Skin manifestations include heliotrope rash, periorbital oedema, Grotton's sign (violaceous papules over the knuckles with scaling), photosensitivity, and subcutaneous calcifications. Associated malignancies include lung, breast, lymphoma, ovarian, and GI tract. Topical and systemic corticosteroids may be helpful in alleviating symptoms.

Erythemas

Several erythemas may be associated with cancer. Erythema gyratum repens is a condition characterised by erythematous gyrate bands then occur in a wave like pattern with pruritus. It is almost always associated with a malignancy, most commonly lung cancer followed by breast or GI cancer. Lesions typically regress with treatment of cancer.

Paraneoplastic Pemphigus

It is characterised by persistent painful erosions of the oral mucosa, lips and conjunctiva. It occurs with sarcomas and lymphoma. Other manifestations include erythema and blistering of the trunk and extremities. Treatment with steroids and azathioprine results in occasional responses and treatment of the malignancy often leads to improvement in the skin lesions.

MISCELLANEOUS PARANEOPLASTIC SYNDROMES

Anorexia and Cachexia

Cancer anorexia cachexia syndrome is the most common paraneoplastic syndrome consisting of anorexia, weight loss and wasting. Cancer cachexia may be associated with a hyper, hypo or eumetabolic state. Multifactorial derangements in biochemical pathways lead to cachexia. Patients who have more than 10% of weight loss have poorer survival. The central control of appetite may be altered by release of serotonin. Tumours produce factors that alter the perception of smell and taste of food leading to poor intake. This further aggravated problems like dysphagia and odynophagia as a result of local tumour effects. Maldigestion and malabsorption may result from obstruction of biliary or pancreatic pathways. Pharmacological approaches to improving nutritional status in cancer patients include appetite stimulants, anabolic steroids, corticosteroids and progestational agents. Unfortunately, most of these are not of proven benefit.

Hypertrophic Osteoarthropathy

This clinical syndrome is characterised by clubbing and periostitis of the long bones. Incomplete forms have been recognised including clubbing alone, isolated periostitis and pachydermia associated with minor manifestations like synovial effusions, seborrhoea, folliculitis, hyperhidrosis, hypertrophic gastropathy and acro-osteolysis. Hypertrophic osteoarthropathy (HOA) may be primary or secondary. It is associated with pulmonary, cardiac, liver, intestinal, mediastinal and miscellaneous problems. The most common disorders are non-small cell lung cancer (adenocarcinoma), lung metastasis, hepatocellular carcinoma, oesophageal cancer, thymoma and other non-malignant pulmonary conditions. The treatment of HOA is disappointing. Successful treatment of the underlying disease is associated with regression of the abnormalities. However, lung cancer associated HOA is usually diagnosed late, making successful treatment difficult. Patients with pain are treated with non-steroidal anti-inflammatory drugs.

21.16 Cancers in the Predisposed Host

K Pavithran

Cancer is a genetic disease, caused by alterations, loss, or amplification of genes that are important for normal cellular functions, including many proto-oncogenes and tumour suppressor genes. Cancer develops in a multi-step process, resulting from multiple genetic events. Predisposition to cancers occurs due to hereditary factors, immunodeficiency states (primary or secondary—acquired immunodeficiency syndrome or post-transplant setting), chemotherapy or radiotherapy.

HEREDITARY CANCER PREDISPOSITION SYNDROMES

Familial occurrence of cancer has been recognised for many centuries. Genes whose alterations result in hereditary predisposition to cancers have been classified as oncogenes or tumour suppressor genes. A minority of human cancer predisposition syndromes result from inherited mutations of oncogenes (e.g. *RET, MET, KIT*). The majority of cancer predisposition syndromes are due to inherited defects in tumour suppressor genes. Major cancer predisposition syndromes are given in **Table 1**.

Table 1: Cancer Predisposition Syndromes

Syndrome	Gene
Hereditary breast and ovarian cancer syndrome	*BRCA1, BRCA2*
Familial adenomatous polyposis	*APC, MYH*
Hereditary non-polyposis colon cancer syndrome	*hMSH2, hMLH1, hMSH6*
Multiple endocrine neoplasias (I, II)	*MEN1, RET*
Familial retinoblastoma	*RB1*
Neurofibromatosis I, II	*NF1, NF2*
von Hippel-Lindau syndrome	*VHL*

HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Hereditary breast and ovarian cancer syndrome (HBOC) is inherited in an autosomal dominant fashion with a penetrance of approximately 85%. Germ-line mutations in BRCA1 and BRCA2 account for about 90% of cases of inherited HBOC. HBOC patients develop breast cancer at an early age and are at elevated risk for cancers in other organs (e.g. pancreas, stomach, fallopian tube and prostate cancer in male BRCA carriers. Cancers arising in BRCA1 mutant patients are usually high-grade invasive ductal carcinomas.

Neurofibromatosis Type I

Neurofibromatosis type 1 (NF1) is inherited in an autosomal dominant fashion, with a penetrance of 100% for neurofibromas.

HEREDITARY NON-POLYPOSIS COLON CANCER (LYNCH SYNDROME)

Hereditary non-polyposis colon cancer is the most common cancer syndrome and is inherited in an autosomal dominant fashion with a penetrance of about 90%.

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is a highly penetrant, autosomal dominant disorder. The hallmark of FAP is the presence of at least a hundred (and often over a thousand) adenomatous polyps in the colorectum. A subset of these polyps will progress to malignant colon cancer. The cancer risk for FAP patients is virtually 100% by the age of 40 years.

IMMUNODEFICIENCY AND CANCER

Neoplasms are the second most common cause of mortality (after infections) among patients with primary and acquired immunodeficiencies.

Carcinomas After Allografting

Compared with the general population, the risk of developing cancer after organ transplantation is increased three- to five-fold. The risk of post-transplant carcinomas after bone marrow transplantation is influenced by the patient's inherent susceptibility to carcinogenesis and use of radiotherapy. The incidence of cancer in solid-organ transplant recipients increases greater than 1% per year after transplant such that about 20% of patients will experience a cancer within 10 years following transplantation. Many of these cancers involve the skin (squamous cell carcinoma, basal cell carcinoma, melanoma and Merkel cell carcinoma).

Lymphoproliferative Diseases (LPD) After Allogenic Organ Transplantation

The term 'post-transplant lymphoproliferative disease' (PTLD) are lymphoid or plasmacytic proliferations that develop as a consequence of immunosuppression in a transplantation recipient. The incidence of PTLD is approximately 1% for renal and 2% for hepatic transplants, but varies from 2% to 10% for heart, heart-lung, and bone marrow transplants and 20% of small bowel transplants. The interval from time of transplant to onset of PTLD is highly variable and depends on the type of allograft (arise more quickly in patients who have received a bone marrow or stem cell transplant), Epstein-Barr virus status (in EBV positive patients PTLD usually develops within the first year), and the immunosuppressive regimen used (more with high-dose cyclosporine). Majority (>90%) of PTLD in solid organ recipients are of host origin whereas majority of PTLD in bone marrow allograft recipients are of donor origin. The clinical presentations of PTLD vary considerably. PTLD has been grouped into four morphological categories, namely early lesions, monomorphic PTLD, polymorphic PTLD, and classical Hodgkin's lymphoma-like PTLD. The most common symptoms are non-specific, including fever, lymphadenopathy, weight loss, abdominal pain, and splenomegaly.

The initial treatment for PTLD involves modification of immuno-suppression. Using or changing immunosuppression to sirolimus can induce complete responses. Early-onset lesions and polymorphic are more likely to respond to reduction

in immunosuppression. In those who fail to respond to modification of immunosuppression, chemotherapy forms the backbone of therapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or rituixmab. Single agent rituximab produces response rates of around 60%.

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED MALIGNANCIES

Individuals with human immunodeficiency virus (HIV) infection are at increased risk for developing various neoplasms. The clinical course of specific malignancies is often markedly altered in the setting of HIV-positive infection as compared to the HIV-negative counterpart.

Acquired immunodeficiency syndrome (AIDS) defining neoplasms are: (1) kaposi's sarcoma (KS), (2) aggressive β-cell non-Hodgkin's lymphoma (NHL), both peripheral and primary central nervous system (CNS) lymphomas, and (3) cervical cancer. A number of other cancers also occur with increasing frequency in HIV-infected patients, including Hodgkin's disease (HD), multicentric Castleman's disease, angiosarcoma, multiple myeloma, lung cancer, and seminoma. Introduction of highly active antiretroviral therapy (HAART) for HIV infection has resulted in fewer AIDS complications, including malignancies.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is the most common HIV-associated tumour. KS is an angio-proliferative lesion caused by human herpes virus 8 (HHV-8).

AIDS-related KS

Co-infection with HIV increases the risk of KS by more than 100,000 times, and the clinical course can be more aggressive than that of classical KS. KS lesions typically arise on the skin or mucous membranes as flat deep purple plaques. Other sites that are commonly involved are lymph nodes and gastrointestinal (GI) tract. Skin lesions most commonly appear on the legs and face. Diagnosis is usually established by skin punch biopsy. As per the AIDS Clinical Trials Study Group (ACTG), patients are classified as "good risk" or "poor risk" according to the extent of tumour, immune status as measured by CD4+ T-cell count and evidence of HIV-associated systemic illness. KS is not yet curable. Treatment is only palliative in nature. HAART is fundamental to the oncologic therapy of AIDS-KS. If HAART does not result in immunologic and virologic response, additional therapies are required like surgical excision, cryotherapy, photodynamic therapy, intra-lesional injection (e.g., vinblastine), topical 9-cis-retinoic acid, carbon dioxide laser therapy and radiotherapy. Systemic drug therapy is usually with immunotherapy (interferon) or cytotoxic chemotherapy (liposomal anthracyclines or paclitaxel) or combination chemotherapy (doxorubicin, bleomycin, and vinca alkaloid).

Acquired Immunodeficiency Syndrome-Related Lymphoma

AIDS-related lymphoma (ARL) is the second most frequently occurring AIDS-associated malignancy. The risk of developing NHL in the HIV-infected population increases by nearly 100 times the risk in the non-HIV infected population. Introduction of HAART has reduced the incidence of ARL by up to 50%. EBV and HHV-8 has a role in the pathogenesis of ARL.

Predominant related ARLs are—Burkitt's lymphoma, diffuse large β-cell lymphoma, primary effusion lymphoma (PEL); also termed body-cavity lymphoma and plasmablastic lymphoma (PBL) of the oral cavity.

Patients with ARL and AIDS associative Non-Hodgkin's lymphoma (NHL) usually present in advanced stage, have a high incidence of B symptoms and majority of them have some extranodal disease and in one-third of the cases all disease is extranodal. The GI tract is a common site of extranodal involvement. Prognosis depends upon the CD4+ cell count. In the pre-HAART era, survival was very poor, currently the median survival is more than 2 years.

Optimal therapy is not well defined. Treatment consists of standard-dose chemotherapy. Routine CNS prophylaxis is advised for these patients as there is a high predilection for leptomeningeal involvement (15% to 20%). All patients should receive prophylaxis for *Pneumocystis jirovecii* pneumonia regardless of the CD4+ count. Data regarding the use of rituximab is conflicting, as rituximab was associated with excessive toxicity in some series, however, one recent report shows, it is very effective. HAART therapy is continued during the period of chemotherapy unless contraindicated.

Primary effusion lymphoma

It accounts for about 4% of all HIV-associated NHLs. It is caused by HHV-8 infection with a predilection for the serous body cavities. Primary effusion lymphoma occurs as a late manifestation of HIV infection. Patients have a poor clinical outcome and a shorter overall survival (6 months). Combination chemotherapy is the mainstay of the treatment along with HAART.

Plasmablastic lymphoma

It is a rare AIDS-associated NHL, with predilection for the mucosa of oral cavity. It has also been reported in other sites, such as stomach, cervical lymph nodes, lungs, orbit, and paranasal sinuses. The treatment of PBL is not well defined and patients have been treated heterogeneously with chemotherapy and/or radiotherapy.

Human papillomavirus (HPV) associated cancers in AIDS

HPV associated cancers in AIDS include cervical cancer and anal cancer.

Cervical cancer

Immunosuppression and HPV co-infection play a major role on the pathogenesis of the disease. HPV16, 18, 45, and 31 are commonly associated with invasive cervical cancers; that are usually more aggressive and have a higher recurrence rate. The management is similar to patients from the general population without HIV infection. The use of HAART does not seem to have an impact in patient outcome. Rigorous cervical cancer screening programmes in HIV infected patients could have an impact in reducing the incidence and mortality rates in the HPV/HIV infection setting.

Anal cancer

Anal cancer is also associated to oncogenic types of HPV and its incidence has dramatically increased among HIV patients. Chemoradiotherapy (fluorouracil and mitomycin) produces a similar response to those of the general population, with a survival rate of 55% to 75% and preservation of the sphincter in 60% to 90% of cases. The use of screening techniques, such as anal Papanicolaou smear and anoscopy and biopsy are necessary to diagnose intraepithelial lesions or true invasive

cancers and any person diagnosed with anal squamous cell carcinoma must be evaluated for HIV infection.

CANCERS FOLLOWING CHEMOTHERAPY

Many of the cytotoxic agents are potentially mutagenic and carcinogenic, the degree varies among different drugs. Now more and more people are getting cured of their disease after radiotherapy and/or chemotherapy, this has led to therapy-related secondary malignancy, developing years after primary therapy.

After chemotherapy, secondary malignancies are mainly secondary acute myeloid leukaemias (AML). Secondary lymphatic leukaemias are very rare (about 5%). Most of these secondary leukaemias appear in the first 10 years after chemotherapy, especially after alkylating agents or nitrosourea derivatives. Of the alkylating agents, melphalan is thought to be the most leukaemogenic. Risk factors for secondary malignancies include the cumulative dose of the cytostatic agent, age over 40 years, the combination of chemotherapy and radiotherapy.

Based on their characteristics, secondary leukaemias can be divided into two types; secondary leukaemia after administration of alkylating agents, or after therapy with topoisomerase-II inhibitors (epipodophyllotoxin—etoposide) (**Table 2**).

The cumulative 10-year incidence of secondary leukaemia varies greatly, depending on the underlying disease. For example, after curative treatment for Hodgkin's disease, incidence is cited at 1.5% to 10%, and peaks about 4 to 8 years after therapy.

Table 2: Clinical Characteristics of Secondary Acute Myeloid Leukaemia

	DNA-damaging Agents	Topoisomerase II Inhibitors
Latency (in years)	4 to 6 years (range: 1 to 20 years)	1 to 3 years (range: 0.5 to 4.5 years)
Presentation	Antecedent myelodysplastic syndrome	Abrupt, no prodrome
Genotype	Losses, deletions (-5,-7)	Translocations 11q23-based; t(8;21); t(15;17)
Phenotype	M6 and M7 (with myelofibrosis)	Monocytic (M4 and M5)
Prognosis	Less favourable	Favourable

SECONDARY CANCERS FOLLOWING RADIOTHERAPY

Radiotherapy can also induce tumours, with chemotherapy and/or radiotherapy-associated secondary malignancies. Following radiotherapy, it is primarily solid tumours that develop; secondary leukaemias are rare. Following criteria are suggested to diagnose post-irradiation secondary tumour: (1) tumour must have arisen within a previous radiation field, (2) secondary malignancy should differ histologically from the primary, irradiated tumour, (3) if the secondary tumour is leukaemic, the latency period should be more than 2 years, and if it is a solid tumour, more than 6 years, and (4) amount of statistical data should be large enough so that a possible association can be reasonably assumed.

The interval between irradiation and development of a secondary tumour varies. Leukaemias may develop as early as 2 years post radiation, with incidence peaking 5 to 10 years after radiotherapy. Thereafter, risk decreases with time. For solid tumours, intervals of at least 6 years are usual. The risk increases with increasing radiation dose and decreasing age. Children are more prone to develop secondary cancers than adults. Patient who receives neck radiation are at risk for the subsequent occurrence of thyroid cancer. Children who receive prophylactic cranial irradiation for acute lymphatic leukaemia are at increased risk of brain tumours.

EVALUATION OF PATIENTS AT RISK FOR SECOND MALIGNANT NEOPLASMS

In the past history, one should ask for the risk factors like: (1) history of treatment with radiation therapy, an alkylating agent, and/or a topoisomerase-II inhibitor, (2) history of hereditary retinoblastoma (unilateral with a positive family history or bilateral), (3) carrier of ataxia-telangiectasia, (4) post-surgical chronic lymphoedema, and (5) oestrogen treatment.

In the present history, ask for any pain in the previously irradiated area, pallor, bleeding tendencies (e.g. blood in stool, inter-menstrual bleeding). This should be followed by a detailed physical examination. Examination of irradiated patients will help in the early identification of thyroid nodules and skin cancer. Annual mammography should be initiated, not later than 10 years after breast irradiation.

Investigations including radiographs of any painful area or mass in a previously irradiated area, stool examination for occult blood (any patient who received any abdominal irradiation), Pap smear, urine cytology (in any patient with haematuria and a history of bladder irradiation and/or treatment with a cyclophosphamide or ifosfamide), mammogram, depending upon the clinical situation are recommended. All patients who have been treated with an alkylating agent or a topoisomerase-II inhibitor should have a complete blood count every 6 to 12 months for a minimum of 12 years after diagnosis.

Transplant recipients should be warned as to the dangers of sun exposure. They should undergo full skin examination by their transplant care provider. Studies have demonstrated a benefit to systemic retinoid chemoprophylaxis in transplant recipients.

FOLLOW-UP

All former cancer patients should remain under a physician's care indefinitely. For children, there are special after-treatment follow-up clinics in major cancer centres. This helps in regular monitoring of these patients and in giving advises. They should be counselled regarding the potential for the adverse effects of tobacco use, including the potential to interact with the adverse effects of their prior therapy, such as irradiation of the oropharynx, oesophagus, and/or lungs.

21.17 Oncological Emergencies

Avinash Deo

INTRODUCTION

Emergencies in cancer can be catastrophic. Oncological emergencies are often a part of the initial presentation of a cancer patient. The management of oncological emergencies needs understanding of the disease process. The goals of therapy have to be clear and have to be based on the biology of the underlying neoplasm. Many seeming hopeless situations in fact have a good outcome if treated appropriately. Oncological emergencies result from the mass effect of the tumour and the effect of metabolites secreted by the tumour. The common oncological emergencies are listed in **Table 1**.

Table 1: Oncological Emergencies

Metabolic emergencies
Tumour lysis syndrome
Hypercalcaemia
Hypoglycaemia
Lactic acidosis
Hyperuricaemia
Syndrome of inappropriate ADH secretion (SIADH)
Urological emergencies
Haemorrhagic cystitis
Priapism
Haematological emergencies
Haemolytic uraemic syndrome
Febrile neutropaenia
Cardiac and vascular emergencies
Cardiac tamponade
Thrombosis and pulmonary thromboembolism
Emergencies due to pressure effects of the tumour
Superior vena cava syndrome
Spinal cord compression
Intestinal obstruction

SYNDROME OF INAPPROPRIATE ADH SECRETION

Ectopic production of antidiuretic hormone (ADH) by tumours results in water retention, hyponatraemia, and increased urinary osmolarity. About three-fourth of the patients with syndrome of inappropriate ADH secretion (SIADH) have small cell cancer of the lung. It is also associated with the use of vincristine, cyclophosphamide, ifosfamide and melphalan and with brain metastasis. The symptoms of SIADH are those of hyponatraemia and water intoxication. The diagnosis is made by a euvolaemic hyponatraemia in the absence of hypothyroidism, renal dysfunction, or Addison's disease. Tumour-associated SIADH is differentiated from other causes of SIADH by exclusion, though the differentiation has little bearing on the therapy. The treatment of the primary is the cornerstone of the therapy. Radiation is administered for brain metastasis. Fluid restriction, demeclocycline (300 to 600 mg twice daily) and hypertonic saline are administered as required.

TUMOUR LYSIS SYNDROME

Tumour lysis syndrome (TLS) is a complex of metabolic derangements resulting from the kidney's inability to handle products of cell lysis. Potassium, phosphates, and purine metabolites are the major intracellular components that are toxic when released into the extracellular space. These are eliminated by the kidney. The kidney has a finite capacity to eliminate these compounds. The excretory capacity of the kidney may be overwhelmed if these compounds are released too rapidly in large amounts, or when the kidney function is compromised. Hyperkalaemia poses the greatest immediate risk to the patient with TLS. Uric acid is formed from xanthine by the action of xanthine oxidase and is the end-product of purine catabolism. Uric acid precipitates in the tubules leading to renal impairment and compromises the ability of the kidney to excrete potassium. Hyperphosphataemia results secondary to hypocalcaemia due to calcium chelation. Hypocalcaemia worsens the effects of hyperkalaemia. Tumour lysis is most commonly seen in high-grade haematological malignancies (e.g. acute leukaemias and high-grade lymphomas). It is most commonly seen after therapy but may occur spontaneously. Patients with a large tumour burden, patients with pre-existing metabolic derangements like hyperuricaemia and hyperkalaemia and patients with impaired renal function are prone to TLS. Prevention is the best treatment for TLS. Established TLS is a life-threatening condition. Patients should be adequately hydrated (3 litres per day) and initiated on 300 mg of allopurinol per day. Most favour alkalinisation of the urine. The treatment of established TLS is that of the derangements it causes. Allopurinol should be administered to prevent formation of uric acid. Allopurinol has no effect on uric acid which is already formed. Hydration and diuresis eliminate pre-formed uric acid. Recombinant urate oxidase can destroy uric acid and may be considered in patients who are refractory to allopurinol and hydration. Hyperkalaemia is treated with potassium restriction, hydration, diuresis, glucose-insulin drip, beta-2 agonist aerosols and dialysis. Hyperphosphataemia is treated with phosphate restriction and dialysis.

SUPERIOR VENA CAVA SYNDROME

The superior mediastinum is a space through which tubular structures pass from the neck to the thorax. Lymph nodes draining the lung are found in the fatty tissues. As the superior mediastinum has rigid walls, structures passing through it are prone to compression by space occupying pathologies. The commonest cause of superior mediastinal syndrome is lung cancer followed by lymphomas. Superior vena cava syndrome (SVCS) due to catheter-induced thrombosis is being seen more often with the increasing use of venous access devices.

The common manifestations of SVCS include dyspepsia, swelling of the face and upper extremities, cough, chest pain and dysphagia. Examination shows distended neck

veins and chest wall oedema, plethora of face, and oedema of the arms.

Radiograph of the chest is normal in only 15% of the patients. Computed tomography (CT) is performed to define the extent of disease and invasion of adjacent structures including the great vessels, bronchus, and the spinal cord. Venography is indicated if a surgical bypass is contemplated. The investigations to establish diagnosis include sputum cytology, examination of pleural fluid, bronchoscopy, thoracoscopy, mediastinoscopy, lymph node biopsy, and bone marrow biopsy. There is no increased risk of bleeding in areas drained by the SVC because of increased pressure. Invasive procedures can be carried out safely if the need arises.

The treatment of SVCS is disease-specific. SVCS is seldom a dire emergency. Patients with small cell cancer of the lung with SVCS should be treated with chemotherapy and radiation. The response rate exceeds 95%. About 70% of the patients remain free from the disease despite relapses in other parts. Patients with non-small cell lung cancer with SVCS have a poor outcome compared to those without SVCS. They should be treated with radiotherapy. Patients with SVCS due to lymphoma should be treated with chemotherapy with radiation being used for patients who have large mediastinal masses. Catheter-induced SVCS may be treated with thrombolytic agents early (< 5 days) in the course of the disease. Catheters of patients with prolonged symptoms should be removed and this should be done under cover of heparin. All patients of SVCS should be given head elevation and oxygen therapy. Diuretics can reduce oedema but dehydration increases the risk of thrombosis. Anti-coagulants are not of proven use and may interfere with diagnostic procedures. Percutaneously transluminal angioplasty with stent insertion may be considered in patients to provide symptomatic relief pending diagnosis and in patients who cannot be offered therapy. Stenting is superior to radiation.

HYPERCALCAEMIA

Hypercalcaemia is seen in about 10% to 20% of the patients with malignancy. It is commonly seen with multiple myeloma, breast cancer, lung cancer, kidney cancer, and head and neck cancer. Hypercalcaemia results from bone resorption from metastasis or from the effect of factors secreted by the tumour on calcium metastasis. Patients who are asymptomatic with serum calcium levels less than 13 mg/dL do not need aggressive treatment. Volume repletion, limitation of immobilisation, and treatment of the primary may bring down the calcium levels. All symptomatic patients and those patients with serum calcium more than 13 mg/dL should be treated. Hydration brings down the calcium by 2 mg/dL. Though the fall is modest, hydration forms a critical part of treatment of hypercalcaemia. Dehydration leads to an impaired ability to eliminate calcium by the kidney. One to two litres of 0.9% saline may be administered over 2 hours with 20 to 40 mg frusemide. Bisphosphonate (zolendronate 4 mg over 15 to 30 minutes) results in normalisation of serum calcium by 4 to 10 days. The fall lasts for 4 to 5 weeks. Other active agents include gallium nitrate, calcitonin, and plicamycin.

SPINAL CORD COMPRESSION

Though about 1% to 6% of the cancer patients have spinal cord compression, only 1 in 500 patients present with spinal cord compression. Cancers associated with spinal cord compression are breast cancer, multiple myeloma, prostate cancer, lung cancer, and nasopharyngeal cancer. The thoracic spine is involved in about 66% of the cases and the lumbar spine in about 20%. Cervical spine and sacrum are rarely involved. Prostatic and colorectal carcinomas show a predilection for the lumbar spine.

The compression usually occurs due to the extension of disease from a vertebral metastasis. Lymphomas and neuroblastomas can compress the spine by transforaminal extension of para-vertebral mass. Myelopathy of spinal cord compression results from physical damage to the cord and cord oedema due to impaired venous drainage.

Spinal cord compression presents with low back pain. The pain is worse on getting up in morning and may increase on coughing and sneezing. Radiation indicates root involvement. Pain is followed by neurological symptoms. Symptoms of neurogenic bladder occur late.

Magnetic resonance imaging (MRI) is the most important investigation in patients with suspected malignant spinal cord compression. CT-guided myelography may be performed where MRI is contraindicated. Plain radiographs lack sensitivity. The immediate treatment consists of glucocorticoids. Dexamethasone 6 to 10 mg is the drug of choice. The compression may be relieved by radiotherapy or surgery.

RAISED INTRACRANIAL PRESSURE

Normal brain function requires a normal intracranial pressure (ICP). Increase in brain volume like that seen with tumours can be offset by a decrease in the cerebrospinal fluid (CSF) volume, but the compensatory mechanism has its limits. Patients manifest central nervous system (CNS) dysfunction once this limit is breached. ICP may increase due to increase in volume of intracranial structures or an imbalance between production and resorption of CSF. Tumours, brain oedema, extra-axial mass lesions of dura and subdura, intracranial haematoma and subdural empyemas result in an increase in the intracranial contents and rise in the ICP. Malignancy-related increases in CSF volume are rare due to increased production. Absorption of CSF may be hampered by obstruction to the flow of CSF, due to mass lesion along the path of flow described above or by the involvement of the meninges by meningitis or carcinomatosis.

The commonest cause of increased ICP is brain metastasis. Lung cancer, breast cancer, melanoma, choriocarcinoma, renal cell carcinoma, and papillary cell carcinoma of the thyroid are the common causes of metastasis to the brain. Some malignancies like acute lymphoblastic leukaemia have a tendency to involve the meninges. Primary brain tumours particularly those with a periventricular predilection can cause raised ICP. Iatrogenic causes of raised ICP include radiotherapy and meningitis. Cancer patients are immunodeficient and prone to herpes simplex virus (HSV) encephalitis, cryptococcal meningitis, cerebral toxoplasmosis, aspergillosis, and candidiasis. Dural venous sinus thrombosis, either spontaneous or as a result of L-asparaginase therapy, presents with only symptoms of raised ICP in one-third of the cases.

Raised ICP manifests as headache, vomiting, and somnolence which progresses to coma. Focal neurological deficit gives a clue

to the location of the mass. Examination shows papilloedema in about 50% of the patients. Gadolinium-enhanced MRI is the investigation of choice. An unenhanced CT is a quick and readily available alternative that is adequate to determine obstruction to the flow of CSF, uncal, transtentorial and transfalcian herniation and the presence of haemorrhage into a tumour.

The patients should be nursed with their head slightly elevated; dehydration should be corrected using isotonic fluids and corticosteroids administered unless a CNS lymphoid malignancy is suspected. Dexamethasone 24 to 40 mg per day is usually used. Mannitol (0.75 to 1g/kg initial dose followed by 0.25 to 0.5 g/kg every 3 to 6 hours as a 20% to 25% solution) can reduce ICP. The effect of mannitol is transient. Therapy should be stopped if osmolarity exceeds 300 mOsml/L. The fastest method to reduce ICP is intubation and hyperventilation. The target pCO_2 is 25 to 30 mm Hg. Lower levels compromise cerebral blood flow. Obstructive hydrocephalus is neurosurgical emergency treated with external ventriculostomy or placement of a third ventriculostomy. A ventriculo-peritoneal shunt should be avoided as there is a risk of peritoneal seeding. Appropriate therapy for the primary disease should be carried out.

MALIGNANCY-ASSOCIATED HAEMOLYTIC URAEMIC SYNDROME

Haemolytic uraemic syndrome manifests as microangiopathic haemolytic anaemia, thrombocytopaenia, and renal failure. The causes of malignancy-associated haemolytic uraemic syndrome include adenocarcinomas particularly those of the gastrointestinal tract, chemotherapy drugs, and stem cell transplant. Drug-induced haemolytic uraemic syndrome is most commonly seen with mitomycin C and fluorouracil. Other implicated agents include cytosine arabinoside, bleomycin, cisplatin, daunomycin, deoxycoformycin, estramustine, gemcitabine, immunotoxins, and semustine. The outcome of malignancy-associated haemolytic uraemic syndrome is poor. The incriminated agent if any should be withdrawn. Plasma exchange may be attempted but its efficacy is not as much as in idiopathic variety. Cryosupernatant which is free of von-Willebrand factor may be a better replacement than plasma.

HYPERURICAEMIA

Hyperuricaemia may be seen in absence of TLS. It is common in high-grade tumours like acute leukaemias and non-Hodgkin lymphoma. Hyperuricaemia results from increased uric acid production from increased cell turnover. The management of hyperuricaemia is similar to that in patients with TLS.

HAEMORRHAGIC CYSTITIS

Haemorrhagic cystitis presents as suprapubic discomfort, dysuria, frequency and urgency of micturition with haematuria. It is seen with ifosfamide, cyclophosphamide (high dose) and pelvic radiation (cervical cancer, bladder cancer and rectal cancer). Chemotherapy-induced haemorrhagic cystitis is prevented by the use of mesna in an appropriate dose. Radiation cystitis requires discontinuation of radiation. Gross haemorrhage can result in urinary retention due to large clots. Severe haemorrhage is treated with continuous infusion with haemostatic agents (0.5% to 1% silver nitrate or 1% alum) into the bladder. Formalin (1% to 5% solution) may be instilled cystoscopically for 3 to 10 minutes in life-threatening haemorrhage. Other agents which have been tried are prostaglandins, oral conjugated oestrogens or hyperbaric oxygen. Open cystostomy with bladder packing may be used if other measures fail.

PRIAPISM

Priapism may complicate the course of 10% of the patients. Priapism results from penile metastasis. It may also be seen in haemolymphatic malignancy with high counts. The therapy involves analgesics and treatment of the underlying malignancy.

21.18 Supportive Care in Cancer

Madhuchanda Kar, Rakesh Roy

INTRODUCTION

The success story of treatment of cancer in the last decade is largely contributed by the rapid advances in supportive care. This has led to more aggressive chemotherapy with intention to cure, bone marrow transplant in haematological malignancies and palliative therapy for incurable advanced stage cancer patients. The main types of supportive care are directed towards management of following conditions.

ANAEMIA ASSOCIATED WITH CANCER

Anaemia in cancer patients could be due to the bone marrow infiltration, bleeding, hypersplenism, haemolysis, defective iron utilisation, treatment related (extensive radiotherapy or chemotherapy) and diminished nutritional status with deficiencies. 40% of patients with non-myeloid malignancies have anaemia. Overall incidence of anaemia during chemotherapy or radiotherapy is 54% with highest in patients with lung (71%) or gynaecological cancer (65%) and it increases with the number of chemotherapy cycles. Anaemia has a negative impact on the quality of life (QoL) and is an important factor in cancer-related fatigue.

Grading of Anaemia

Treatment-related anaemia is graded according to the National Cancer Institute – Common Toxicity Criteria of Adverse Events (CTCAE v3)

Grade 0 : Haemoglobin within normal limits

Grade 1 : Lower normal level of haemoglobin 10 g/dL

Grade 2 : 8 to less than 10 g/dL

Grade 3 : 6.5 to less than 8 g/dL

Grade 4 : Less than 6 g/dL

Grade 5 : Death

Evaluation of Anaemia

Drug history, haemogram, peripheral blood smear with reticulocyte count, serum iron, transferrin saturation with ferritin levels, Coomb's test, folate and vitamin B12 status and bone marrow examination. Occult blood test in stool, urine routine examination, and evaluation of renal function are the common tests for its diagnosis.

Indications for the Use of Erythropoiesis Stimulating Agents (ESAs)

1. In non-haematological malignancies erythropoiesis stimulating agents (ESAs) are used for the treatment of symptomatic chemotherapy-induced anaemia in adult patients to prevent repeated transfusions and their hazards and improve quality of life. If the Hb level increases by 1 g/dL in 4 weeks then the dose may remain same or reduced by 25% to 50% but if the haemoglobin (Hb) rise is less than 1 g/dL above baseline, the dose should be increased. If the Hb rise is less than 1 g/dL above baseline after 8 to 9 weeks or if Hb 13 g/dL then treatment with ESAs should be discontinued.
2. Amongst haematological malignancies low-risk myelodysplastic syndromes and post-allogeneic transplantation are indications. There is no difference between different ESAs in relation to effectiveness and safety and they should not be used in patients with poorly-controlled hypertension. The relative risk of thromboembolic events increases with ESAs.

NEUTROPAENIA

Neutropaenia in cancer patients is due to bone marrow infiltration from disease or treatment-related (chemotherapy and radiation therapy). The implications are life-threatening infections and delay in treatment. The risk associated with neutropenia increases with its duration and grade. It occurs more in patients older than 65 years, patients with poor performance status, chronic obstructive pulmonary disease, diabetes mellitus, and existing renal or cardiac dysfunctions. Timely intervention reduces morbidity and mortality. Neutropaenia grading scale as per recommendations of the World Health Organization (WHO) is given below:

Grade I : Not significant = 1500 to 2000 ANC(ANC – absolute neutrophil count)

Grade II : Minimal = 1000 to 1500 ANC

Grade III : Moderate = 500 to 1000 ANC

Grade IV : Severe = less than 500 ANC

Febrile Neutropaenia

It is defined as single oral temperature of 38.3°C or 38.0°C over 1 hour with less than 500 neutrophils/mm^3 or less than 1,000 neutrophils/mm^3 with a predicted decline to 500/mm^3 over the next 48 hours. The absence of granulocytes, disruption of mucociliary barriers and shifts in inherent microbial flora along with anti-microbial usage predispose the neutropaenic cancer patients to infections. History taking, physical examination, obtaining cultures, and starting antibiotics empirically are the key. Primary sites of infection are the alimentary tract (i.e. mouth, pharynx, oesophagus, intestine, and rectum), sinuses, lungs, genito-urinary tract, and skin.

The first approach is empiric intravenous monotherapy with either a carbapenem or an extended spectrum anti-pseudomonal cephalosporin followed by combination of aminoglycoside plus an antipseudomonal penicillin. If there is no remission of fever within 48 hours, consider vancomycin depending on potential infecting organisms. Vancomycin can be started upfront in case of catheter-related infections or where there is substantial mucosal damage. If still no remission occurs in next 48 hours then start empirical antifungals. Risk assessment should be performed as part of the initial evaluation. Risk factors are mentioned in **Table 1**.

For lung infiltrates consider additional empiric coverage for atypical pneumonia pathogens (fluoroquinolone, macrolide, or doxycycline) and empiric trimethoprim/sulfamethoxazole or pentamidine for patients allergic to sulphur or patients at high risk for *Pneumocystis jirovecii* pneumonia, Rimantadine, Amantadine during influenza season can be considered.

Table 1: Multinational Association of Supportive Care in Cancer (MASCC) Scoring Index

Burden of illness : No or mild symptoms	5
Burden of illness : Moderate symptoms	3
Burden of illness : Severe symptoms	0
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumour/lymphoma with no previous fungal infection	4
No dehydration	3
Outpatient status at the time of onset of fever	3
Age <60 years	2

Using the MASCC-Risk Score: scores ≥ or 21 are at low risk of complications.

Fungal infections are common in neutropaenic patients so empiric use of fluconazole was common. *Candida albicans* have recently been surpassed by non-albicans species which are resistant to fluconazole. Empiric antifungal therapy previously involved amphotericin B at the expense of greater toxicity. The newer lipid formulations of amphotericin B are less toxic. Voriconazole is approved for use in invasive aspergillosis. Primary antifungal prophylaxis involves fluconazole 400 mg daily or itraconazole 400 mg daily.

The use of growth factors for the treatment of febrile neutropaenia is not recommended always except in settings where there is septicaemia, tissue infection, co-morbidities, and prolonged neutropaenia. They reduce duration of neutropaenia but do not alter morbidity and mortality. The granulocyte colony stimulating factor (G-CSF) is given at a dose of 5 µg/kg per day till stable ANC recovery. Pegfilgrastim is a single dose colony stimulating factor and is equally effective.

VENOUS THROMBOEMBOLISM (VTE)

Venous thromboembolism (VTE) represents one of the most important causes of morbidity and mortality in cancer patients with highest incidence in metastatic brain, lung, uterus, bladder, pancreas, stomach, and kidney cancer. The absolute risk depends on tumour type, site and stage, administration of chemotherapy or hormone therapy, surgical intervention, the presence of indwelling catheters, age, pre-chemotherapy platelet and leucocyte count, immobilisation, and previous history of VTE.

Prophylaxis with unfractionated heparin, low molecular weight heparin (LMWH) or fondaparinux in hospitalised cancer patients confined to bed with acute medical complication is recommended. Use of vena caval filters are advocated for recurrent pulmonary embolism. Long term treatment with LMWH is safe and more effective than oral anticoagulation with vitamin K antagonists.

CANCER RELATED FATIGUE

Definition of cancer related fatigue (CRF) (in the 2010 NCCN CRF guidelines) is a distressing persistent subjective sense of physical emotional and/or cognitive tiredness to exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning. Patient with various types of cancer receiving different types of treatment report the frequency of CRF ranging from 70% to 100%. Persistent CRF is reported by 30% to 40% of cancer survivors. It is a multi-dimensional syndrome and several mechanisms coexist in its pathophysiology.

The first step in the management of fatigue is to identify the potentially reversible contributors. Causes and remedy are mentioned in **Table 2**. After that clinicians may choose to select from amongst the established and investigational drugs used for the symptomatic pharmacologic management of CRF. Methylphenidate has been the most frequently used. Exercise may be beneficial in reducing CRF. Psychological interventions include cognitive behavioural therapy, education or counselling, and supportive or expressive therapy.

Table 2: Frequent Contributors to Fatigue and Suggested Treatments

Mood disorders	Anti-depressants
Endocrine	Thyroid, testosterone replacement
Dehydration	Fluid replacement
Pain	Opioids, adjuvant analgesics
Infections	Antimicrobials as appropriate
Anaemia	Blood transfusion as appropriate
Cachexia	Nutritional and pharmacological interventions
Chemotherapy	Dose and drug modification as appropriate

CANCER PAIN

Incidence of Pain

Over 80% of cancer patients with adjuvant metastatic disease suffer from pain, caused mostly by direct tumour infiltration. Approximately 20% of pain in cancer patients may be attributed to the effects of surgery, radiotherapy, or chemotherapy. The pain may be nociceptive, neuropathic, or a combination of both. The pain management is based on WHO step ladder pattern as given below:

Treatment of mild pain (WHO analgesic ladder-step I): Mild pain (Numerical Rating Scale [NRS]: 1-4) is treated with non-opioid analgesics such as acetaminophen/paracetamol or NSAIDs with or without adjuvants (medicines which are primarily not analgesics but aid in analgesia) like sedatives and steroids.

Treatment of moderate pain (WHO step II): Moderate pain (NRS: 5-7) have been treated with a combination of step I plus a weak immediate-release opioid such as codeine, dihydrocodeine, tramadol, or propoxyphene.

Treatment of severe pain (WHO step III): Severe pain (NRS: 8-10) is best managed by a strong opioid and step I. Morphine is most commonly used via oral route. Transdermal Fentanyl is best reserved for patients whose opioid requirements are stable.

Scheduling and Titration

All patients should receive round-the-clock dosing with provision of a 'breakthrough dose' to manage transient excerbation of pain which is breakthrough pain. The 'breakthrough dose' is usually equivalent to +10% to 15% of the total daily dose.

Alopaecia

It is undoubtedly one of the most distressing complications of chemotherapy. Hair loss starts from the first cycle and peaks up at 2 months. Regrowth occurs once chemotherapy ends. However, the texture may vary. Anthracyclines, taxanes, and cyclophosphamide are major culprits. Chemotherapy-induced alopecia (CIA) is traditionally categorised as acute diffuse hair loss caused by dystrophic anagen effluvium. The major approach to minimize CIA is by scalp cooling though robust data are missing. Minoxidil was able to reduce the severity or shorten the duration of CIA, but could not prevent CIA.

Chemotherapy Induced Nausea and Vomiting

Another distressing consequence of cancer chemotherapy is nausea and vomiting. Antineoplastic drugs with high emetogenic potential are cisplatin, cyclophosphamide greater than1500mg/m^2, dacarbazine, lomustine, streptozocin. Combination protocols are most dangerous. Chemotherapeutic agents induce nausea and vomiting through central mechanisms (stimulation of chemoreceptor trigger zone) and peripheral gut mucosal receptors through 5-HT receptors. Clinically, three forms of chemotherapy induced nausea and vomiting (CINV) are recognised. Anticipatory CINV occurs before patients receive chemotherapy and is mediated by cortical mechanisms. Acute CINV is seen up to 24 hours post-chemotherapy and nausea and vomiting developing more than 24 hours after chemotherapy up to day 5 is termed as delayed nausea and vomiting.

To prevent CINV, a three drug regimen including single doses of a 5-HT3 receptor antagonist [ondansetron (32 mg) or palonosetron (0.25 mg)], dexamethasone (12 mg) and aprepitant 125 mg day 1, 80 mg day 2 and day 3 (a neurokinin 1 receptor antagonist) given before chemotherapy is recommended. The combination of dexamethasone and aprepitant is also suggested to prevent delayed nausea and vomiting on the basis of its superiority to dexamethasone alone. The ideal approach to the treatment of anticipatory emesis is maximum effective control of acute and delayed emesis.

Diarrhoea

Causes of diarrhoea in cancer patients are injudicious use of antibiotics, co-morbid infection, partial intestinal obstruction, surgery (post-gastrectomy, short-bowel syndrome), acute or chronic radiation toxicity, and chemotherapy.

Chemotherapy-induced diarrhoea (CID) can cause significant morbidity and mortality and at times severe enough to require a dose reduction or a delay, or a discontinuation of chemotherapy. 5-FU (5-flurouracil), irinotecan, and capecitabine are most notorious in this respect. The incidence of all grades of diarrhoea during chemotherapy has been reported to be as high as 82%, with up to one-third of patients experiencing severe (grade 3 or 4) diarrhoea (**Table 3**). Newer oral tyrosine kinase inhibitors have diarrhoea as one of the side effects.

Chemotherapy-induced diarrhoea (CID) can result in life-threatening dehydration, electrolyte imbalances, renal insufficiency, nutritional deficiencies, and affects quality of life. Diarrhoea is also associated with an increased risk of infectious complications in patients with chemotherapy-induced neutropaenia.

Acute medical management of CID includes loperamide or diphenoxylate as first-line agents. Subcutaneous octreotide is recommended for intractable grade 2 diarrhoea and may be considered for grade 1 CID that does not resolve with high-dose loperamide. Hospitalisation is recommended for patients with grades 3 and 4 CID. In-hospital care includes rehydration, antibiotic therapy, and octreotide. A chemotherapy dose reduction is generally advised for patients who have experienced grade 3 or 4 diarrhoea in a previous chemotherapy cycle. Patients should be advised to take low residue diet and ample fluids and avoid caffeinated beverages and alcohol.

Table 3: Chemotherapy Induced Grades of Diarrhoea – National Cancer Institute

Grades	0	1	2	3	4
	None	<4 stools per day	4 to 6 stools per day nocturnal stools	>7 stools per day but less than 10 or incontinuous	>10 stools per day

Dihydropyrimidine dehydrogenase (DPD) plays a central role in 5-FU metabolism, and DPD deficiency is well documented as possibly resulting in severe 5-FU-associated toxicity. The morbidity associated with irinotecan chemotherapy may also be reduced by screening candidates for uridine diphosphate glucuronyl transferase polymorphisms.

Supportive care in oncology has made substantial strides in clinical medicine in the last decade. A working knowledge of the common conditions and their prevention and management will help improve quality of life of cancer patients.

22.1 Basic Considerations in Psychiatry

Ashit Sheth

Psychiatric disorders may occur from disturbances of one or more of the following interrelated factors like biological factors, learnt behaviour, psychological adaptation, and social and environmental conditions. Subjective reports of the patient and other informants form the cornerstone for psychiatric diagnosis and management. There may be no demonstrable physical signs for diagnosis. Proper diagnosis can be reached only through accurate history taking, mental status examination and physical examination.

PSYCHIATRIC HISTORY

The psychiatric history is a record of the patient's life. The doctor should communicate empathy and respect to the patient. Identifying data of the patient covers demographic details of patient such as age, sex, marital status, occupation, and religion. It also includes source of information, and their reliability.

The chief complaint states the reason why the patient is consulting a psychiatrist. It should be recorded in the patient's or the informant's own words. A history of present illness is most helpful in making a diagnosis.

The nature of onset, acute or gradual; the presence or absence of precipitating events; the course and duration of the illness (fluctuating, continuous or episodic); and the impact of the illness on the patient's personal, occupational and social life.

The details of nature of behavioural changes (e.g. irritability, bizarre behaviour) and the presence of physical (headache, vomiting, and fever) and psychological symptoms (forgetfulness, personality changes, confusion) suggestive of organic brain damage should be looked into.

Any history of substance abuse or excessive consumption of prescription drugs (pain killers, cough syrup, etc.) should always be asked for.

Past illness includes details of past episodes of both psychiatric and medical illnesses. Inquire into previous history of similar episodes, hospitalisation, medication, suicide attempts and substance use. Also, collect information about previous treatments and their response.

General medical history includes available information on medical illnesses, injury or trauma, reproductive history, history of neurological disorders, drug allergies and sensitivities. A careful record should be made of present medications taken for physical or mental problems.

A personal history to include the nature of delivery, milestones, presence of neurotic traits in childhood (thumb-sucking, nail-biting, bed-wetting), personality as a child, and behaviour during schools should be asked for; behaviour during adolescence, sexual knowledge and practices, history of sexual abuse, marital history, other sexual relationships and occupational history.

Family history includes details of mental illnesses, epilepsy and mental retardation in the family (preferably for three generations), consanguinity in family, family relationships and support that the family can give to the patient.

Premorbid personality of the patient prior to the onset of illness needs to be assessed. Especially look for mood fluctuations, suspiciousness, being aloof, excessive fantasy thinking and aggressive behaviour.

MENTAL STATUS EXAMINATION

Besides a history, signs can be delineated by performing the mental status examination of patient. The latter is the description of the patient's appearance, speech, actions and thoughts during the interview.

Attitude and Appearance

It includes overall physical impression reflected by posture, poise and grooming. Signs of anxiety, e.g. wide eyes and perspiring forehead, convey valuable insight into the patient's mental state. A paranoid patient's attitude will be uncooperative, guarded or hostile.

Consciousness

Consciousness is the state of awareness. Disturbances in consciousness include disorientation in time, place or person, clouding of consciousness, stupor, delirium, and coma.

Disturbances of attention include distractibility, hyper vigilance and trance.

Emotion

It is a complex feeling state with psychic, somatic and behavioural components. It has two aspects namely mood and affect. Mood is a pervasive or sustained emotion that colours a person's perception of life. Affect is an objective observation of the underlying mood state.

Some common disturbances of mood and affect are given in **Table 1**.

Motor Behaviour

It is the capacity to initiate action as expressed through a person's behaviour.

The various types of motor behaviour disturbances are given in **Table 2**.

Thought

Disorders of thought can be of form, possession, stream or content.

Formal thought disorder or loosening of associations is said to occur when there is illogical thinking, deviations in the train of thinking or incoherent mixture of words and phrases and a lack of association between one thought and another.

Table 1: Common Disturbances of Mood and Affect

Dysphoria: unpleasant mood
Euthymia: normal mood
Irritability: easily prone to anger
Euphoria: subjective feeling of happiness
Elation: happiness that is communicable to the examiner
Depression: feeling of sadness
Anxiety: feeling of apprehension
Agitation: anxiety with motor restlessness
Panic: intense attacks of fear associated with other autonomic and psychic features of anxiety
Depersonalisation: feeling of unreality concerning oneself or one's environment
Apathy: dulled emotional tone associated with indifference
Blunted affect: lack of intensity of affective response and absence of reactivity of affect
Labile affect: sudden changes and shifts, in emotions, unrelated to external stimuli

Table 2: Types of Motor Behaviour Disturbances

Negativism: active or passive opposition to commands or suggestions
Automatic obedience: excessive co-operation with any command and obeying of commands automatically
Catalepsy: maintaining the same posture for long periods of time
Waxy flexibility: body positions are maintained in which they are placed, however uncomfortable or odd they might be
Echopraxia: imitation of actions of others
Stereotype: repetitive fixed pattern of physical actions or speech
Somnambulism: sleepwalking
Compulsion: uncontrollable impulse to perform an act involuntarily
Stupor: is defined as absence of motor behaviour

Stream of thought

Flight of ideas is excessive speech with a rapid shift from one idea to another without reaching the goal. Circumstantially it is the tendency to digress from the main theme or addition of unnecessary details but ultimately reaching the desired goal.

Content of thought

Disturbance in this consists of delusions, obsessions, hypochondriac beliefs and phobias. Delusions are false, unshakable beliefs, not consistent with the patient's intelligence and cultural background. Delusions can be of the following kinds: persecutory, grandiose, self-referential, control, nihilistic or somatic, based on the predominant content of the delusion.

Obsessions are repetitive, intrusive thoughts, ideas or impulses that are recognised by the patient as irrational but which are associated with inability to control them. Hypochondriacal beliefs manifest as an excessive preoccupation with health and a belief that one suffers from a disease in the absence of any organic pathology. Phobia is an irrational fear of an object, activity or situation with an avoidance of the feared object.

Perception

Perceptual disorders can be broadly classified as hallucinations or illusions. Hallucinations are false sensory perceptions not associated with external stimuli. These can be auditory, visual, tactic, olfactory or gustatory. Illusions are false-sensory perceptions of real external stimuli. Sensory distortions are distortions in size or shape of a real external object, e.g. micropsia or macropsia.

Memory

Memory is tested by following simple methods:

Immediate: 'Repeat these numbers after me: 7, 3, 1, 8, 6'

Recent: 'I want you to remember these three things: a cocker spaniel, a red pencil, and a refrigerator. Keep them in mind. I'll ask you to repeat them after a few minutes'. 'What did you eat for dinner last night? What did you have for breakfast?'

Long-term: 'What was your address when you were in grade school? Who was your teacher in fifth grade?'

Hint: Asking overlearned facts such as birthdates or social security numbers does not accurately test long-term memory.

Disturbances of memory

Amnesia: Partial or total inability to recall experiences.

Paramnesia: Falsification of memory due to problems in recall, e.g. confabulation unconscious filling of gaps in memory by imagined experiences that the person believes in *Deja vu*: Incorrect visual recognition of an event or situation as having occurred earlier.

Orientation

Orientation is judged by asking the patient about day, date, month, year, identifying the immediate relatives. Disturbance of orientation occurs in organic brain syndrome.

Intelligence

It is the problem solving ability of an individual.

General level of intelligence is judged at the time of history-taking. Intelligence is reflected in patient's performance at school or at his job. Intellectual abilities are generally affected in dementia.

Insight

It is the awareness that the person is psychologically ill and he requires help.

It is assessed by asking the patient the relevant questions about his perception of his illness. Following questions would elicit the level of insight

Whether patient feels that he is ill?

Whether patient is psychologically or physically ill?

Whether he is willing to take treatment for his problem?

Insight is generally lost in psychosis—schizophrenia, mania, sometimes in depression.

CLASSIFICATION OF PSYCHIATRIC DISORDERS

Classification is required in psychiatry, as in other branches of medicine, so that doctors and others can communicate easily about the nature of patient's problems and about prognosis and treatment, and research can be conducted with comparable groups of patients. Psychiatric disorders were traditionally classified as organic or functional (based on aetiology). However, this has now become redundant as more

organic factors are emerging as causation of major functional disorders. Another system of classification was to divide functional disorders into psychosis and neurosis. Though these terms have survived over a period of time, a host of new nomenclatures now dominate the current classification systems - ICD-10 (International Classification of Disease, 10th Edition) and DSM IV (Diagnostic and Statistical Manual of Mental Disorders, 4th Edition). The ICD-10 (formulated by the World Health Organization) classifies mental and behavioural disorders.

Organic Factors Including Symptomatic Mental Disorders

This includes the various types of dementias, delirium or acute confusional states due to various causes, psychotic conditions because of brain disease or systemic disease and personality and behavioural changes of a similar aetiology. This block comprises a range of mental disorders grouped together.

On the basis of their common demonstrable aetiology in cerebral disease, brain injury or other insults leading to cerebral dysfunction. The dysfunction may be primary, i.e. because of disease or insult to the brain, or secondary, i.e. because of the effect of other systemic disorders, like endocrine or metabolic disorders.

Mental and Behavioural Disorders Due to Psychoactive Substance Abuse

This group consists of disorders attributable to the use of one or more psychoactive substances. This includes intoxication, dependence syndromes, withdrawal states, psychotic disorders and amnestic syndromes related to alcohol, cannabis, opiates and other psychoactive drugs.

Schizophrenia, Schizotypal and Delusional Disorders

The schizophrenic disorders are characterised by disorders of thinking and perception and inappropriate or blunted mood. Patients may have bizarre delusions and hallucinations and demonstrate thought disorders (manifested by incoherent speech). All these phenomena occur in clear consciousness.

Schizotypal disorder is characterised by eccentric behaviour and anomalies of thinking and affect that resemble schizophrenia though characteristic abnormalities of schizophrenia such as persistent delusions and hallucinations are absent.

The delusional disorders include a variety of disorders in which long-standing delusions constitute the only conspicuous feature which cannot be classified as organic, schizophrenic or mood-related. Acute and transient psychotic disorders are a group of psychiatric disorders that have an acute onset (within two weeks), a rapidly changing and variable clinical picture and the presence of associated stress. These are usually short-lasting and have a good outcome.

Mood Disorders

Here the basic disturbance is a change in mood to depression or elation. All the other symptoms related to activity, social behaviour and thinking can be understood on the basis of the mood disturbance. Persistent and recurrent depressive mood is classified as major depressive disorder. Depression with lesser intensity and long duration is classified as dysthymic disorder. The other type of mood disorder is characterised by episodes of mania and/or depression. When there are repeated manic episodes or at least two episodes of mania and depression, the disorder is called bipolar affective disorder.

Neurotic, Stress-Related and Somatoform Disorders

These disorders have been grouped together because of their historical association with the concept of neurosis and the association of a substantial proportion of these disorders with psychological causation.

They consist of anxiety disorders, i.e. phobic anxiety disorders, panic disorders, generalised anxiety disorders, obsessive compulsive disorders and adjustment and stress-related disorders, dissociative disorders and somatoform disorders.

Behavioural Syndromes Associated with Physiological Disturbances and Physical Factors

These include eating disorders, non-organic sleep disorders and sexual dysfunctions not due to an organic cause.

Disorders of Adult Personality and Behaviour

These include a variety of behaviour patterns which tend to be persistent and are the expression of an individual's lifestyle and mode of relating to self and others. It consists of the following subgroups:

- Specific personality disorders
- Enduring personality change
- Habit and impulse disorders which include pathological gambling, fire-setting and kleptomania, gender identity disorders, disorders of sexual preference and other disorders such as factitious disorder (Munchausen's syndrome).

Disorders of Childhood and Adolescence

These include mental retardation and developmental disorders.

SPECIAL DIAGNOSTIC TESTS

There are a number of tests and evaluation procedures that help in the complete assessment of a mentally ill individual.

Psychological Tests

These help in providing information about intelligence, personality, adjustment and underlying psychopathology. Neuropsychological tests focus exclusively on assessing organic brain damage and the various lobe functions. Commonly used psychological tests include the following.

Intelligence tests

Wechsler adult intelligence scale (revised) and the Stanford-Binet tests of intelligence are useful in diagnosing and assessing mental retardation and may facilitate other diagnosis. Intelligence tests can be verbal or performance-based.

Personality tests

The commonly used tests are the Minnesota multiphasic personality inventory (MMPI), multiphasic questionnaire (MPQ) and the Catell's 16-PF (16 personality factor). The BAI (Bell's Adjustment Inventory) also gives an idea about the patient's adjustment in various areas.

Projective tests

The commonly used tests are Rorschach ink blot test, sentence completion tests, the thematic appreciation test and the object sorting test. Projective tests are unstructured tests

which facilitate the subject to respond in ways that reflect fantasies and individual modes of adaptation. Conscious and unconscious attitudes may be deduced by the subject's responses. Specific responses are found in various psychiatric conditions such as schizophrenia affective disorder and help in arriving at a diagnosis or tapping hidden conflicts.

Tests for Organic Brain Damage

These assess memory, problem-solving and lobe functions. These tests are helpful in dementias, amnesias and other organic dysfunctions. Some of these tests are the Bender-Gestalt test, Wechsler memory scale, PGI memory scale, and neuropsychological batteries such as Halstead Reitan battery and Luna Nebraska battery.

Electrophysiological investigations

Electroencephalography, evoked potentials and event-related potentials are now being used as aids in psychiatric diagnosis. Characteristic latency and wave abnormalities are seen in schizophrenia and affective disorders. Sleep EEG in affective disorders to detect REM and NREM abnormalities and smooth pursuit eye movement recording in schizophrenia are being increasingly used as diagnostic aids.

Imaging

Computed tomography (CT scan), positron emission tomography (PET) and nuclear magnetic resonance imaging (MRI) are particularly useful in dementias and other organic psychiatric conditions and have limited use in the study of conditions such as obsessive compulsive disorders.

Neuroendocrine tests

Dexamethasone-suppression test (DST) is used to confirm a clinical impression of major depressive disorder.

Urine testing for substance use

A variety of substances (e.g. alcohol, barbiturates, benzodiazepines, heroin, cannabis, cocaine, etc.) can be detected in patient's urine if the urine is tested in a specific period after ingestion. This is important as substance abuse can mimic a number of psychiatric disorders.

22.2 Anxiety Disorders

Uday Chaudhuri

Anxiety is a normal emotion under circumstances of threat. It is thought to be part of the evolutionary 'fight or flight' reaction of survival. The idea of anxiety as a psychiatric disorder is evolving rapidly. It is characterised by the concept of core symptoms of excessive fear or worry.

In comparison to major depression, which is characterised by core symptoms, the depressed mood or loss of interest, anxiety disorder have considerable symptom overlap with major depression symptoms surrounding core features, particularly sleep disturbance, problems in concentrating, fatigue and psychomotor and arousal symptoms. This is outlined in **Figure 1**.

Each anxiety disorder also has a great deal of symptom overlap with other anxiety disorders.

WHAT THEREFORE, IS AN ANXIETY DISORDER?

All these disorders seem to maintain the core features of same form of anxiety or fear coupled with some form of worry, but their natural history overtime shows them to morph from one into another, to evolve into full syndrome expression of anxiety disorders symptoms.

Associated symptoms of anxiety with brain regions and circuits that regulate them are depicted in **Figure 2**.

Anxiety disorders have core features of fear and worry that cut across the entire spectrum of anxiety disorders sub-types, from generalised anxiety disorder to panic disorder, social anxiety disorder, post-traumatic stress disorder, and obsessive compulsive disorder.

A great deal of progress has been made in elucidating the role of amygdala is the fear response and the role of cortico-striatal-thalamic-cortical circuits is the symptom of worry (**Figure 2**).

Numerous neurotransmitters are involved in regulating those circuits that underlie anxiety disorders. GABA is a key neurotransmitters, as well as benzodiazepine anxiolytic that act on this neurotransmitter system. Serotonin, norepinephrine, alpha 2 delta ligands, voltage gated calcium channels, are important regulators of anxiety circuits. The symptoms commonly attributed to these neurotransmitters and part of anxiety disorder are given in **Table 1**.

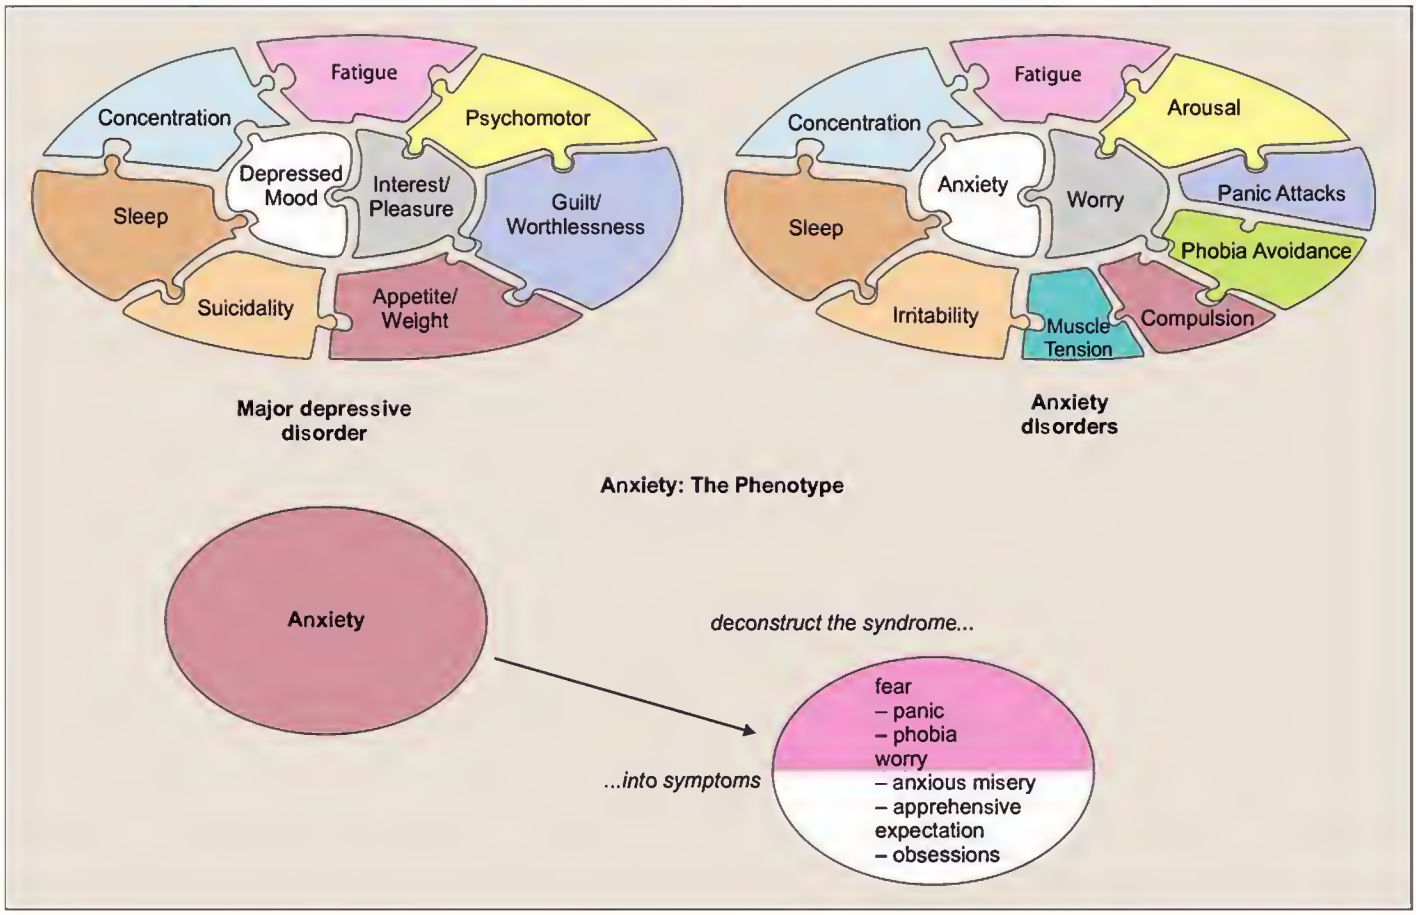

Figure 1: Overlap of MDD and anxiety disorders.

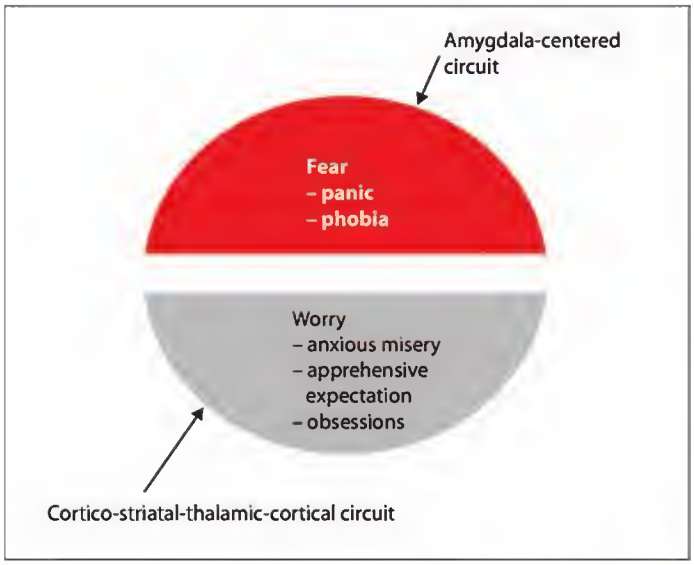

Figure 2: Associated symptoms of anxiety with brain regions and circuits that regulate them.

Table 1: Symptoms of Anxiety Disorder

Psychological
Apprehension
Fear of impending disaster
Irritability
Depersonalisation
Somatic
Tremor
Sweating
Palpitations
Chest pain
Breathlessness
Headache
Dizziness
Diarrhoea
Frequency of micturition
Initial insomnia
Poor concentration

Anxiety disorders are amongst most common psychiatric condition in 15% to 20% of medical clinic patients.

Anxiety, as a symptom, can be a part of other psychiatric disorders (particularly depression), or a consequence of physical illness such as thyrotoxicosis or be drug-induced (e.g. caffeine). Anxiety disorders may be associated with a comorbid disorder like substance abuse disorder.

Symptoms can be psychological, physical or a mixture of both (Table 1). Intervention is required when symptoms become disabling and interfere with functioning. Certain medical conditions which mimic anxiety disorder are given in Table 2.

Table 2: Medical Conditions which may Mimic Anxiety Disorder

Hyperthyroidism
Phaeochromocytoma
Hypoglycaemia
Paroxysmal arrhythmias
Alcohol withdrawal
Temporal lobe epilepsy

There are several disorders within the overall spectrum of anxiety disorders, each with its own characteristic symptoms generalised anxiety disorder (GAD), panic disorder, social anxiety disorder (SAnD), obsessive compulsive disorder (OCD), and post-traumatic stress disorder (PTSD) (Tables 3 to 7).

Table 3: Generalised Anxiety Disorder (GAD)

Signs and symptoms	Excessive anxiety; at least 6 months; difficult to control worry/hypervigilant Associated with 3 or more: Restless/on edge, easily fatigued, concentration problems, irritability, muscle tension, sleep disturbance Causes significant distress Often physical complaints like dizziness, tachycardia, tightness of chest, sweating, tremor
Causes	Neurotransmitter dysregulation: NE, 5-HT, GABA Autonomic nervous system activation; locus caeruleus/NE release/limbic system One year prevalence rate: 1%; lifetime prevalence rate 5% Familial association Over half: onset in childhood
Rule outs	Anxiety disorder due to a medical condition (hyperthyroidism; phaeochromocytoma) Substance-induced anxiety or caffeine-induced anxiety disorder Other anxiety disorders: panic disorder, OCD, etc. DSM-IV criteria help rule out
Labs/Tests/Exams	Self-rated scales: Beck anxiety inventory (BAI); state trait anxiety inventory Observer-rated scale: Hamilton anxiety rating scale (HAM-A) Psychiatric evaluation Physical examination Routine lab tests; thyroid function tests
Interventions	Pharmacologic: benzodiazepines very effective (diazepam, lorazepam); non-benzodiazepines: buspirone Beta-blockers: propranolol CBT Deep muscle relaxation Individual and family therapy Education

Table 4: Obsessive-Compulsive Disorder (OCD)	
Signs and symptoms	Obsessive – recurrent, intrusive thoughts that cause anxiety or compulsions – repetitive behaviours (hand washing, checking) that reduce distress/anxiety and must be adhered to rigidly Driven to perform compulsions Time consuming (>1 hour per day), interfere with normal routine Recognises thoughts/behaviours are unreasonable
Causes	Genetic evidence Neurobiological basis: orbitofrontal cortex, cingulated, and caudate nucleus Neurochemical: serotonergic and possibly dopaminergic Association between OCD and Tourette's and others Lifetime prevalence of 2.5% Women >men Average onset: 20 years Childhood: 7 to 10 years
Rule-outs	Other anxiety disorders: phobias Impulse control disorders Obsessive-compulsive personality disorder Body dysmorphic disorder Depression Neurological disorder
Labs/Tests/Exams	Yale-brown obsessive compulsive scale (Y-BOCS) Psychiatric evaluation Mental status examination Neurologic examination
Interventions	Pharmacologic: SSRIs (fluoxetine: higher doses); fluvoxamine; clomipramine Beta-blockers: propranolol Behaviour therapy: exposure and response prevention Deep muscle relaxation individual and family therapy Education

Table 5: Post-Traumatic Stress Disorder (PTSD)	
Signs and symptoms	Traumatic event (self/family) witness others; threat of harm or death or actual death and helplessness Re-experiencing event 'flash-backs' (triggers: sounds/smell) Hypervigilance (unaware re-enactment related to trauma) Persistent anxiety/outbursts Acute (<3 months); chronic (≥3 months); delayed (>6 months)
Causes	Rape, torture, child abuse, disaster, murder, war, etc. Physiologic/neurochemical/endocrinological alterations Sympathetic hyperarousal Limbic system (amygdala dysfunction) 'Kindling': neuronal excitability Risk factor: previous trauma Lifetime prevalence – 8% (US)
Rule-outs	Acute stress disorder Obsessive-compulsive disorder Adjustment disorder Depression panic disorder Psychotic disorders Substance-induced disorder Psychotic disorder due to a general medical condition Delirium
Labs/Tests/Exams	PTSD scale (clinician administered) Psychiatric evaluation Mental status examination Neurologic examination CAGE, SMAST Physical exam, routine blood studies No laboratory test can diagnose
Interventions	Debriefing (rescuers, etc.) Individual or group psychotherapy CBT EMDR (eye movement desensitisation and reprocessing) Pharmacotherapy: antidepressants – SSRIs, SNRIs, MAOIs, TCAs; antipsychotics; anxiolytics; mood stabilisers Family and community support/art therapy/psychodrama

Table 6: Panic Disorder (PD)	
Signs and symptoms	Excessive panic; at least 6 months; difficult to control worry/hypervigilant Associated with 3 or more symptoms : restless/on edge, easily fatigued, concentration problems, irritability, muscle tension and sleep disturbance Causes significant distress Often physical complaints: dizziness, tachycardia, tightness of chest, sweating, tremor
Causes	High level of anxiety since childhood Autonomic nervous system activation; locus caeruleus/NE release/limbic system One year prevalence rate: 1%; lifetime prevalence rate: 5% Familial association
Rule-outs	Medical disorder, substance abuse, misinterpretation of bodily/mental experiences, drug-induced, hyper-vigilance; chronic worry
Labs/Tests/Exams	Self-rated scales: beck anxiety inventory (BAI); state trait anxiety inventory Observer-rated scale: Hamilton anxiety rating scale (HAM-A) Psychiatric evaluation Physical examination Routine lab tests; thyroid function tests
Interventions	Cognitive therapy, SSRIs

Table 7: Social Phobia (SP)	
Signs and symptoms	Excessive panic; at least 6 months; difficult to control worry, hypervigilant Associated with 3 or more symptoms: restless/on edge, easily fatigued, concentration problems, irritability muscle tension, sleep disturbance Causes significant distress Often physical complaints: dizziness, tachycardia, tightness of chest, sweating, tremor
Causes	Strong genetic loading High level of anxiety since childhood Autonomic nervous system activation; locus caeruleus/NE release/limbic system One year prevalence rate: 1%; lifetime prevalence rate: 5% Familial association
Rule-outs	Schizophrenia Patient comfortable with social isolation Presence of hallucinations and delusions Depression Patient does not want to face people as he feels inadequate and guilty Presence of other symptoms of depression Lab tests fear of humiliation in interpersonal situations
Labs/Tests/Exams	Self-rated scales: Beck anxiety inventory (BAI); state trait anxiety inventory Observer-rated scale: Hamilton anxiety rating scale (HAM-A) Psychiatric evaluation Physical examination Routine lab tests; thyroid function tests
Interventions	Cognitive therapy, SSRIs, social skills training

DIFFERENTIAL DIAGNOSIS

Anxiety is usually transient as a part of 'adjustment disorder' and subsides without treatment. Generalised anxiety (chronic anxiety associated with worry) is an important cause of medically unexplained somatic complaints. Phobic anxiety is characterised by avoidance of feared situation (e.g. social situation, specific situation, public speaking – generalised avoidance in agoraphobia) and it is a common association with panic disorder.

MANAGEMENT

It includes a combination of psychological, pharmacological and psychosocial intervention. A holistic approach is required as it interferes with all three conditions of health: physical, mental and social well-being.

Psychological Intervention

Psycho-education and family education, reassurance, relaxation training, health maintenance activities, and cognitive behaviour therapy (CBT) are some of the common psychological approaches.

Pharmacological Intervention

It involves short time therapy with benzodiazepines (not more than 2 to 4 weeks) and as and when required a treatment of acute anxiety spell.

Long-term therapy with selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine reuptake inhibitors (SNRIs) and some tricyclic antidepressants (TCAs) like imipramine and clomipramine. Buspirone has also got a role in the treatment of anxiety.

Management of Anxiety Disorder Subtypes

Generalised anxiety disorder

Today, first line treatments include SSRIs (selective serotonin reuptake inhibitors, namely fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram and escitalopram) and SNRIs, (selective serotonin and norepinephrine reuptake inhibitors (SNRI), venlafaxine as well as benzodiazepines and buspirone. Some prescribers are reluctant to give benzodiazepines for anxiety disorders in general for GAD in particular owing to the long-term nature of GAD and the possibility of dependence, abuse potential and withdrawal reaction with benzodiazepines. Benzodiazepines can be useful to 'top up' an SSRI or SNRI. Benzodiazepines can also be useful for occasional intermittent use when symptoms surge and relief is needed quickly.

If a GAD patient is not doing well after several weeks or months of treatment switching to another SSRI/SNRI or buspirone or anxiolytic with a benzodiazepine can be considered. Failure to respond to first line of treatment can lead to trail of the novel alpha 2 delta ligands, gabapentin or pregabalin. One also can try sedative antidepressants such as mirtazapine, trazodone, or tricyclic antidepressants or even sedating antihistamines such as hydroxyzine.

Adjunctive treatments that can be added to first or second line treatment for GAD include hypnotics for continuing insomnia, atypical antipsychotics in low dose for severe, refractory and disabling symptoms unresponsive to aggressive treatment and cognitive behaviour therapy.

Panic disorders

Panic attacks occur in many conditions, not just panic disorder, and panic disorder is frequently comorbid with other anxiety disorder and with major depression.

First line treatment included SSRIs and SNRIs as well as benzodiazepines. To note benzodiazepines are often used as second line options, during treatment initiation with an SSRI/SNRI, for emergent use, during a panic attack, or for incomplete response. Second line treatments include the novel alpha 2 delta ligands, gabapentin and pregabalin as well as tricyclic antidepressants.

Mirtazapine and trazadone can be helpful in some cases as augmenting agents to first line treatment (SSRIs/SNRIs), when there is partial response to treatment. The MAO inhibitors are much neglected in psychopharmacology in general, and for the treatment of panic disorder in particular. However, MAOIs can have purposeful efficacy in panic disorder in specialised setting, where various agents have failed.

Various adjunctive treatments are important in panic disorder. Atypical antipsychotics for severe and treatment resistant cases, cognitive behaviour therapy to augment psychopharmacotherapy and to modify cognitive distortions.

22.3 Bipolar Mood Disorders

Lakshman Dutt, Rakesh Sanghadiya

INTRODUCTION

Mood disorders encompass a large group of disorders in which pathological mood and related disturbances dominate the clinical picture. The term mood disorders (also known as affective disorders) refer to sustained emotional states, not merely to the external expression of a transitory emotional state.

Mood disorders are best considered as syndromes consisting of clusters of signs and symptoms sustained over weeks to months and which represent marked departure from a person's habitual functioning and tend to recur often in periodic or cyclical fashion.

EPIDEMIOLOGY

Lifetime prevalence of mood disorders is; unipolar major depressive disorder (5% to 17%), bipolar I disorder (0% to 2.4%), bipolar II disorder (0.3% to 4.8%), cyclothymia (0.5% to 6.3%) and hypomania (2.6% to 7.8%).

TYPES OF MOOD DISORDER

Manic episode

Manic episode or bipolar affective (mood) disorder, current episode hypomanic, (with or without psychotic symptoms), current episode mild or moderate depression (with or without) somatic symptoms, current episode severe depression (with or without psychotic symptoms).

Depressive Episode

Depressive episode, mild (with or without somatic syndrome), moderate depressive episode (with or without somatic syndrome); severe (with or without psychotic symptoms), recurrent depressive disorder (moderate with or without somatic syndrome); recurrent depressive disorder (severe with or without psychotic symptoms); cyclothymia and dysthymia as per ICD-10 listing.

Recurrent depressive disorder is also referred as unipolar depression. The other method to classify mood disorder is into major depressive disorder; bipolar I disorder, bipolar II disorder, bipolar III disorder, and bipolar IV disorder.

Age and Sex Distribution

Most consistent finding in all studies on the prevalence and incidence of unipolar major depression is that it was almost two-fold more common among women than men. The gender difference begins in early adulthood, is most pronounced in people between ages of 30 and 45 and also persists in elderly. The possible reasons for increased vulnerability of depression in females are increased stress sensitivity, maladaptive coping strategies and multiple social roles and substance use disorders most frequently seen in males masking depressive symptoms have been suggested for the explanation of the gender difference. Gender ratio in bipolar depression is approximately 1:1.

Average age of onset of unipolar depression is between 30 and 35 years, and that of average age of onset of bipolar disorder is around 20 years of age. The prevalence of unipolar depression and bipolar I disorder did not show significant variation based on race and ethnicity. Major depressive disorder and bipolar illness are most frequent among divorced, separated and widowed individuals. Single women have lower rates of depression than married women do; but the opposite is true for men. Although the relationship between depressive symptoms and low socio-economic class is well documented, most studies found a weak correlation between major depressive disorder or bipolar illness and low socio-economic class. Urban communities are more stressed and at risk for depression than rural ones. Most western studies show that major depression was more common in urban population than its rural counterpart.

Despite the fact that more than two-thirds of patients with recurrent major mood disorders show irregular seasonal patterns individually and statistically, spring and fall are the peak time for depression just as summer is for mania. There is a condition known as 'seasonal depression' seen in cold countries where there is less of sunlight because of prolonged winters.

AETIOLOGY

Of the biological amines, norepinephrine (NE) and serotonin (5 HT) are the two neurotransmitters most implicated in the pathophysiology of mood disorders. The correlation suggested by basic science studies between the down-regulation of beta-adrenergic receptors and clinical anti-depressant response is probably the single-most compelling piece of data indicating the direct role for the noradrenergic system in depression. Depletion of serotonin may precipitate depression and some patients with suicidal impulses have low cerebrospinal fluid (CSF) concentration of serotonin metabolite and low concentration of serotonin uptake sites on platelets. The data suggest that dopamine levels are decreased in depression and increased in mania.

Other neurotransmitters like GABA and neuroactive peptides, particularly vasopressin and endogenous opiates, have been implicated in the pathophysiology of mood disorders.

Neuroendocrine Regulation

Major neuroendocrine axes of interest in mood disorder are adrenal, thyroid and growth hormone axis. Other neuro-endocrine abnormalities that may be implicated in patient with mood disorder include decreased nocturnal secretion of melatonin; decreased prolactin release in response to tryptophan administration, and decreased basal level of follicle stimulating hormone (FSH) and luteinising hormone (LH).

Genetic Factors

Adoption, linkage and twins studies also show data supporting the genetic basis for the inheritance of mood disorders.

Cognitive Theory

Depression results from specific cognitive distortion present in persons prone to depression. Those distortion, referred to as

depressogenic schemata are cognitive template data in ways that are altered by early experiences.

Learned helplessness is also another theory for depression.

DIAGNOSIS

In addition to diagnostic criteria for major depressive disorder and bipolar disorders, DSM-IV TR includes specific criteria for mood episodes.

DSM IV TR criteria for major depressive disorder

Bipolar ½: Schizopolar disorder.

Bipolar I disorder

DSM IV TR criteria for manic episodes

Bipolar I½: Depression with protracted hypomania.

Bipolar II disorder

Criteria for bipolar II disorders include one major depressive disorder (MDD) episodes and one hypomanic episode.

Bipolar II½: Depression superimposed on cyclothymic temperament.

Bipolar III disorder

Depression plus induced hypomania.

Bipolar III½: Prominent mood swings occur in context of substance or alcohol use or abuse.

Bipolar IV disorder

Depression superimposed on hyperthymic temperament.

Diagnosis episodes of depressive disorders and manic episode are given in **Tables 1 and 2**.

Table 1: DSM IV TR Criteria for Major Depressive Disorders

Five (or more) of the following symptoms need to be present for a 2 weeks period and represent the change from previous functioning. At least one of the symptoms is either depressed mood or loss of interest.

- Depressed mood most of the time
- Marked decreased interest or pleasure in all
- Significant weight loss when not dieting or weight gain
- Insomnia or hypersomnia
- Psychomotor agitation or retardation nearly every day
- Feeling of worthlessness or inappropriate guilt
- Fatigue or loss of energy
- Decreased ability to think or concentrate
- Recurrent thought of death

The symptoms do not meet criteria for mixed episode.

The symptoms caused clinically significant distress or impairment in social, occupational or other important area of functioning.

The symptoms are not due to direct physiological effects of substance or a general medical condition.

The symptoms are not better accounted for by bereavement.

MENTAL STATUS EXAMINATION

Depressive Episode

General features

Generalised psychomotor retardation is most common although psychomotor agitation may also be seen especially in older patient.

Classically a depressed patient has a stooped posture, no spontaneous movements and a down-cast aerated gaze.

Table 2: DSM IV TR Criteria for Manic Episode

A distinct period of abnormally and persistently elevated, expansive or irritable mood, lasting at least one week (or any duration if hospitalisation is necessary).

During the period of mood disturbance three or more of the following symptoms have persisted (four if mood is only irritable) and have been present for a significant degree.

- Inflated self-esteem or grandiosity
- Decrease need for sleep
- More talkativeness
- Flight of ideas or subjective experience that thoughts are racing
- Distractibility
- Increase in goal directed activity
- Excessive involvement in pleasurable activities

The symptoms do not meet criteria for mixed episode.

The mood disturbance is severe to cause marked impairment in social occupational or other areas of functionary.

The symptoms are not due to direct physiological effects of substance or general medical condition.

Mood affect and feelings

Depression is the key symptom although 50% of patients deny depressive feeling, family members often bring these patients for treatment because of social withdrawal and generalised decreased activity.

Speech

Depressed patients show decrease in rate and volume of speech, they respond to questions with single words and exhibit delayed response to questions.

Perceptual disturbances

Depressed patient with delusion or hallucination are said to have major depressive disorder with psychotic features.

Delusions and hallucinations that are consistent with a depressed mood are said to be mood congruent that include those of guilt, sinfulness, worthlessness, poverty, failure persecution.

Thoughts

Depressed patients have negative views of world and of themselves. They may have delusion/ideation of hopelessness, helplessness, suicidal ideations, guilt and shame and are preoccupied with loss of sleep; weakness and fatiguability.

Impulse control

About 10% to 15% of all depressed patients commit suicide and about two-thirds have suicidal ideations.

Manic Episodes

General description

Manic patients are excited, talkative sometime amusing and frequently hyperactive. At times, they are grossly psychotic and disorganised and require physical restraints and intramuscular sedative drugs.

Mood, affect and feelings

Manic patients are euphoric but they can also be irritable. They also have a loco frustration. Tolerance which may lead to feeling of anger and hostility. They may be emotionally labile.

Speech

Manic patients are difficult to interrupt. As the mania gets more intense, speech becomes louder, rapid and filled with jokes, rhymes and plays on words; sometimes loosening of association or flights of ideas may also be present.

Perceptual disturbances

Mood congruent manic delusions are often concerned with great wealth, extraordinary abilities or power.

Thought

Manic patient's thought content includes themes of self-confidence and self-aggrandisement.

Sensorium and cognition

Grossly, orientation and memory are intact, although some manic patients may be so euphoric that they answer incorrectly. Kreplin called the symptom 'delirious mania'.

Impulse control

About 75% of all manic patients are associative or threatening. Manic patients do attempt suicide or homicide.

Judgment and insight

Impaired judgment is a hallmark of manic patients. They may break laws about credit cards, sexual activities, finance and sometimes involve their families in financial ruin.

Reliability

Manic patients are notoriously unreliable in their information because lying and deceit are common in mania.

TREATMENT OBJECTIVES

Bipolar disorder is a lifelong illness. Therefore, maintenance treatment is the core of management. Treatment of choice should be made by collaborative effort between patients and physician. The goal of acute therapy is to stabilise acute episodes with the goal of remission. The goal of maintenance therapy is to optimise protection against recurrence of episode. Concurrently attention needs to be devoted to maximising patient functioning and minimising sub-threshold symptoms and adverse effects of treatment.

Treatment Options of Mood Disorders

Drugs used in treatment of mood disorders are described in Table 3.

Table 3: Drugs Used in Treatment of Mood Disorders

Drugs	Uses	Adverse effects
Lithium	Acute and prophylactic treatment of mania/ hypomania and bipolar depression	Cognitive dysfunction Tremor Gastrointestinal Weight gain Foetal abnormalities
Valproate/ Divalproex	Acute mania and maintenance treatment of bipolar disorder? Bipolar depression	Drug-drug interaction Foetal abnormalities
Carbamazepine	Acute and prophylactic treatment of mania	Drug-drug interactions Laboratory monitoring is required
Oxcarbazepine	Acute treatment of mania	—

Lithium

Lithium is indicated in treatment as well as prophylaxis of bipolar disorders as for manic episodes. Maintenance therapy prevents or diminishes intensity of subsequent episode in those patients with a history of mania. However, blood lithium monitoring is required frequently as it is highly renal toxic drug. Therapeutic blood level is 0.6 to 1.2 mEq/dL of blood. So the drug is to be adjusted accordingly and renal functions are required to be monitored. A watch has to be kept on developing symptoms of lithium toxicity.

Valproate/Divalproex

This is indicated for the treatment of manic episodes. Effectiveness for long-term use in mania has not been systematically evaluated. Long-term usefulness for individual patients should be continuously re-evaluated.

Olanzapine

It is indicated for short-term treatment of acute mania episodes associated with bipolar I disorder. Effectiveness for long-term treatment of acute mania has not been systematically evaluated. Risk and benefit in long-term use (>4 weeks) should be periodically re-evaluated for the individual patient.

Other Anti-Convulsants

Gabapentin, levetiracetam, tiagabine and topiramate are the other anticonvulsants that can be used. Their efficacy is not yet proven.

Atypical Anti-Psychotics

There is convincing evidence for efficacy in acute treatment of mania, especially for olanzapine, risperidone, aripiprazole, ziprasidone and quetiapine. Onset of action is within 2 to 4 days. There is strong evidence for maintenance efficacy (both mania and depression) for olanzapine.

American Psychiatry Association guidelines for mood disorders are given in Table 4.

Table 4: American Psychiatry Association Guidelines for Mood Disorders

1. Initiate either lithium or divalproex plus a second-generation anti-psychotic
2. For less ill patient, monotherapy with lithium, divalproex or anti-psychotic may be sufficient
3. For mixed episode, divalproex or anti-psychotic is preferred over lithium
4. Atypical anti-psychotics are preferred over typical anti-psychotics
5. Carbamazepine or oxcarbamazepine are alternative to lithium or divalproex
6. For breakthrough episode, first optimise the maintenance medication dose
7. Consideration adding on anti-psychotic
8. If this does not work, consider adding lithium, divalproex, carbamazepine or oxcarbamazepine
9. Clozapine or electroconvulsive therapy should be considered for treatment refractory patients

Treatment Options of Bipolar Depression

Drugs used in treatment of bipolar depression are given in Table 5.

Emerging Trend Pharmacotherapy of Acute Mania

This includes combination treatment with lithium and divalproex as corner stones of treatment. Increasing use of atypical anti-psychotics for acute treatment and for maintenance (Figure 1).

Table 5: Drugs Used in Treatment of Bipolar Depression

Lamotrigine in acute treatment of bipolar depression
Olanzapine for bipolar-I depression
Olanzapine plus fluoxetine in bipolar I depression
Paroxetine has very low switch rates
SSRIs: fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram
Bupropion and esitalopram
SNRIs: venlaflexine, milnacipran, duloxetine

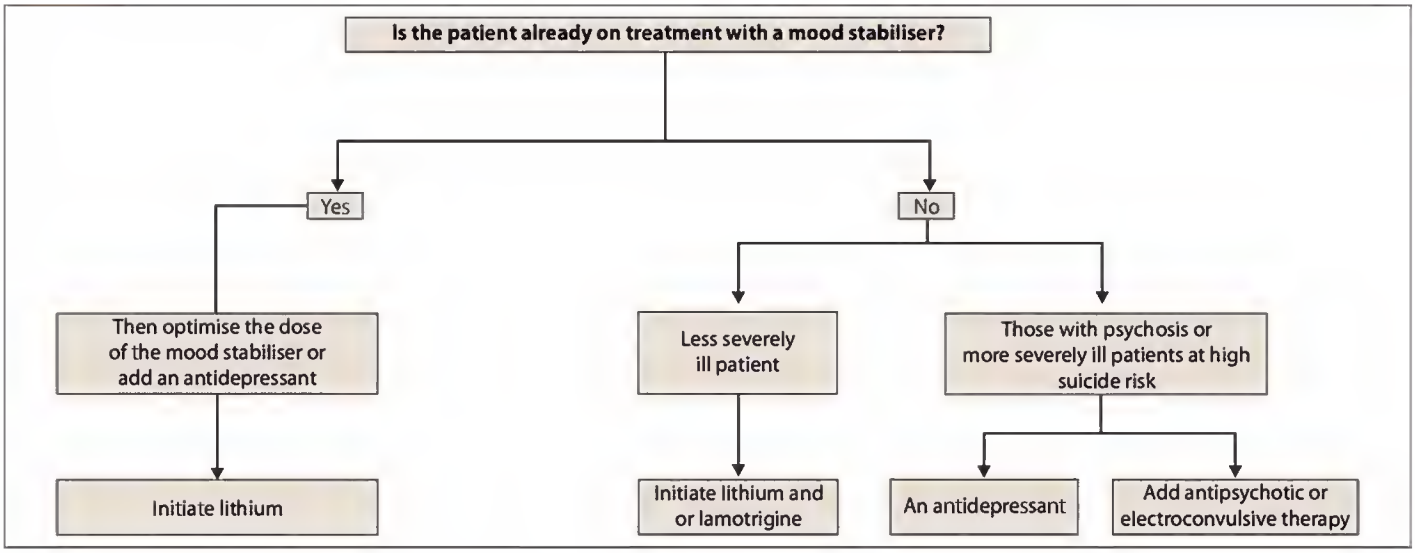

Figure 1: Approach to the patient with Bipolar depression.

22.4 Somatoform Disorders

Vihang N Vahia, Amit Kulkarni

INTRODUCTION

Until late 1970s, the phenomenon of expressing emotional distress and seeking attention through the manifestation of physical symptoms used to be considered a gender- and culture-specific phenomenon. It was hypothesised to be a frequent occurrence and be restricted to certain social strata. In the year 1980, the term somatoform disorders (SDs) was introduced to designate syndromes that are present with multiple pain or other physical symptoms associated with significant dysfunction and social or occupational impairment, where physical examination or laboratory tests failed to explain the symptoms. Clinicians need to differentiate exclusively physical from mixed physical and psychiatric aetiology. Most patients of SD present with mixed aetiology. The crucial task then, is to identify physical and psychological factors that may cause, contribute, complicate, contaminate, co-exist or complement each other. Resentment against doctors, doctor shopping and persistent demands for investigations are common.

The term 'somatoform disorders' incorporates a variety of diverse clinical presentations of physical symptoms that share the diagnostic prerequisite of absence of a physical aetiology to explain emergence of the presenting symptoms. The symptoms tend to be chronic, at times mimic delusional or obsessional features. Despite the prevalence of the non-organic physical illness being lesser than some other psychiatric syndromes, it constitutes higher fraction of medical service utilisation. The diagnosis is valid only in the absence of any other mental or physical disorder or direct effect of a substance that may otherwise explain the symptoms.

Current nomenclature identifies eight categories: (1) somatisation disorder, (2) undifferentiated SD, (3) conversion disorder, (4) pain disorder, (5) hypochondriasis, (6) body dysmorphic disorder, (7) somatoform autonomic dysfunction, and (8) SD not otherwise specified.

AETIOLOGY

Precise aetiology and pathophysiology of somatisation is not known. Physiological stimulation or excitement mediated arousal of sympathetic nervous system leads to rise in blood pressure, tachycardia, gastric hypermotility, muscle tension and pains like tension headaches. Thus sub-syndromal depression and anxiety may have aetiological significance. Heightened awareness of body sensations, along with a cognitive or subjective bias, generates a conviction of being medically ill.

Multiple Hypotheses

Somatic symptoms may be learned illness behaviour to dominate or manipulate relationships.

Psychoanalysts

Psychoanalysts consider SDs as manifestations of repressed anger, impulses, guilt, intrapsychic conflicts or low self esteem.

Developmental Theories

Early parental separation, traumatic childhood, sexual abuse, presence of somatisation in parents and restrictive parenting are implicated in emergence of SD.

Biological Theories

These include bifrontal impairment of cerebral hemispheres and non-dominant hemisphere dysfunction, heightened awareness and misinterpretation of normal body sensations, serotonin and endorphin hypothesis and familial and genetic theories.

PREVALENCE

Precise prevalence for various SDs is not known. Available data indicates prevalence rates to vary between 0.1% and 6%, depending upon the category and surveyed population. A Belgian study ranked SD as third commonest psychiatric disorder after anxiety and depression.

MORTALITY/MORBIDITY

The SDs are not potentially fatal. However, high rates of suicide, side-effects related to use of multiple drugs, polypharmacy and indiscreet drug use merit caution. Medications may be prescribed or surgery could be advised for a misdiagnosed physical illness.

Gender

Female to male ratio varies between 2:1 and 10:1 for various categories of SD except hypochondriasis where it is 1:1.

Age of Onset

Most cases are present with the history of SD in childhood, adolescence or early adulthood. Onset of unexplained physical symptoms in middle-age ought to prompt search for other psychiatric or physical disorders.

GENERAL PRINCIPLES OF MANAGEMENT

The most common primary presentation of SD is some intriguing physical symptoms. Multiple investigations and doctor shopping are frequent. Symptoms may mimic serious medical illness like myocardial infarction or acute abdomen. Tricyclic antidepressants and second generation antidepressant (e.g. duloxetine) drugs have been used with variable success. Pimozide was once recommended as the treatment of choice for mono-symptomatic presentations. Benzodiazepines and narcotic analgesics should be avoided.

Psychosocial interventions include psychoeducation of the patient and his family, good doctor-patient relationship, reassurance that the symptoms are not life-threatening and avoiding repeated investigations, reassurance by quoting other cases of spontaneous improvement is often effective, regular non-invasive medical assessment would reduce anxiety and help-seeking behaviours, and avoiding excessive dependence on the doctor or drug.

CATEGORIES OF SOMATOFORM DISORDER

Somatisation Disorder

Clinical presentation and diagnosis

Somatisation disorder (SOMD) presents multiple physical symptoms beginning before the age of 30 years. DSM IV requires the presence of symptoms for at least 6 months, whereas ICD-10 (WHO) requires minimum duration of 2 years for diagnosis of SOMD. Clinical presentation must include four pain symptoms, related to at least four different sites or functions (common sites of pain are head, back, abdomen, chest, limbs, rectum and joints. Symptoms may be induced during menstruation, sexual intercourse or urination); two unexplained gastrointestinal symptoms other than pain (like nausea, bloating, diarrhoea, indigestion, intolerance to several foods); one sexual or menstrual complaint other than pain (like sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy); and one pseudo-neurological complaint (like aphonia, paresis or paralysis, hypoaesthesia or anaesthesia, blindness or inability to move).

Patients are symptomatic for several years but refuse to accept the medical verdict of absence of any physical illness. Symptoms induce appreciable impairment in functioning. Unlike the factitious disorders, symptoms are not intentionally produced or feigned.

Alcohol, substance use or abuse of prescribed drugs are common co-morbidities.

Management

Do not brush off the patient. Realise that presenting symptoms are a façade of serious emotional turmoil that lies within. A good therapeutic alliance facilitates continuing care by one doctor only. Discourage frequent visits. Give assurance by partial physical examination with minimum investigations. Therapeutic intervention in the form of explaining or educating the patients and their family about the temporal relationship between onset of stress and occurrence of symptoms and that the symptoms do not have a physical correlate is known to help resolution of symptoms. Management of demonstrable mood events with antidepressant medication is advised.

Course and prognosis

This is a chronic and debilitating disorder with fluctuating course. Acute symptoms may last for 6 to 9 months; residual symptoms tend to persist for up to 1 year. Most patients seek help within a year of onset of the symptoms. Persistent symptoms, especially sexual symptoms, may induce marital discord.

Conversion Disorder

Clinical presentation and diagnosis

This disorder is characterised by presentation of sudden physical symptoms following severe conflict or stress. Patients characteristically present with one or more symptom or deficits affecting voluntary motor or sensory functions. The list of possible symptoms include pseudoseizures, impaired coordination, paralysis, lump in the throat, aphonia, urinary retention, loss of pain or touch sensation, double vision, tunnel vision, blindness, deafness and hallucination. Clinical presentations have variable combinations. The symptoms are not intentionally produced or feigned. Severity of the impairment attributed to the symptoms warrant medical evaluation. Many patients seem to be indifferent (*La belle* indifference) rather than be pained by the symptoms or the extent of impairment. Conversion symptoms may be associated with symptoms of other psychiatric disorders.

Management

Management has to be individualised. Some patients remit spontaneously or with resolution of the conflicts. Environmental manipulations by a non-judgemental and non-confrontational therapist help. Some patients benefit from antidepressant drugs. Behaviour therapy or psychotherapy is aimed at helping the patient to cope with stress or modify the stress inducing stimuli. Avoid benzodiazepines or use only for short duration.

Course and prognosis

This is a complex disorder. Initial presentations remit within a short duration despite non-specific treatments. However, recurrence is frequent.

Pain Disorder

Clinical presentation and diagnosis

Irrespective of the age, gender, culture, aetiology, duration and past history, pain is associated with anxiety, discomfort and social, occupational or some other impairment. Diagnosis of pain disorder implies that the severity of pain and distress is out of proportion to the physical condition and that psychological factors are judged to have contributed to onset, severity, exacerbation or maintenance of pain. This diagnosis is valid only in the absence of other physical condition such as dyspareunia or other psychiatric disorders. It may be classified as acute if present for less than 6 months or chronic when persistent for longer duration.

Pain disorders present with one or two symptoms that become a major focus in the life of the patient. Work, school, family and social obligations may be ignored or abandoned to be able to spend long hours visiting medical services. Some chronic cases may reveal familial patterns of chronic pain, depression and alcohol use.

Management

Minimal but all indispensable investigations to rule out any possible physical condition are vital. Diagnosis of exclusion, i.e. psychogenic pain as no physical cause could be identified, may be misleading. Establish diagnosis after demonstrating a temporal relationship between onset and maintenance of pain and some stress or vicarious benefits. Effective doctor-patient relationship needed with regular reassurance to the patient. Behaviour therapy, biofeedback, psychotherapy that explores interpersonal or other conflicts, have all been reported to have varying benefits. Advocate gradually increasing the activities. Tricyclic antidepressant drugs, like amitriptyline, imipramine and dothiepine in small doses, have been popular. Exact mechanism of action is not clear, but is hypothesised to enhance pain threshold. Their analgesic action is independent of their antidepressant action. Amongst the newer antidepressant drugs, duloxetine, (see section on Psychopharmacology) is currently marketed for pain disorder.

Course and prognosis

Acute pain resolves early. However chronic pain has variable onset and tends to persist. Pain may not resolve if there is presence of comorbid general medical condition causing longer duration of acute pain, untreated associated psychiatric disorder.

Hypochondriasis

Clinical presentation and diagnosis

Hypochondriasis is defined as preoccupation of having developed or the possibility of developing a serious physical disease. Medical examination would reveal absence of a new disease even if it may confirm a pre-existing illness. All attempts to convince the patient of absence of any serious illness are rejected, often resulting in severe distress and doctor-shopping (medical or alternative therapists and faith-healers). Subjective conviction of presence of undiagnosed illness may mimic an overvalued idea or an obsession. However, the belief is not of delusional intensity and is not restricted to personal appearance. Duration of the symptoms should be at least 6 months in the absence of any other psychiatric disorders.

Management

Team approach of mental health consultant and primary care physician discourages doctor-shopping. Psychoeducation about the meaning of the symptoms may allay fears of a serious illness. Concentrate on symptom relief without confronting the patient. Most patients should be reassured with minimal investigations to rule out a serious illness. Explore gradually underlying psychiatric co-morbidity or the emotional turmoil that lies within. Management of co-morbid anxiety or depression is absolutely essential.

Course and prognosis

This is a chronic relapsing disorder. Only about 50% of cases show some improvement. Waxing and waning symptoms and being not convinced of the absence of a physical illness cause significant impairment.

Body Dysmorphic Disorder (Dysmorphophobia)

Clinical presentation and diagnosis

The disorder presents with a preoccupation with an imagined defect in personal appearance or excessive concern for a slight or insignificant physical anomaly. The preoccupation induces considerable personal and occupational impairment. Common complaints relate to flaws of face or hair, nose, eyes, eyelids, eyebrows, lips, ears, breasts, genitals, wrinkles, asymmetry of the face, swelling or excessive hair or similarly perceived anomalies of any other body part.

Many patients avoid social contacts to escape criticism of their presumed anomaly. These symptoms may compel the patient to spend long hours before a mirror, install special lights or use magnifying lens to scrutinise the perceived anomaly.

Management

This disorder is difficult to treat. Attempts to deal with symptoms with rational approach are often not successful. Cosmetic surgeries help some patients, but then some patients often report dissatisfaction or even worsening.

Course and prognosis

The disorder commences in adolescence or childhood. They tend to withdraw and spend time scrutinising the appearance. The disorder tends to run a chronic course with few symptom-free intervals.

Somatoform Autonomic Dysfunction

This category of SD is described in the international classification of disorders. Patients present with physical symptoms related to an organ which is innervated or controlled by the autonomic nervous system. Cardiac, gastrointestinal, respiratory and some genitourinary symptoms fall into this category. The symptoms may be associated with objective signs of autonomic arousal like palpitations, sweating, flushing and tremors. Some patients present with idiosyncratic symptoms like fleeting aches and pains, burning, heaviness, tightness, sensation of being bloated or distended. Characteristically, the symptoms affect but do not indicate dysfunction of the target organs.

Autonomic arousal related anxiety is observed in these patients. Antidepressant drugs and non-drug therapies as applicable for other categories of SDs are indicated here. Caution against the use of benzodiazepines, sedating drugs and narcotic analgesic drugs is emphasised.

Undifferentiated Somatoform Disorder

This is a residual category. The term is applied to persistent somatoform symptoms that do not meet the full criteria of SOMD. The disorder is common at primary care where patients may present with only one circumscribed symptom. It is important to rule out improper history that may confound the diagnosis.

Chronic fatigue, loss of appetite and gastrointestinal or urinary symptoms are the frequent presentations. Symptomatic management is usually not effective. Management strategies for SOMD are applicable here.

Somatoform Disorders Not Otherwise Specified

This is a residual category. The term is applicable for conditions that do not meet the diagnostic criteria for other forms of SDs. Pseudocyesis, chronic fatigue or hypochondriacal symptoms that are not of psychotic intensity but cause impairment, in the absence of any other mental or physical disorder are some examples.

LABORATORY INVESTIGATIONS

It is prudent to recommend minimal investigations and resist repeated tests. However, it is essential to rule out uncommon general medical condition especially while dealing with persistent symptoms. Tests to rule out thyroid dysfunctions, phaeochromocytoma, porphyria, substance use and occult alcoholism may be considered. Imaging studies and invasive procedures are usually not contributory.

INPATIENT CARE

The SOMDs rarely require hospitalisation. Severe conversion disorders, co-morbid substance use or iatrogenic complications due to invasive or surgical procedures may mandate hospital care.

OUTCOME

The SDs may be mild and transient or severe and chronic. Early treatment, supportive social environment, higher education, absence of ongoing stress, willingness to accept non-physical aetiology and participate in psychoeducation therapy to understand pathophysiology and develop adaptive skills are associated with better prognosis.

22.5 Psychotic Disorders and Schizophrenia

R Thara

These are a group of psychiatric illnesses that alter a person's ability to think clearly, make good judgments, respond emotionally, communicate effectively, understand reality and behave appropriately. When symptoms are severe, people with psychotic disorders have difficulty staying in touch with reality and are unable to meet the ordinary demands of daily life. Psychotic disorders have major implications in clinical care and public health.

SCHIZOPHRENIA

Several historical writings describe the mentally unsound. The term *unmada* (denoting insanity) first appeared in *Atharvaveda*, believed to be written around 1500 BC. A thousand years later, *Samhitas*, documented clinical sub-varieties of *unmada*. In *Ayurveda,* conditions such as *vatanmada*, *pithanmada* and *kaphonmada*, corresponding to psychosis and depressive states, have been described. Ancient Greeks and Romans were aware of mental health issues. This is evident from writings of Aretaes (AD 1) and Soranus (AD 100), who described the 'insane' as people who are free to wander about, availing themselves of the healing properties of facilities such as medicinal baths and temples along with the physically ill. Thus, in ancient times, schizophrenia was a recognised disorder. The empirical approach to this disorder had its beginnings in the eighteenth century.

Two names associated with the modern history of schizophrenia are Emil Kraepelin and Eugene Bleuler. Through systematic observation, Kraepelin documented that this disorder has its beginnings in early life and takes an essentially downhill course culminating in an intellectually deteriorated state. He used the term 'dementia praecox' for this condition. In 1911, Eugene Bleuler in Zurich, Switzerland, found that not all patients failed to improve. On the basis of his observation of patients' reactions to personal and social influences, he preferred to call the disorder 'schizophrenia', or 'schizophrenic psychoses'.

Schizophrenia affects 0.5% to 1% of the population. Described as the 'greatest disabler of youth', it is universal in its distribution throughout the world. It affects men and women, rich and poor, literate and illiterate. The high-risk age for schizophrenia is between 15 to 35 years. It can, however, occur in children and the elderly.

Signs and Symptoms

Usually, a slow change in the person's personality is an indication of the onset of schizophrenia. A sudden development of abnormal behaviours may also be the first manifestation of a break down.

Hallucinations

The person has sensory perceptions without a stimulus. This may be a voice or voices talking or calling to him, commenting, instructing and sometimes telling him to do awful things – 'I hear a female voice all the time, threatening to kill me'. He may respond to these voices and appear as if talking to self. Other types of hallucinations are visual, gustatory, tactile or olfactory.

Delusions

These are false beliefs that no amount of reasoning will distort. These may be in the form of suspiciousness, directed against one or many people. The person may feel persecuted and feel that someone is out to get him; e.g. 'my food tastes bad, I think it is poisoned' or 'people are following me when I walk on the road'. He may feel afraid or become violent as if trying to protect himself from a persecutor.

Sometimes the person may imagine himself to be a great man or even God – 'I am the son of Jawaharlal Nehru' (grandiose delusions). At times, the person is convinced that objects or people or events are controlling his thoughts and actions – 'My movements are being watched and controlled by a space satellite'. Other delusions refer to the individual's body, to physical or paranormal explanations.

Other essential symptoms to make a diagnosis of schizophrenia include disorganised speech or behaviour and negative symptoms like affective flattening, amotivation, alogia and apathy.

Persons with schizophrenia are also known to experience neuropsychological deficits during the course of the illness. Cognitive impairment is characterised by deficits in attention, learning, memory and executive functions. These deficits have been demonstrated to be associated with dysfunctions in the frontal, temporal and parietal lobes of the brain.

International Classification of Diseases WHO (ICD-10) has given diagnostic guidelines to make diagnosis of schizophrenia which states that (Reproduced from ICD-10; WHO):

1. Duration of symptoms should be at least one month or more which are present for most period of time of the day.
2. One very clear-cut symptom or two or more symptoms if symptoms are not very clear from the group (a) to (d) or two or more symptoms from group (e) to (h). Group of symptoms in (i) is for simple schizophrenia:
3. (a) Thought echo, thought insertion or thought withdrawal and thought broadcasting;
   (b) Delusions of control, influence, or passivity; clearly referred to body or limb movements or specific thoughts, actions or sensation, delusional perception;
   (c) Hallucination voices giving a running commentary on the patient's behaviour, or discussing the patient among themselves or other types of hallucinatory voices coming from some part of the body;

(d) Persistent delusions of other kind that are culturally inappropriate and completely impossible, such as religious or political identity, super human powers and abilities (e.g. being able to control the weather or being in communication with aliens);

(e) Persistent hallucinations in any modality when accompanied either by fleeting or half-formed delusions without clear affective content or by persistent overvalued ideas or when occurring every day for weeks or months on end;

(f) Breaks in interpolations in train of thoughts, resulting in incoherence or irrelevant speech or neologism;

(g) Catatonic behaviour such as excitement, posturing, or waxy-flexibility, negativism, mutism, stupor;

(h) Negative symptoms such as marked apathy, paucity of speech, blunting or incongruity of emotional responses, usually resulting into social withdrawal and lowering of social performance, it must be clear that these are not due to depression or to neuroleptic medication; and

(i) A significant and consistent changes in the overall quality of some aspects of personal behaviour, manifest as loss of interest, aimlessness, idleness, a self-absorbed attitude, and a social withdrawal.

Subtypes of Schizophrenia

Several subtypes of schizophrenia, based on the clinical picture, have been described in the International Classification of Diseases (ICD 10, WHO) as well as the Diagnostic and Statistical Manual (DSM, fourth revision). The common subtypes are listed in **Table 1**. To make the diagnosis of subtype, first a diagnosis of schizophrenia should be made based on the above criterion and subtype to be diagnosed. For all subtypes the duration criteria of one month of persistent symptoms will be essential.

Table 1: Subtypes of Schizophrenia

Paranoid
Catatonic
Simple
Undifferentiated
Hebephrenic
Residual

Paranoid schizophrenia (diagnostic guidelines ICD 10)

(a) Delusion of persecution, reference, exalated birth, special mission, bodily change or jealousy;

(b) Hallucinatory voices that threaten the patient or give commands or auditory hallucinations without verbal form such as whistling, humming or laughing; and

(c) Hallucinations of smell or taste or of sexual or other bodily sensations; visual hallucinations may occur but are rarely predominant.

Catatonic schizophrenia (diagnostic guidelines ICD-10)

One or more should dominate the clinical picture:

(a) Stupor (marked decrease in reactivity to the environment and in spontaneous movements and activity) or mutism;

(b) Excitement (apparently purposeless motor activity, not influenced by external stimuli);

(c) Posturing (voluntary assumption and maintenance of inappropriate or bizarre postures);

(d) Negativism (an apparently motiveless resistance to all instructions or attempts to be moved or movement in opposite direction);

(e) Rigidity (maintenance of rigid posture against efforts to be moved);

(f) Waxy flexibility (maintenance of limbs and body in externally imposed position); and

(g) Other symptoms such as command automatism (auromatic compliance with instructions) and perseveration of words and phases.

Simple schizophrenia (diagnostic guidelines ICD-10)

Slowly progressive with negative symptoms specified in (i) above without any history of hallucinations, delusions or other or of psychotic episode with significant change in personal behaviour manifest as marked loss of interest, idleness and social withdrawal over a delusion, or other, or of psychotic episode with significant change in personal behaviour manifest as marked loss of interest, idleness and social withdrawal over a period of at least one year.

Undifferentiated schizophrenia (diagnostic guidelines ICD-10)

This category should be reserved for disorders that:

(a) Meet the general criteria for schizophrenia; and

(b) Are either without sufficient symptoms to meet the criteria for only one of subtypes, or with so many symptoms that more than one of paranoid, hebephrenic or catatonic subtypes are met.

Hebephrenic schizophrenia (diagnostic guidelines ICD -10)

General criteria for the diagnosis of schizophrenia must be satisfied. It should normally be diagnosed for the first time only in adolescents or young adults. Two or three months of continuous observation is necessary, affective changes are prominent shallow and inappropriate mood with giggling and self-absorbed smiles, delusions and hallucinations are fleeing and fragmentary, behaviour irresponsible and unpredictable. Thought is disorganised, volition is lost and has prolonged course and poor prognosis.

Residual schizophrenia (diagnostic guidelines ICD-10)

(a) Prominent negative schizophrenic symptoms, i.e. psychomotor slowing, under-activity, blunting of affect, passivity, and lack of initiative, poverty of quantity or content of speech, poor non-verbal communication by facial expression, eye contact, voice modulation and posture, poor self-care and social performance;

(b) Evidence in the past of at least one clear cut psychotic episode meeting the diagnostic criteria of schizophrenia;

(c) A period of at least one year during which the intensity and frequency of florid symptoms such as delusions and hallucinations have been minimal or subsequently reduced and the negative schizophrenic syndrome has been present; and

(d) Absence of dementia or other organic brain disease or disorder and of chronic depression or institutionalism sufficient to explain the negative impairments.

It is a chronic stage in which there is clear progression from an early stage to a later stage of long-term irreversible (though not necessarily) negative symptoms.

DIFFERENT TYPES OF PSYCHOTIC DISORDERS

Although schizophrenia and bipolar disorders are the major categories, a number of other categories are delineated.

Schizoaffective Disorder

People with this illness have symptoms of schizophrenia, as well as a serious mood or affective disorder, such as severe depression, mania (a disorder marked by periods of excessive energy) or bipolar disorder (a disorder with cyclical periods of depression and mania).

Schizophreniform Disorder

People with this illness have symptoms of schizophrenia, but the symptoms last less than 6 months.

Brief Psychotic Disorder

People with this illness have sudden, short periods of psychotic behaviour, often in response to a very stressful life event. Recovery is often quick, usually less than a month.

Delusional Disorder

People with this illness have delusions involving real-life situations that could be true, such as being followed, being conspired against, or having a disease. These delusions persist for at least one month.

Shared Psychotic Disorder

This illness occurs when a person develops delusions in the context of a relationship with another person who already has his or her own delusion(s).

Substance-Induced Psychotic Disorder

This condition is caused by the use of or withdrawal from some substances, such as alcohol and crack cocaine, that may cause hallucinations, delusions or confused speech.

Psychotic Disorder due to a Medical Condition

Hallucinations, delusions or other symptoms may be the result of another illness that affects brain function, such as a head injury, brain tumour, epilepsy, encephalitic, etc. causing abnormal and psychotic like behaviour.

Acute and Transient Psychotic Disorders

There is acute onset of delusions, hallucinations and incoherent speech. Complete recovery occurs within one to three months.

Culture-Bound Syndromes

Recurrent, locality specific patterns of aberrant behaviour.

GENERAL SYMPTOMS OF A PSYCHOTIC DISORDER

Prior to the onset of a psychotic break down, certain prodromal symptoms make their appearance. These are listed in **Table 2**.

Table 2: Common Prodromal Features Before First Episode of Psychosis

Reduced concentration, attention
Reduced drive and motivation
Depressed mood
Sleep disturbance
Anxiety
Irritability
Social withdrawal
Suspiciousness
Deterioration in role functioning

Symptoms vary from person to person and may change over time. The common symptoms are listed in **Table 3**. The major symptoms of psychotic disorders are hallucinations and delusions.

Table 3: Common Symptoms of Psychotic Disorders

Hallucinations
Delusions
Disorganised or incoherent speech
Confused thinking
Strange, possibly dangerous behaviour
Slowed or unusual movements
Loss of interest in personal hygiene
Loss of interest in activities
Problems at school or work and with relationships
Cold, detached manner with the inability to express emotion
Mood swings or other mood symptoms, such as depression or mania

Hallucinations are unusual sensory experiences or perceptions of things that are not actually present, such as seeing things that are not there, hearing voices, smelling odours, having a 'funny' taste in the mouth and feeling sensations on the skin even though nothing is touching the body.

Delusions are false beliefs that are persistent and organised, and that do not go away after receiving logical or accurate information. For example, a person who is certain his or her food is poisoned, even if it has been proven that the food is fine, is suffering from a delusion.

EPIDEMIOLOGY

Relevant epidemiological data about acute psychotic illnesses, psychotic disorders due to general medical condition or substance use are lacking.

CAUSES

The exact cause of psychotic disorders is not known. Many factors may play a role. Some psychotic disorders tend to run in families, suggesting that the likelihood to develop the disorder may be inherited. Environmental factors like stress, drug abuse, and major life changes may play a role. In addition, people with certain psychotic disorders may have an imbalance of certain chemicals in the brain. They may be either very sensitive to or produce too much of dopamine. The imbalance of dopamine affects the brain's reaction to stimuli like sounds, smells and sights which leads to hallucinations and delusions. Cultural, socio-political factors and certain medical conditions may influence symptom formation.

There are no laboratory tests to specifically diagnose psychotic disorders, except those that accompany a physical illness, such as a brain tumour, the physician may use various tests, such as blood tests and X-rays, CT scan, MRI of brain to rule out physical illness as the cause of the symptoms.

PREVENTION

There is no known way to prevent most psychotic disorders, but many of the related symptoms can be prevented with early detection and treatment and can help decrease the disruption to the person's life, family and friendships. Avoiding drugs and alcohol can prevent psychotic disorders associated with these substances.

AETIOLOGY

Schizophrenia is now believed to be a disorder of the brain. Genetic factors, early developmental problems and biochemical imbalances are hypothesised to precipitate the illness. The exact nature of genetic factors is not known. It is commonly accepted that there is a genetic vulnerability to develop the illness. People with schizophrenia are known to be particularly sensitive to effects of stress. Those who are introvert, shy, have difficulty in making friends may be more prone to develop this disorder. No one is born with schizophrenia, but some are born with a predisposition to develop the illness.

PREVALENCE AND INCIDENCE OF SCHIZOPHRENIA

Prevalence of schizophrenia is almost the same all over the world. In a recent review of 1,721 prevalence estimates in 46 countries, the reported point and lifetime prevalence is 4.6 and 4 per 1,000 respectively. The most striking feature in this report was the higher rate in the developed countries of the world. There were no gender differences or between urban and rural sites. Migrants, those living in very deprived environments, some ethnic minorities, and children with one or both parents afflicted by schizophrenia are more susceptible to develop the illness.

The incidence rate of schizophrenia all over the world is around 0.5 per thousand. The debate whether it is different in the third world is on-going. A recent review of the incidence of schizophrenia showed an asymmetrical distribution of incidence rates around the world, with many high rates skewing the distribution. The incidence of schizophrenia varies in a five-fold range, between 7.7 and 43.0 per 100,000. Males have a significantly higher incidence of schizophrenia compared with females (male to female risk ratio = 1.4).

COURSE AND OUTCOME

Most people get better with treatment. Some people, who had one episode of the problem, may never have another attack. Many people however, are likely to have one or more recurrences of the problem. In a small group of patients, especially those who do not respond to medication, the symptoms are likely to persist continuously (**Figure 1**).

Outcome in schizophrenia is multi-dimensional. Clinical symptoms and social and occupational functioning are taken into account while assessing the outcome. Sometimes parameters such as quality of life, extent of burden on the caregivers also has to be considered. International, multi-centric studies have shown that availability of effective medicines, better community care, increasing awareness about the illness, greater family support and community tolerance, better job opportunities in the unorganised sectors of employment, especially in the rural areas, and ensuring regular intake of medicines by family members seems to have improved the outcome in a substantial number of persons with schizophrenia. The International Pilot Study of Schizophrenia showed that persons in developing countries had a better outcome than those living in developed nations. This has since then been replicated in several other studies. A twenty-year follow-up of 90 first-break schizophrenia patients showed that only 5 of the original 90 persons with schizophrenia included in the study were continuously ill. Social functioning was good in patients and many held jobs. Greater family support and community tolerance, better job opportunities in the unorganised sectors of employment, especially in the rural areas, and ensuring regular intake of medicines by family members could all be playing a part.

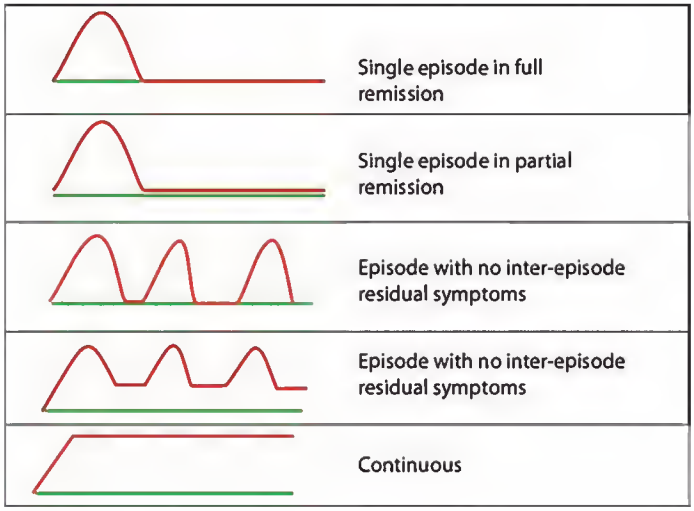

Figure 1: Course of schizophrenia.

TREATMENT

The goals of care are to identify the illness early, treat the symptoms, provide skills to the family, maintain improvement over a period of time, prevent relapses and reintegrate the ill person in the community. The treatment of schizophrenia has three main components. First, there are medications to relieve symptoms and prevent relapse. Second, education and psychosocial interventions help patients and families cope with the illness and its complications, and help prevent relapses. Third, rehabilitation helps patients reintegrate into the community and regain educational or occupational functioning.

Medical Treatment

Medical treatment is the most important and must be adhered to strictly. Anti-psychotic drugs help control acute symptoms and some symptoms of the chronic state, such as apathy and social withdrawal. Although medications do have some side-effects, the beneficial effects of the medications far outweigh the adverse effects. Occasionally, electroconvulsive therapy or shock treatment (ECT) is advised during an acute phase of schizophrenia, but usually in conjunction with drugs.

The most commonly used drugs in the treatment of schizophrenia are known as anti-psychotics or neuroleptics. Conventional or typical neuroleptics are those that have been in use for several decades. Unconventional or atypical anti-psychotics have been recently introduced and their mechanism of action is different from that of conventional drugs. Anti-psychotics can be taken orally, in the form of a syrup or tablet and some are available as injections.

Typical/conventional anti-psychotics

These include phenothiazines, butyrophenones and thioxanthines which act by blocking a particular kind of receptor in the brain called the D2 receptor. There is reliable evidence that in the acute phase of the illness, these drugs are effective in controlling the positive symptoms (delusions, hallucinations and thought disorder). About 60% to 75% of patients improve in 6 to 12 weeks. The common drugs used

extensively in many developing countries are chlorpromazine, haloperidol, thioridazine and trifluoperazine. The problem with this group of drugs is that they have both short- and long-term side-effects which could range from the mildly unpleasant to the potentially debilitating. Despite side-effects, the low cost, availability and years of experience in using these drugs make them still suitable for developing countries.

Depot injections

These are slow-release forms of antipsychotics, administered through injections about once every six weeks. Because of the convenient dosage schedule, many patients comply better with depot injections than tablets, but the side-effects experienced with the former are often worse than those with oral medication. Atypical drugs are not currently available as depot injections.

Atypical/unconventional anti-psychotics

These are indicated for patients who do not respond to conventional antipsychotic drugs. Drugs in this group are clozapine, olanzapine, risperidone, aripiprazole, quetiapine and sulpiride. The primary advantages of atypical anti-psychotics are their effectiveness in dealing with the negative symptoms (such as apathy, social withdrawal and blunted emotions) and some behavioural problems, as well as the relatively lower occurrence of side-effects. Their high cost, however, limits their use in most developing countries.

Psychosocial Rehabilitation

Psychosocial rehabilitation is another vital component of the management of schizophrenia. It is basically a set of techniques aimed at reducing symptoms and decrease impact of illness, improve skills and capability of the person and increases family support in day-to-day management, disabilities. Recent years have witnessed tremendous progress in rehabilitation measures all over the world which includes social skills training, group therapy, cognitive retraining and vocational rehabilitation.

Cognitive retraining focuses on remediation of cognitive deficits such as problems in attention, concentration etc. By using different types of computerised and non-computerised tests, the impairment of cognitive functions can be assessed and some of these tests can also be used to reduce the deficits.

RECOMMENDED READINGS

22.6 Delirium, Dementia, and Other Cognitive Disorders

Venu Gopal Jhanwar

OVERVIEW

Cognition includes memory, language, orientation, judgment, conducting interpersonal relationships, performing actions (praxis), and problem solving. The organic problem may be a primary brain disease or a secondary manifestation of some general disorder. All of the cognitive disorders show some degree of impaired thinking depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (e.g. depression) are often present as significant comorbidities.

In the text revision of the fourth edition of Diagnostic Statistical Manual of Mental Disorders (DSM-IV-TR), three groups of disorders – delirium, dementia, and the amnestic disorders are characterised by the primary symptom common to all the disorders, which is an impairment in cognition (as in memory, language, or attention) (**Table 1**). Although other psychiatric disorders can exhibit some cognitive impairment as a symptom, cognitive impairment is the cardinal symptom in delirium, dementia, and the amnestic disorders.

In the past, these conditions were classified under the heading 'organic mental disorders' or 'organic brain disorders'. Traditionally, those disorders had an identifiable pathological condition such as brain tumour, cerebrovascular disease, or drug intoxication. Those brain disorders with no generally accepted organic basis (e.g. depression) were called functional disorders. This century-old distinction between organic and functional disorders is outdated and has been deleted from the nomenclature. Every psychiatric disorder has an organic (i.e. biological or chemical) component, thus the terms functional and organic are not used in DSM-IV-TR.

Table 1: Classification

Delirium
Dementia
Amnestic disorder
Personality changes due to a general medical condition
Substance-induced hallucinosis

CLINICAL FINDINGS

The manifestations are many and varied, and include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional liability, lack of initiative, impaired impulse control, inability to reason through problems, sexual acting-out, attention problem, aggression, depression, anxiety, irritability, confabulation, impaired intellectual functions, visual and auditory hallucinations, delusions and impaired sleep.

It is important to differentiate between delirium and dementia on the basis of clinical presentation. Delirium is an acute state because of underlying medical conditions which may show complete recovery whereas dementia is a progressive disease.

DELIRIUM

Delirium, a term used to describe an acute confusional state, is a transient global disorder of attention, with clouding of consciousness. Onset is usually rapid. Often goes unrecognised despite clear evidence that it is usually the cognitive manifestation of serious underlying medical or neurologic condition.

Many terms are used to describe delirium, including encephalopathy, acute brain failure, acute confusional state, and post-operative or intensive care unit (ICU) psychosis. Delirium has many clinical manifestations, but essentially it is a relatively acute decline in cognition that fluctuates over hours or days. Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with inability to concentrate, maintain attention, and sustain purposeful behaviour. There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Amnesia is retrograde (impaired recall of past memories) and anterograde (inability to recall events after the onset of the delirium). Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common.

Delirium is a common disorder; 15% to 45% of hospitalised patients, particularly elderly, are prone to develop delirium. The average duration is about 1 week, full recovery in most cases. Dementia and pre-existing cognitive dysfunction serve as major risk factors for delirium, and at least two-third cases of delirium occur in patients with co-existing underlying dementia.

As the diagnosis of delirium is clinical and made at the bedside, a careful history and physical examination is mandatory when evaluating patients with possible confusional states. Screening tools can help in identifying patients with delirium, such as the Confusion Assessment Method (CAM), the Mini-Mental State Examination (MMSE).

The first aim of treatment is to identify and correct the aetiologic medical condition. Routine laboratory tests may include serum electrolytes, serum glucose, blood urea, serum creatinine, liver function tests, thyroid function tests, complete blood count, serum calcium, phosphorus, magnesium, vitamin B12, folate, blood cultures, blood gas analysis, urinalysis, and cerebrospinal fluid analysis. Discontinue medications that may be contributing to the problem. EEG, CT and MRI evaluations may be helpful in diagnosis.

The two major symptoms of delirium that may require pharmacological treatment are psychosis and insomnia. Most commonly used drug for psychosis is haloperidol and risperidone. Depending on age, weight, and physical condition of patient, the initial dose of haloperidol may range from 2 to 4 mg intramuscularly, repeated in an hour if the patient remains agitated. As soon as the patient is calm, oral

medication in liquid concentrate or tablet form should begin. Use of other antipsychotics, such as paliperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole, may be considered for delirium management, but clinical trial experience with these agents for delirium is limited. Insomnia is best treated with short-acting benzodiazepines (e.g. lorazepam 1 to 2 mg at bedtime). Benzodiazepines with long half should be avoided unless they are being used as part of the treatment for the underlying disorder (e.g. alcohol withdrawal).

Table 2: Aetiology of Delirium and Other Cognitive Disorders

Disorder	Possible Causes
Intoxication	Alcohol, sedatives, analgesics, psychedelic drugs and stimulants
Drug withdrawal	Withdrawal from alcohol, sedative-hypnotics, corticosteroids
Medications	Anti-cholinergic medications, anti-depressants, digoxin, H2-blocking agents, salicylates, and a wide variety of other over-the-counter and prescribed medications
Long-term effects of alcohol	Wernicke-Korsakoff syndrome
Infections	Septicaemia; meningitis and encephalitis due to bacterial, viral, fungal, parasitic, or tuberculous organisms or CNS syphilis; acute and chronic infections due to the entire range of microbiologic pathogens
Seizure disorders	Ictal, interictal, and postictal dysfunction
Endocrine disorders	Thyrotoxicosis, hypothyroidism, adrenocortical dysfunction (including Addison disease and Cushing syndrome), phaeochromocytoma, insulinoma, hypoglycaemia, hyperparathyroidism, hypoparathyroidism, panhypopituitarism, diabetic ketoacidosis
Respiratory disorders	Hypoxia, hypercapnia
Metabolic disturbances	Fluid and electrolyte disturbances (especially hyponatraemia, hypomagnesaemia and hypercalcaemia), acid-base disorders, hepatic disease (hepatic encephalopathy), renal failure, porphyria
Nutritional deficiencies	Deficiency of vitamin B1 (beriberi), vitamin B12 (pernicious anaemia), folic acid, nicotinic acid (pellagra); protein-calorie malnutrition
Trauma	Subdural hematoma, subarachnoid haemorrhage, intracerebral bleeding, concussion syndrome
Cardiovascular disorders	Myocardial infarctions, cardiac arrhythmias, cerebrovascular spasms, hypertensive encephalopathy, haemorrhages, embolisms, and occlusions indirectly cause decreased cognitive function
Neoplasms	Primary or metastatic lesions of the central nervous system, cancer-induced hypercalcaemia
Collagen-vascular and immunologic disorders	Autoimmune disorders, including systemic lupus erythematosus, Sjögren syndrome, and AIDS
Degenerative diseases	Alzheimer' disease, Pick' disease, multiple sclerosis, parkinsonism, Huntington chorea, normal pressure hydrocephalus

DEMENTIA

Dementia is defined as a progressive impairment of cognitive functions occurring in clear consciousness (i.e. in the absence of delirium). It is an acquired persistent and progressive deterioration in cognitive abilities that impairs the successful performance of activities of daily living. Memory is the most common cognitive ability lost with dementia.

Global impairment of intellect is the essential feature, manifested as difficulty with memory, attention, thinking, and comprehension. Other mental functions can often be affected, including mood, personality, judgment, and social behaviour. The disorder can be progressive or static, permanent or reversible. Approximately 15% of people with dementia have reversible illnesses if treatment is initiated before it becomes irreversible.

Prevalence is approximately 5% in the general population older than 65 years of age and it doubles every 5 years; reaching 30% to 50% in the general population older than 85 years of age.

Table 3: The Most Common Causes of Dementia in Individuals Older than 65 Years of Age

- Alzheimer's disease
- Vascular dementia
- Mixed vascular and Alzheimer's dementia
- Other illnesses that account for approximately 10%
  - Pick's disease
  - Lewy body dementia
  - Huntington's disease
  - Parkinson's disease
  - Normal pressure hydrocephalus (NPH)
  - Alcoholic dementia
  - Infectious dementia, such as HIV or syphilis

ALZHEIMER'S DISEASE

Alois Alzheimer first described the condition in 1907 that later assumed his name. The final diagnosis of Alzheimer's disease (AD) requires a neuropathological examination of the brain; nevertheless, dementia of the Alzheimer's type is commonly diagnosed in the clinical setting after other causes of dementia have been excluded from diagnostic consideration.

Some of the risk factors for AD are older age, family history, lower education level, and female gender. Education, cognitive exercises, and social support may be protective.

The classic gross neuroanatomical observation of a brain from a patient with AD is diffuse atrophy with flattened cortical sulci and enlarged cerebral ventricles. The classic and pathognomonic microscopic findings are senile plaques, neurofibrillary tangles, neuronal loss (particularly in the cortex and the hippocampus), synaptic loss (perhaps as much as 50 per cent in the cortex), and granulovascular degeneration of the neurons. Neurofibrillary tangles are composed of cytoskeletal elements, primarily phosphorylated tau protein, although other cytoskeletal proteins are also present.

The neurotransmitters that are most often implicated in the pathophysiological condition of AD are acetylcholine and norepinephrine, both of which are hypothesised to be hypoactive in AD.

The diagnosis of dementia is based on the clinical examination, including a mental status examination, and on information from the patient's family, friends, and employers. Symptom compromises of memory loss and at least one other cognitive domain, most commonly aphasia (typically, word finding difficulty), apraxia (inability to perform motor tasks, such as cutting a loaf of bread, despite intact motor function), agnosia (inability to recognise objects), and impaired executive function (poor abstraction, mental flexibility, planning, and judgment). The diagnosis of dementia requires a significant decline in function that is severe enough to interfere with work or social life. Work-up is directed at identifying any potentially reversible causes of dementia. However, such cases are indeed rare.

PHARMACOTHERAPY

Clinicians may prescribe benzodiazepines for insomnia and anxiety, anti-depressants for depression, and anti-psychotic drugs for delusions and hallucinations.

Donepezil, rivastigmine, galantamine, and tacrine are cholinesterase inhibitors used to treat mild-to-moderate cognitive impairment in AD. They reduce the inactivation of the neurotransmitter acetylcholine and, thus, potentiate the cholinergic neurotransmitter, which in turn produces a modest improvement in memory and goal-directed thought.

Donepezil is well tolerated and widely used. Tacrine is rarely used, because of its potential for hepatotoxicity. Memantine (NMDA antagonist) protects neurons from excessive amounts of glutamate, which may be neurotoxic. The drug is sometimes combined with donepezil.

Starting doses, respectively, of donepezil, galantamine, and rivastigmine, are 5 mg orally once daily (maximum 10 mg once daily), 4 mg orally twice daily (maximum 12 mg twice daily), and 1.5 mg orally twice daily (maximum 6 mg twice daily). The doses are increased gradually as tolerated. The most bothersome side-effects include diarrhoea, nausea, anorexia, weight loss, and syncope.

Nonpharmacologic Approaches

Behavioural problems in demented patients are often best managed with a nonpharmacologic approach. Initially, it should be established that the problem is not unrecognised delirium, pain, urinary obstruction, or faecal impaction.

VASCULAR DEMENTIA

Dementia associated with cerebral vascular disease can be divided into two general categories: multi-infarct dementia and diffuse white matter disease (also called *subcortical arteriosclerotic encephalopathy* or *Binswanger's disease*). Individuals who have had several strokes may develop chronic cognitive deficits, commonly called *multi-infarct dementia*. The strokes may be large or small (sometimes lacunar) and usually involve several different brain regions. The occurrence of dementia depends partly on the total volume of damaged cortex, but it is also more common in individuals with left-hemisphere lesions, independent of any language disturbance. Patients typically report a history of discrete episodes of sudden neurologic deterioration.

Risk factors for vascular dementia are those for stroke, i.e. older age, hypertension, cigarette use, atrial fibrillation, diabetes mellitus and hyperlipidemia. Physical examination usually shows focal neurologic deficits such as hemiparesis, a unilateral Babinski reflex, a visual field defect, or pseudobulbar palsy. Recurrent strokes result in a stepwise progression of disease. Neuroimaging studies show multiple areas of infarction. Thus, the history and neuroimaging findings differentiate this condition from AD. However, both AD and multiple infarctions are common and sometimes occur together.

Treatment of vascular dementia must be focused on the underlying causes, such as hypertension, atherosclerosis, and diabetes. Recovery of lost cognitive function is not likely to occur, although fluctuations with periods of improvement are common.

PICK'S DISEASE

The Pick's disease constitutes approximately 5% of all irreversible dementias. It is most common in men, especially those who have a first-degree relative with the condition.

In contrast to the parietal-temporal distribution of pathological findings in AD, Pick's disease is characterised by a preponderance of atrophy in the frontotemporal regions. These regions also have neuronal loss, gliosis, and neuronal Pick's bodies, which are masses of cytoskeletal elements. Pick's bodies are seen in some postmortem specimens but are not necessary for the diagnosis.

LEWY BODY DISEASE

Lewy body disease is a dementia clinically similar to AD and often characterised by hallucinations, parkinsonian features, and extrapyramidal signs. Lewy inclusion bodies are found in the cerebral cortex, amygdala, cingulate cortex, and substantia nigra. Dementia can precede or follow the appearance of parkinsonism. Patients with DLB are extremely sensitive to dopaminergic medications, which must be carefully titrated; tolerability may be improved by concomitant AD medications.

HUNTINGTON'S DISEASE

It is a subcortical type of dementia, characterised by more motor abnormalities and fewer language abnormalities than in the cortical type of dementia. The dementia of Huntington's disease exhibits psychomotor slowing and difficulty with complex tasks, but memory, language, and insight remain relatively intact in the early and middle stages of the illness.

It is an autosomal dominant, degenerative brain disorder. A DNA repeat expansion (CAG repeat) of the mutant gene on chromosome 4 forms the basis of a diagnostic blood test for the disease gene. The clinical hallmarks of the disease are chorea, behavioural disturbance, and frontal executive disorder.

PARKINSON'S DISEASE

An estimated 20% to 30% of patients with Parkinson's disease have dementia, and an additional 30% to 40% have measurable impairment in cognitive abilities. High association of depression is also seen.

HIV-RELATED DEMENTIA

Encephalopathy in HIV infection is associated with dementia and is termed acquired immune deficiency syndrome (AIDS)

dementia complex, or HIV dementia. An estimated 75% of patients with AIDS have involvement of the central nervous system (CNS) at the time of autopsy. The development of dementia in people infected with HIV is often paralleled by the appearance of parenchymal abnormalities in MRI scans. Other infectious dementias are caused by *Cryptococcus* or *Treponema pallidum*. Dementia is usually seen in advanced stage of HIV infection.

HEAD TRAUMA-RELATED DEMENTIA

It is characterised by emotional lability, dysarthria, and impulsivity. There will be a positive history of head injury in past.

Potentially Reversible Dementia or Conditions where Progress of Dementia can be Arrested

Available data reveals that up to 23% of patients qualify for the group of 'potentially reversible' dementias and that includes medication related dementia, psychiatric disorders specifically depressive disorders (pseudo-dementia), surgical brain lesions, i.e. normal pressure hydrocephalus, tumours, chronic sub-dural haematoma, metabolic disorders such as hypothyroidism, hypo-parathyroid, vitamin B12 deficiency, CNS infections (like late stage of neuro-sphylius, HIV, etc). In an Indian report 18% cases of dementia were found to be because of (untreated/poorly treated) neuro-infections and B12 deficiency. It is very important to look for these conditions as further damage can be minimised with proper and timely intervention.

AMNESTIC DISORDERS

These include a variety of diseases and conditions that present with an amnestic syndrome. The syndrome is defined primarily by impairment in the ability to create new memories.

Three Variations of the Amnestic Disorder Diagnosis, Differing in Aetiology

1. Amnestic disorder caused by a general medical condition (e.g. head trauma)
2. Substance-induced persisting amnestic disorder (e.g. caused by carbon monoxide poisoning or chronic alcohol consumption)
3. Amnestic disorder not otherwise specified for cases in which the aetiology is unclear

Thiamine deficiency, hypoglycaemia, hypoxia (including carbon monoxide poisoning), and herpes simplex encephalitis, tumours, cerebrovascular diseases, seizures, electroconvulsive therapy (ECT), and head trauma can cause amnesia.

22.7 Substance Related Disorders

SM Channabasavanna

INTRODUCTION

The term 'substance abuse' refers to the abuse of both alcohol and other drugs.

Categories of substances, commonly liable to abuse for their mind altering properties, include alcohol, cannabinoids, opioids, sedative/hypnotics, inhalants, hallucinogens, cocaine, amphetamines and similarly acting agents (stimulants), and nicotine. Abuse and dependence is also described with caffeine (a stimulant), anabolic steroids and nitrous oxide. Non-dependence producing substances that are abused include anti-depressants, analgesics, antacids, laxatives and vitamins. Specific categories of substances liable to abuse and dependence are discussed separately.

EPIDEMIOLOGY

Lifetime prevalence rates for alcohol use in the general population in India vary from 24% to 74% among males and from 10% to 58% among students. In a recent National Household Survey of alcohol and other drugs among 40,697 males between 12 years and 60 years, 21% reported current alcohol use. A recent study carried out in Karnataka reported alcohol use during the last year by 5.8% of female respondents.

Until the 1980s, apart from alcohol, substances of abuse were predominantly of plant origin cannabis and raw opium. In the last 20 years beside heroin use (the adulterated form is 'brown sugar'), other drugs that have emerged as drugs of abuse include synthetic and semisynthetic opiates, benzodiazepines, antihistaminics and inhalants. Surveys among college students report that 1.5% to 19% use drugs other than alcohol and tobacco, most commonly cannabis, psychotropics and opiates. The National Household Survey reported any current illicit drug use in 3.6% of the surveyed population, cannabis use in 3% and opiate use in 0.7%. However, there are regional differences in substance abuse patterns, with cannabis in Southern India, raw opium in the North West, injecting of opiates escalating in the 1990s in the North-East regions and spreading to the metropolitan cities. It is also important to remember that substance use, especially illicit use, is often a hidden phenomenon and does not show up clearly in conventional epidemiological studies.

While most substance abusers have a 'drug of choice', polysubstance abuse is the most commonly observed pattern, determined by availability and cost. Most of the opiate and cannabis users start their drug taking with tobacco and alcohol, and progress to other drugs of abuse. Although drug abuse was traditionally thought of as a 'student problem', it is now seen in all social strata, with vulnerable groups, such as non-student youth, industrial and transport workers, slum dwellers and migrant populations, becoming increasingly affected.

RANGE OF SUBSTANCE RELATED DISORDERS

Substances can cause problems due to intoxication, overdose, dependence or withdrawal and can have a wide range of physical, psychological, occupational and social adverse consequences. Harmful use is defined as a pattern of use causing damage to physical and mental health. Specific mental disorders induced by substances include delirium, amnestic disorders, dementia, psychosis, mood disorders, anxiety disorders, sexual dysfunction and sleep disorders.

Dependence

This is a pattern of use characterised by a compulsion to use the substance; development of tolerance (need to increase the dose of the substance for the same effect, or reduced effect with the same quantity of the substance); a stereotyped pattern of use, primacy of substance use over other activities; repeated withdrawal symptoms (which occur with abrupt cessation or reduction of use), relief drinking or use of substance (drinking or using substance to overcome withdrawal symptoms) and reinstatement after abstinence (relapse to old substance use patterns).

Withdrawal symptoms may be psychological (intense craving, irritability, mood changes) or physiological (tremors, sweating, sleep disturbances, nausea). Severe withdrawal may be associated with seizures and delirium, as in the case of alcohol and sedative/hypnotics.

AETIOLOGY

Current models of dependence describe it as a result of multiple interacting factors that influence drug-taking. Drug availability, social acceptability and peer pressure are common determinants of initial experimentation with drugs. Personality and biological predisposition influence the perception of drug effect and the changes produced in the central nervous system (CNS) by repeated drug use. The pharmacological properties of the drug also determine whether use will lead to dependence.

An explosion in knowledge of the neurobiology of addiction has helped greatly in understanding mechanisms like tolerance and withdrawal and holds promise for newer pharmacological interventions. Pathways and structures critical for the reinforcing action of a number of dependence producing drugs like opioids, amphetamine and cocaine, as well as alcohol and nicotine, have their origins in the dopaminergic neurons with cell bodies in the ventral tegmental area and their projections to the nucleus accumbens and the related structures that make up the 'extended amygdala'. This area has inputs from the forebrain, midbrain and hypothalamus. Dopamine release in this area is critical for the reinforcing effects of substances. Many other neurotransmitters are also involved and mediate the effects, side-effects and withdrawal effects of the substance. For example, alcohol (ethanol) exerts its action by enhancing the inhibitory action of the gamma-amino butyric acid (GABA) neurotransmitter and

reducing the excitatory action of the glutamate neurotransmitter. By its blocking action at the *N-m*ethyl-*D-a*spartate (NMDA) receptor, ethanol can indirectly alter the release of other neurotransmitters like serotonin, dopamine, norepinephrine, glutamate, aspartate and GABA. The brain reward systems also interact with systems regulating response to stress – the hypothalamic-pituitary adrenal axis and the extrahypothalamic corticotrophin-releasing factor system. Chronic substance use leads to a dysregulation in homeostasis across these systems and counter adaptive responses.

SCREENING FOR SUBSTANCE USE DISORDERS

A good assessment forms the cornerstone in the accurate diagnosis and management of substance use disorders. Eliciting a history of substance use must be part of general history taking in every patient presenting to any medical set up, especially in emergency and trauma settings (**Table 1**). Assessment of substance use disorders must be carried out just as the assessment of any other medical disorder. Any labelling of an individual, as an 'addict' or 'alcoholic', should be avoided. An empathic biopsychosocial approach focussed on motivating the individual to stop or modify his/her substance use pattern is most useful in clinical practice.

Table 1: History-Taking for Substance Use

Various drugs used
Age at initiation
Factors for initiation
Maintaining factors
Quantity/frequency of use
Route of administration
Last use
Physical, behavioural and psychological effects of use
Physical, behavioural and psychological effects of stopping
Consequences of continued use (physical, psychological, occupational, financial, social)
Features of dependence
Past attempts at abstinence
High-risk behaviour
Motivational level to stop or reduce use of substance
Link with presenting problem (e.g. injury, insomnia, gastritis)

Investigations in Substance Use Disorders

Assessment in substance use disorder should include assessment of health damage. In addition to routine investigations, those appropriate to each category of substance (e.g. tests of liver function in alcohol dependence) must be carried out. Testing for human immunodeficiency virus (HIV) and hepatitis B are essential in the context of high-risk sexual behaviour and intravenous drug use. Drug screening in body fluids particularly urine, blood, breath (alcohol) are useful strategies for confirmation of substance use in clinical settings, for medicolegal purposes and monitoring adherence to treatment. Psychological and cognitive assessments are often required for the assessment of personality, co-morbid psychiatric disturbances and cognitive impairment.

BROAD PRINCIPLES OF MANAGEMENT

The general approach to the management of substance use disorders includes management of intoxication, detoxification, management of associated physical and psychological complications, motivating the person to change, pharmacological intervention, psychosocial interventions including behavioural counselling, psychotherapy, involvement of family and participation in support groups. After care and prevention of relapse are critical components of care for dependence, as it is typically a chronic disorder prone to relapses. Community-based approaches, including camp approaches and self-help groups, are useful strategies. Harm minimisation (reducing harmful consequences of continued use) is also a well-recognised management strategy for difficult-to-manage substance use disorders.

Traditionally, broad approaches to substance abuse prevention have included supply reduction (policies and activities aimed at minimising the availability of alcohol and other drugs to people) and demand reduction (aimed at decreasing the internal need or demand for substances by people).

Alcohol Abuse and Dependence

Early problems related to alcohol often go unrecognised and untreated until dependence sets in and it is often only in this situation that medical intervention is offered. About one in two persons who drink have problems related to alcohol use. Alcohol contributes to more than 60 different health conditions in any given society. It contributes to at least 15% to 20% of mortality, mainly through accidents and injuries. Heavy and regular alcohol use is also associated with increased disability, suicide and psychosocial problems. A significant relationship is emerging between alcohol use, high-risk sexual behaviour and vulnerability to HIV/AIDS.

Pharmacology of Ethanol

The ethanol content of different alcoholic beverages varies with spirits, such as whisky, brandy, rum and gin, and distilled liquors, such as arrack containing 35% to 50% alcohol, wines about 12% alcohol and beers ordinarily contain 4% to 5% alcohol. The higher the alcoholic content of the beverage, higher is the blood alcohol concentration (BAC). Alcohol is absorbed largely from the proximal part of the small intestine, although modest amounts are absorbed from the stomach and large intestine, and small amounts from the mucous membranes of the mouth and oesophagus. Drinking on an empty stomach, gulping drinks, consuming carbonated drinks, such as soda along with the alcohol, all enhance absorption. Presence of fats, proteins and carbohydrates in the diet, presence of congeners can slow down absorption. Congeners found in alcoholic beverages, especially illicitly brewed alcohol (such as methanol, butanol, aldehydes, esters, histamines, phenols, tannins and heavy metals such as iron, lead and cobalt) can contribute to organ damage.

Blood alcohol peaks 30 to 60 minutes after consumption on an empty stomach. While absorption patterns are similar, higher blood alcohol levels are achieved for the same dose in women (lesser body water) and persons with a higher fat content.

The alcohol quantity across different alcoholic beverages can be uniformly expressed as 'standard drinks' or standard units. One standard unit is equal to 30 mL of spirits, 60 mL of wine, or half a bottle of beer. Each standard drink is equal to about 10 gm of ethanol. It takes approximately 1 hour for 1 unit of alcohol to be completely metabolised by the body.

Only 2% (at low alcohol concentrations) and 10% (at high alcohol concentrations) is excreted through the lungs, urine and sweat, the greater part is metabolised to acetaldehyde.

Alcohol is metabolised primarily through the cytosolic pathway by alcohol dehydrogenase to acetaldehyde, which in turn is rapidly destroyed by acetaldehyde dehydrogenase (ALDH) in the cytosol and mitochondria. Another metabolic pathway is through the microsomal ethanol oxidising system, which accounts for about 10% of the metabolism at high blood alcohol concentrations. Low doses of acetaldehyde may cause stimulation and behavioural reinforcement. Accumulation of acetaldehyde in the liver, brain and body tissues may result in body damage.

Behavioural Effects

Behavioural effects are given in Table 2.

Table 2: Behavioural Effects at Different Blood Alcohol Concentrations

BAC (mg/dL)	Behavioural Effects
<80	Euphoria, feelings of relaxation, increased self confidence, reduced alertness, excessive talk, clumsiness in motor movements
>80	Noisiness, moodiness, impaired judgement and driving ability
100-200	Blurred vision, gait unsteadiness, gross motor incoordination, slurred speech, aggressive or quarrelsome behaviour, loud talk
200 to 300	Amnesia for the experience
300 to 350	Coma
350 to 600	Death

Systemic Effects With Chronic Alcohol Use

Table 3 outlines the various systemic effects of alcohol abuse.

Biological Vulnerability

Studies suggest that the heritable risk for the development of alcohol dependence is 50% to 60%. There have been many studies to support the heritable nature of alcoholism, including family, twin and adoption studies, which indicate a four-fold increase in the risk for developing alcoholism in children of alcoholics. Genetic variations in the alcohol metabolising enzyme [antidiuretic hormone (ADH) and ALDH] can alter the risk for alcohol dependence. Molecular genetic studies using restriction fragment length polymorphisms (RFLP) suggest an allelic association of the D2 (dopamine) receptor gene, located on the q22-q23 region of chromosome 11 to chronic use. Recent research has also focused on genes regulating GABA and glutamate neurotransmission, as well as genes that regulate the serotonergic system.

Neurotransmitter Changes

Different neurotransmitters are also known to alter alcohol consumption patterns. Dopamine may contribute to the motivation and reinforcement of alcohol consumption. Serotonin levels appear to be lower in the brains of alcohol dependents compared to controls. It may promote alcohol's intoxicating and rewarding effects. Glutamate (an excitatory neurotransmitter) receptors in the brain are inhibited by alcohol and this may account in part for the cognitive dysfunction associated with alcoholism. Alcohol also acts on the inhibitory GABA receptor, especially the GABA receptor, which may mediate the sedative effects of alcohol. Alcohol-induced changes in GABA receptor function may contribute to alcohol dependence and tolerance, and abnormalities in the GABA system may predispose to alcoholism. In addition, various neuromodulators affected by alcohol include endogenous opioid peptides (which may mediate alcohol reinforcement and excessive alcohol consumption), adenosine (which may mediate many of alcohol's acute and chronic effects on the CNS such as incoordination, intoxication and sedation).

Table 3: Systemic Effects of Alcohol Abuse

Nutritional and metabolic effects
- Vitamin deficiencies – B1 (beriberi or Wernicke-Korsakoff's syndrome, B3 (pellagera), B6 (peripheral neuropathy), folate and vitamin A
- Metabolic – hypoglycaemia, ketoacidosis, hypocalcaemia, hypophosphataemia, hypomagnesaemia

Gastrointestinal effects
- Acute or chronic gastritis – evasive/hemorrhagic/non-erosive atrophic
- Mallory-Weiss lesion
- Malabsorption syndrome
- Alcoholic liver disease and cirrhosis
- Pancreatitis

Cancers
- Head and neck, oesophagus, stomach, liver and pancreas

Haematological effects
- Anaemia-microcyte hypochromic (secondary to blood cover), megaloblastic (secondary to folate deficiency)
- Mild thrombocytopaenia and granulocytopaenia

Cardiovascular effects
- Hypertension
- Cardiomyopathy
- Arrhythmia
- Risk factor for haemorrhagia stroke and coronary artery disease (CAD)

Impaired immune respirator
- Secondary infections viz. pneumonia and tuberculosis

Musculoskeletal system
- Myopathy
- Osteoporosis

Sexual dysfunction
- Erectile dysfunction
- Testicular atrophy and sterility

Nervous system
- Acute intoxication
- Sleep disturbances
- Peripheral neuropathy
- Seizures
- Delirium tremens
- Wernicke-Korsakoff's syndrome
- Cognitive impairment
- Cerebellar degeneration

Psychiatric complications
- Depression
- Delusional disorder
- Psychosis resumes of schizophrenia
- Personality disorder

Foetal alcohol syndrome
- Low birth weight
- Hyperactivity
- Subnormal intelligence
- Facial abnormalities (short palpebral fissures, short upturned nose, mid-facial hypoplastia, low nasal bridge, thin upper lip)

Social complications

Psychosocial Theories

Social factors, such as broken families, single parent families, parental 'models', peer pressure, availability of alcohol and cultural sanction of drinking, all contribute to the development of alcohol abuse and dependence. Psychological vulnerability, including stress, low self-esteem, poor coping and poor communication skills may predispose to alcoholism. Alcoholism has also been described as a learnt behaviour, with the temporary relief from anxiety with alcohol acting as a reinforcer, perpetuating alcohol use. Thus, alcohol dependence may be aptly described as a biopsychosocial disorder, with a complex interplay of environmental, genetic and psychosocial factors.

Assessment of Alcohol Related Problems

Thirty to forty per cent of patients presenting to the physician for physical illness are likely to have problem alcohol use. Thus, it is advisable that every patient is routinely asked about alcohol and nicotine consumption, patterns of use, including frequency, quantity and related physical and psychosocial problems. This will facilitate early identification as well as reduce the stigma associated with self-reporting alcohol use. The index of suspicion of alcohol complicating the presenting problem should be higher in certain conditions, listed in the accompanying Table 4.

Table 4: High Index of Suspicion of Alcohol as a Contributory/ Causative Factor

Adult onset seizure
Young stroke
Poorly controlled hypertension
Young onset or poorly controlled diabetes
Hepatitis, cirrhosis
Peripheral neuropathy
Pancreatitis
Parotid gland enlargement
Cancer
Gastrointestinal symptoms of undermined cause
Sleep disturbances
Unexplained falls or accidents
Poorly controlled gout
Confusion or cognitive impairment
Non-specific somatic symptoms
Work-related problems such as absenteeism

Alcohol can also interact with a wide variety of medications such as anaesthetics, antihypertensives, antihistaminics, anticonvulsants, antibiotics, analgesics, antidepressants, antipsychotics and sedatives. Patients on such drugs must be asked about alcohol consumption, educated about the interaction and advised to stop or modify alcohol intake as necessary.

There are useful screening tools, such as the Michigan alcohol screening test (MAST) and the CAGE questionnaire, which can help in picking up alcohol problems. The CAGE consists of asking about whether the person has had difficulty cutting down, been annoyed by criticism about his drinking, experienced guilt because of drinking, or needed an eye-opener. Two or more 'yes' responses suggest a problem with drinking. A more recent schedule from the WHO, the alcohol use disorders identification test (AUDIT), measures alcohol consumption quantities, drinking behaviour and related problems. Each of the ten questions is rated on a scale from 0 to 4. A cut-off of eight or more indicates problem drinking.

While screening tools are helpful in identifying problems related to alcohol, a clinical interview with the patient and significant others is invaluable in reaching a diagnosis and making a comprehensive assessment.

Laboratory Assessment

Several biochemical and haematological parameters can help the physician to assess the damage caused by alcohol (values strongly suggestive of heavy drinking indicated in brackets).

Complete haemogram for evidence of anaemia or acute infection, liver function tests and prothrombin time to assess liver dysfunction, lipid profile, blood sugar, urea and electrolytes when patient is acutely ill, serum uric acid, electrocardiogram, echocardiogram to assess cardiac status, chest X-ray to rule out pulmonary tuberculosis, bronchitis and CT scan if head injury is suspected. Carbohydrate-deficient transferrin (20 gm/dL or more) is also helpful in screening for alcohol abuse and for follow-up monitoring.

Management

Early intervention

Research has shown that early, brief intervention can be very effective. A trial period of reduction of drinking or abstinence and review of the presenting problems can be suggested. For patients with a serious problem or a potential risk of serious problems with alcohol (dependent use, strong family history of dependence, serious physical illness, including hepatic dysfunction, cognitive impairment, psychiatric illness, physiological states, such as pregnancy, serious social crises, e.g. threat of job loss or separation from spouse), abstinence must be strongly advised. An empathic rather than aggressive approach, a clear statement of the physician's medical concern, involvement of the significant others in counselling and a joint agreement with the patient regarding the treatment goal have been shown to have significant results in early stage drinkers, as well as motivate alcohol dependents for longer and more intensive treatment programmes. Monitoring health and drinking state at follow-up is crucial to maintain the gains of treatment.

For dependence

For patients with dependence, treatment consists of handling withdrawal-related syndromes and long-term treatment. Withdrawal, if moderate or severe, is best treated pharmacologically, because there is evidence of neurotoxicity associated with abrupt withdrawal of alcohol from the brain. While outpatient and inpatient detoxification have similar outcomes, inpatient detoxification is preferable in cases with serious physical or psychiatric illness, at risk for seizures or delirium, failed-outpatient detoxification, poor social supports and severe craving.

Steps in the management of the dependent alcoholic include:

- Thorough physical examination and investigations for nutritional impairment, electrolyte imbalance, cardiac, hepatic, gastrointestinal and neurological impairment.
- Adequate nutrition and rest.

- Oral or parenteral B-complex can be provided, including 50 to 100 mg thiamine, for 7 to 10 days.
- Symptomatic treatment of underlying problems such as gastritis, diarrhoea or dehydration.

Detoxification

Drugs commonly used to control withdrawal symptoms are the long-acting benzodiazepines (diazepam 5 to 10 mg or chlordiazepoxide 25 to 50 mg 6 hourly) to ameliorate the withdrawal symptoms. Short-acting benzodiazepines (lorazepam 1 to 2 mg or oxazepam 15 to 30 mg repeated four hourly) are preferred in the presence of hepatic damage. The drug dose can be reduced by 20% on subsequent days and gradually tapered over a week to ten days. Other drugs used for detoxification include anticonvulsants, such as carbamazepine, phenytoin, gabapentin, alpha-adrenergic agents such as clonidine, and beta-blockers such as propranolol.

Delirium tremens can be effectively managed with supportive care, correction of fluid and electrolyte imbalance, antibiotics in the presence of infection, high doses of benzodiazepines along with parenteral B-complex. Antipsychotics, such as haloperidol in low doses (2.5 to 5 mg) may be helpful in controlling agitation, but must be used with caution as they may reduce seizure threshold. Alcohol withdrawal seizures do not need long-term anticonvulsant treatment.

Following detoxification, the patient's motivation is strengthened through individual, group and family counselling, which includes educating about alcoholism, interventions to deal with interpersonal, marital, sexual problems, vocational counselling, helping the patient develop better skills of communication, assertiveness (e.g. handling peer pressure), problem solving and coping with stress. The family is supported and helped to provide a supportive environment to the patient to facilitate recovery. For women alcoholics, gender-sensitive treatment programmes addressing psychological and family issues more intensively, need to be provided. Self-help groups, such as the alcoholic anonymous (AA) and Al-Anon, for families are perceived as useful by many patients. Treatment of less severely dependent alcoholics has also been successfully carried out in rural areas through camps.

Pharmacotherapy for long-term treatment

This includes the use of anticraving agents. Acamprosate, a specific glutamate antagonist, in doses of 1 to 2 gm/day in three divided doses, has been associated with modest but statistically significant outcome on parameters such as number of drinking days, time to first drink and frequency of heavy drinking. It is reasonably well-tolerated and free of any significant adverse side-effects except diarrhoea. Naltrexone, an opiate antagonist, in doses of 50 to 150 mg per day has also found to reduce craving and improve abstinence in alcohol-dependent subjects.

For long-term treatment, disulfiram is still the most commonly used drug in India, in the usual dose of 250 mg per day, after informed consent. Disulfiram does not reduce craving. It acts as a deterrent to drinking, as it inhibits alcohol dehydrogenase, leading to an accumulation of acetaldehyde after alcohol consumption. The disulfiram-ethanol reaction is characterised by flushing, nausea, vomiting, tremulousness, fall in blood pressure. Disulfiram is contraindicated in patients with severe heart disease, hepatic dysfunction, seizures, stroke, uncontrolled diabetes and psychiatric illness. It is not advisable to prescribe disulfiram without the patient's consent in view of the potentially serious effects of the disulfiram-ethanol reaction. Supervised disulfiram therapy ensures better compliance and clinical outcome.

Topiramate, a sulphamate fructopyranose derivative which facilitates GABA function and antagonises glutamate function has been shown to decrease drinking in doses of 200 to 300 mg per day. Major concerns with topiramate include reports of renal calculi and word recall difficulties.

Current research is focused on examining the efficacy of combination treatments (e.g. naltrexone and acamprosate, acamprosate and disulfiram) in the outcome of alcohol dependence.

Ondansetron, a 5-HT_3 antagonist (in doses of 4 µg/kg) have been found to have some benefit in early onset severe forms of alcohol dependence associated with multiple-drug dependency and criminality. Specific serotonin reuptake inhibitors (such as fluoxetine, sertraline) have not been found to have any significant effects on the core symptoms of alcohol dependence. However, antidepressants and mood stabilisers may be required for co-morbid anxiety and mood disorders and short-term anti-psychotics for alcohol-related psychotic disorders.

Concurrent medical conditions

Concurrent medical conditions must be appropriately treated.

Monitoring and Follow-Up

Alcoholism, like other chronic illnesses such as hypertension or diabetes has a chronic, relapsing course. While 50% to 60% of patients significantly reduce their drinking or abstain for 6 months, relapse is frequent. Follow-up, therefore is mandatory and is very useful in bringing the patient back into treatment. In addition, as end stage problems are more resistant to treatment, the focus needs to shift to early detection and intervention for alcohol-related problems.

CANNABIS

Cannabis is obtained from *Cannabis sativa* or the Indian hemp and consumed orally as *'bhang'* (dried leaves of the plant), or smoked as *'ganja'* (from the flowers and upper leaves), or *charas* (from the resinous tops) through cigarettes, beedis or chillums. The active ingredient is delta-9-tetrahydrocannabinol (THC), but more than 400 compounds have been isolated from the plant. Though all these compounds are not psychoactive, they have potential physiological effects. The THC is rapidly absorbed from the lungs into blood and then rapidly concentrates in tissues (this may subsequently be released leading to 'flashbacks'). It is primarily metabolised in the liver, and 11-hydroxy THC is one of the psychoactive metabolites. The long half-life (50 hours) can lead to cumulative side-effects. An endogenous cannabinoid-like ligand, 'anandamide', has been isolated within the brain. Recent studies suggest that cannabis use is substantially influenced by genetic factors. Cannabinoids exert many of their actions by influencing several neurotransmitter systems and their neuromodulators including acetylcholine, dopamine, GABA, histamine, serotonin, norepinephrine, opioid peptides and prostaglandins. Cannabinoids enhance the formation of norepinephrine, dopamine and serotonin.

Physiological side-effects include conjunctival injection, bronchodilatation followed by bronchoconstriction, bronchial irritation, decrements in pulmonary vital capacity, mild postural hypotension, dry mouth, occasional diarrhoea, increased appetite and drowsiness. Angina may be precipitated by those with a history of coronary insufficiency. Other adverse effects, less conclusively proven, include reduced testosterone, spermatozoal abnormalities, impaired foetal growth and development with cannabis use in pregnancy, immune response abnormalities, chromosomal abnormalities and inhibition in DNA, RNA and protein synthesis. A link between heavy cannabis use lung cancer and cortical atrophy is suggested but not established.

Cannabis intoxication is characterised by euphoria, impaired thinking, concentration, perceptual and psychomotor function. A 'toxic psychosis', with confusion, delusions, hallucinations, emotional lability, amnesia, disorientation, depersonalisation and paranoid symptoms can occur. This may resolve in a few hours to several days. A psychosis with both manic and schizophrenic symptoms without confusion known as 'cannabis psychosis' has also been described, but not as clearly validated as the toxic psychosis. In chronic users an 'amotivational syndrome' characterised by withdrawal, apathy, lethargy and lack of motivation has been described, predominantly from India. Heavy cannabis use is known to occur in schizophrenia and can exacerbate the condition.

Tolerance and Dependence

Habitual users rapidly develop tolerance to the psychoactive effects of cannabis. Tolerance to physiological effects occurs at different rates, e.g. tolerance to tachycardia develops earlier than tolerance to conjunctival injection. Withdrawal symptoms in heavy cannabis users are milder than in alcohol or opiate withdrawal and characterised by tremor, nystagmus, nausea, vomiting, diarrhoea, irritability, anorexia and sleep disturbances.

Management

Cannabis use can be determined through physical examination for signs of intoxication and urinary cannabinoid screening. Control of the effects is largely symptomatic. Treatment of unpleasant adverse reactions, usually anxiety, consists of calm and gentle reassurance in a warm and supportive atmosphere. Short-term use of anxiolytic agents, such as benzodiazepines, may be necessary in some instances when anxiety symptoms are prominent or severe. Short-term use of low doses of anti-psychotic medication may be required when the patient has significant psychotic symptoms. The subsequent focus is on maintenance of abstinence, problem solving, improvement of self-esteem and involvement in alternative pleasure seeking activities.

OPIOIDS

Many of the opioid drugs, because of their analgesic and sedating properties have a wide application for medical use. Their euphoriant effect, in addition to these properties, makes them liable for misuse. Opioids can be smoked or consumed orally (raw opium, propoxyphene, codeine containing cough syrups), 'chased' (melted on a silver foil and fumes inhaled) in the form of heroin or brown sugar, injected (heroin, morphine, pentazocine, pethidine, buprenorphine). Opiate use can be initiated either through peer pressure, following prescription for pain relief (e.g. postoperative analgesia) and increased accessibility (physicians and nurses).

Opioids bind to different types of receptors in the body, including the CNS, primarily the μ receptors, as well as kappa and delta, which mediate different effects of the drugs. Various neurotransmitter alterations, including that of acetylcholine, serotonin, GABA, norepinephrine and dopamine, may contribute to the development of tolerance and dependence, which varies across different drug types. It has been suggested that a polymorphism of the μ receptor gene may be implicated in the development or protection from opioid addiction.

Opiate overdose can occur either as a suicidal attempt or accidentally and is characterised by respiratory depression, miosis, bradycardia, decreased body temperature, reduced responsiveness and if untreated can lead to death because of respiratory depression and cardiovascular arrest.

Other effects of opiate intoxication include nausea and vomiting, decreased pain perception, and sedation. Adulterants, especially in street drugs, such as 'brown sugar' can contribute to CNS damage, including peripheral neuropathy, amblyopia, myelopathy and leucoencephalopathy. Sharing of injecting equipment, including needles and syringes, and unsterile injecting practices, lead to increased risk for abscesses, cellulitis, endocarditis, hepatitis and HIV infection. In certain parts of India, HIV seropositivity is reported in as many as 50% of intravenous drug users. Tuberculosis is also a serious problem in this group.

Dependence and Withdrawal

Dependence to opiates occurs more rapidly than with other drugs. Mortality in opiate abusers is high and 25% are likely to die within 10 to 20 years of active use, with death resulting from suicide, homicide, accidents or infection. Use of other substances, especially alcohol, cannabis and benzodiazepines, commonly occurs in opiate users. A switch between different types of opiates is common because of restriction of availability.

Withdrawal symptoms due to opiates tend to be opposite to the acute effects. Drugs with shorter half-lives, such as heroin and morphine produce earlier withdrawal symptoms. Withdrawal symptoms generally subside after 5 to 8 days, but a protracted abstinence syndrome with mild symptoms (autonomic dysfunction, papillary dilatation, sleep disturbances) can persist for 6 months and can contribute to relapse.

Management

Opiate overdose is a medical emergency. Management consists of supportive treatment, especially respiratory support and specifically by intravenous or intramuscular administration of the narcotic antagonist naloxone in an initial dose of 0.2 mg, repeated after 3 to 10 minutes if no response occurs. If there is no response after a cumulative 4 to 5 mg, toxicity with non-opioid CNS depressant should be suspected.

Withdrawal is a self-limiting condition. Clonidine, an alpha-adrenergic agonist in doses of 5 mg per kg (up to 0.3 mg three to four times a day) with blood pressure monitoring can decrease autonomic dysfunction in most patients undergoing opiate withdrawal. The other principle is to substitute with another opiate in detoxification, as there is some level of cross-tolerance across different drugs. Thus, buprenorphine, a partial agonist, can be prescribed in doses of 2 to 4 mg per day in three

divided doses (sublingually), for 7 to 10 days and tapered over 10 to 15 days. Alternatively, propoxyphene, 6 to 9 capsules in three divided doses can be given for a similar duration. Methadone, 10 to 25 mg twice daily, increased to control withdrawal symptoms, and reduced by 10% to 20% per day subsequently is used in some countries, but not available for use in India. Symptomatic treatment is required for sleep disturbances, diarrhoea and bodily pains, but judicious prescription for the minimum period must be done to avoid abuse.

Following detoxification, maintenance of abstinence requires improving motivation through counselling, group therapy and involvement of the family. Abstinence maintenance can be achieved through changes in lifestyle and a focus on productivity through rehabilitation. Self-help groups, also provide the much needed peer support to abstain from opiates.

Long-term pharmacotherapy for opiate use includes the use of naltrexone, an opiate antagonist, in doses of 50 to 100 mg per day for at least 6 months. Considering the high relapse rates associated with opiate use, recent literature has suggested the use of 'harm minimisation' methods, which includes supply of disposable needles to users, educating about safe injecting practices and substitution with oral rather than injectable preparations, for people unwilling to give up their drug habit. Sublingual buprenorphine in doses of 2 to 4 mg per day or once in 2 to 3 days is recommended for maintenance, to encourage opiate users to give up street drugs and injecting drug use. Methadone, a long-acting opiate, as well as levoacetyl methanol are prescribed in several countries as substitute drugs that are legally accessible and safer, but not available in India. Prescription monitoring and judicious use of opiates are important strategies to limit opiate misuse.

SEDATIVE, HYPNOTIC AND ANXIOLYTIC ABUSE

While barbiturates were earlier commonly abused, currently benzodiazepines (especially diazepam and shorter acting benzodiazepines such as lorazepam and alprazolam) are more liable to abuse. Such abuse often occurs following prescription of these drugs for conditions such as insomnia. These drugs act primarily through the GABA system. Intoxication resembles alcohol intoxication and is characterised by slurred speech, incoordination, unsteady gait, nystagmus, impaired attention and memory and sometimes stupor or coma. Longstanding use may lead to cognitive impairment and an amnestic disorder. Withdrawal states are characterized by sweating, tachycardia, tremors, insomnia, nausea, vomiting, hallucinations, illusions, agitation, anxiety and sometimes seizures. Severe benzodiazepine dependence must be detoxified under inpatient supervision because of the risk of seizures and delirium during withdrawal. Treatment consists of supportive management and initial stabilisation with the drug at the same dose, and subsequent reduction by 30% on the second and third day. Subsequent tapering must be done slowly with 10% to 20% reductions weekly. If a short-acting benzodiazepine is being abused (e.g. lorazepam), a useful strategy is to shift to an equivalent dose of a longer-acting drug (e.g. diazepam) and taper as discussed earlier. Propranolol, clonidine and carbamazepine have been used as adjuncts.

INHALANT ABUSE

Abuse of volatile solvents, such as petrol, paint thinners, shoe polish, glue and typewriting whitener, are common especially among adolescents from slums and street children. Solvents are commonly used by 'bagging' (emptying the solvent into a plastic bag, holding it to the nose and inhaling), 'huffing' (soaking a rag in the mixture and stuffing it in the mouth and inhaling), sniffing and snorting or direct spraying into the oral cavity. Solvents act primarily as CNS depressants. Inhalants are associated with many potentially serious adverse effects. The most serious of these is death, which can result from respiratory depression, cardiac arrhythmias, asphyxiation, aspiration of vomitus, accident, or injury (e.g. driving while intoxicated with inhalants). Chronic inhalant users may have numerous neurological problems. The CT and magnetic resonance imaging (MRI) reveal diffuse cerebral, cerebellar and brainstem atrophy with white-matter disease, a leucoencephalopathy. Neurological signs and symptoms may include hearing loss, peripheral neuritis, headache, paresthesias, cerebellar signs, persisting motor impairment, Parkinsonism and lead encephalopathy. Other serious adverse effects associated with long-term inhalant use include irreversible hepatic disease or renal damage (tubular acidosis) and permanent muscle damage associated with rhabdomyolysis. Additional adverse effects include cardiovascular and pulmonary symptoms (e.g. chest pain and bronchospasm) as well as gastrointestinal symptoms (e.g. pain, nausea, vomiting, and haematemesis).

Management consists of appropriate medical care. In addition, vigorous treatment is needed for adolescent patients who progress from experimentation to inhalant abuse or dependence. Comprehensive management includes detoxification, a peer counselling system, assessment of physical, cognitive and neurological deficits, building on existing strengths, developing new strengths, attention to personal and family issues and assistance in returning back to the community.

HALLUCINOGENS

Typical drugs in this category include lysergic acid diethylamide (LSD), phencyclidine (angel dust), ketamine (a short-acting anaesthetic), mescaline (from peyote cactus), 'magic' mushrooms (containing psilocybin), methylene-dioxyamphetamine and methylene-dioxymethamphetamine (MDMA). These drugs may be administered orally or intravenously or are occasionally smoked. Hallucinogenic drugs bind to multiple synaptic receptors in the brain. Hallucinogenic potency is associated with binding affinities at the serotonin type 2 [5-HT_2] receptor where these drugs act as partial agonists.

Acute effects of LSD include hyperacusis, synesthetic experiences (stimulation of one sensory modality is perceived as sensation in a different modality, as when a sound produces a sensation of colour), changes in body image and time space perceptions. Hallucinations, intense emotions, panic-like symptoms and paranoid reactions are common. Phencyclidine and ketamine cause mood changes, intense anxiety, perceptual disturbances, paranoid reactions and motor stereotypes. The MDMA deaths have been associated with drug-induced compulsive dancing, hyponatremia, and hyperthermia. Bad trips or 'flashbacks' (the

re-experiencing, following cessation of use of a hallucinogen, of one or more of the perceptual symptoms that were earlier experienced while on the drug) are typical of hallucinogen abuse. These are characterised by marked anxiety, dysphoria, paranoid ideations and intense perceptual disturbances. Persistent psychosis may rarely be induced by hallucinogens.

Hallucinogen overdose requires prompt life-support measures, including treatment of coma, convulsions and respiratory depression in an intensive care set up. Treatment for hallucinogen-related perceptual disorders is palliative. Long-acting benzodiazepines, such as clonazepam, anticonvulsants (valproate and carbamazepine), may be useful. Anti-psychotic agents should only be employed in the treatment of hallucinogen-induced psychoses. Co-morbid conditions, associated with hallucinogen abuse-panic disorder, major depression and alcohol dependence, must also be treated.

COCAINE

Cocaine, extracted from the leaves of the coca plant (*Erythroxylon coca*) is a stimulant and local anaesthetic. Cocaine is used intranasally ('snorting'), orally, intravenously or through inhalation. It has potent pharmacological effects on dopamine, norepinephrine and serotonin neurons in the CNS. Compulsive use of cocaine follows quickly after accidental or experimental use. Acute effects include stimulation of mood, disinhibition, increased cardiac rate, blood pressure and body temperature. Deaths due to respiratory depression, cardiac arrhythmias and seizures have been reported following snorting and intravenous cocaine use. Chronic use may cause paranoid symptoms, visual and auditory hallucinations. Severe depression may accompany drug withdrawal.

Cocaine overdose should be managed in an intensive care unit and supportive care and specific management of complications done. Psychosocial approaches include behaviour modification, supportive psychotherapy, group therapy, family therapy and self-help groups.

AMPHETAMINES

Stimulant drugs, such as amphetamine, methamphetamine (used in the treatment of hyperactivity in children), diethylpropion, benzamphetamine and phentermine, are commonly abused for their fatigue reduction, alerting and euphorigenic properties. These drugs are used orally or injected. The MDMA (ecstasy) is a substituted amphetamine popular with adolescents at rave parties. Amphetamine acts on the dopaminergic neurons in the mesolimbic area, stimulating dopamine release and inhibiting its reuptake. Toxicity is characterised by hypervigilance, grandiosity, psychomotor agitation and socially inappropriate behaviour. Physical signs include mydriasis, hypertension, perspiration and vomiting. Cardiovascular abnormalities can occur. Chronic use can lead to a schizophrenia-like psychosis. Withdrawal is characterised by dysphoria and anhedonia.

Treatment is symptomatic. Antipsychotics such as haloperidol 5 mg, may be required for psychotic symptoms and fluoxetine 20 mg for dysphoria. Comprehensive psychosocial treatment is required.

NICOTINE

Nicotine dependence is the most prevalent, most deadly, most costly, yet most potentially treatable of the substance dependencies. Nicotine is commonly smoked as cigarettes or beedis, or orally consumed as chewing tobacco, khaini or gutka. Cultural acceptance of tobacco use and its licit status makes it one of the biggest preventable hazards. The CNS effects are mediated through nicotinic cholinergic receptors. Tolerance, dependence and a withdrawal syndrome contribute to the strong control exerted by nicotine on smoking behaviour. Withdrawal is characterised by craving, depression, irritability, insomnia, anxiety, poor concentration, restlessness and increased appetite. Though most symptoms peak in 1 or 2 days and subside within 3 to 4 weeks of stopping, craving for tobacco products and increased hunger can persist for longer periods.

More than 4,000 chemicals have been identified in cigarette smoke, and nearly 3,000 in smokeless tobacco. These include chemicals with antigenic, cytotoxic, mutagenic and carcinogenic properties. Common among the carcinogens in cigarette smoke are tar, aromatic hydrocarbons and other poisonous substances such as carbon monoxide, hydrocyanic acid, aromatic amines and various aldehydes. Large population studies have found a strong association between cigarette smoking and atherosclerotic cardiovascular disease, cancer and chronic obstructive pulmonary disease. Smoking is also associated with increased occurrence of gastric and duodenal ulcers, delays healing of such ulcers and increases risk of recurrence. In women, smoking may delay conception and smoking during pregnancy is associated with increased risk of spontaneous abortion, foetal death, neonatal death and sudden infant death syndrome. Prevalence of smoking is higher in persons who are depressed. Passive smoking (involuntary smoke inhalation) is recognised as a cause of lung cancer and coronary heart disease in nonsmokers. Parental smoking in the home is associated with an increased risk of acute respiratory illnesses, middle ear discharges, chronic respiratory problems and lung function impairment in children.

Family, twin and adoption studies suggest a strong genetic contribution to the development of tobacco dependence. As with other drugs, the addictive effect of nicotine is linked to the release of dopamine. Dopamine gene polymorphism (DRD2 A1 allele) is more prevalent in smokers than non-smoking controls and associated with a younger age of onset and more unsuccessful quit attempts. It is hypothesised that the presence of the A2 allele of the DRD2 gene may be negatively associated with tobacco smoking or offer protection against smoking. Action of nicotine on various other neurotransmitters may contribute to the perceived effects for the user: acetyl choline with arousal and cognitive enhancement; serotonin with mood modulation and appetite suppression; norepinephrine with arousal; vasopressin with improved memory and beta-endorphin with reduction of anxiety and tension. Polymorphisms in the serotonergic transporter gene, genetic variations in the nAChR sub-units offer supportive evidence for these mechanisms. Recent genetic research suggests that in smokers, CYP2A6 which is responsible for metabolising nicotine metabolises nicotine rapidly causing heavier smoking. Light smokers carry a mutation of this gene and are unable to metabolise nicotine rapidly. They are thus less prone to get habituated or progress to heavier smoking.

Nicotine intoxication is characterised by abdominal pain, dizziness, headache, nausea, pallor, palpitation, sweating,

vomiting and weakness. Intoxication is rare and treatment is supportive.

The common factors for tobacco addiction are the withdrawal symptoms. Typical physical symptoms during withdrawal include craving, irritability, anxiety, poor concentration, restlessness, sleep disturbance, decreased heart rate and increased appetite or weight gain.

In helping people quit tobacco, the physician needs to address the physical withdrawal symptoms, the psychological dependence and the environmental cues that maintain tobacco use. The benefits of quitting tobacco are well established. Cessation produces immediate and long-term physical, psychological and economic benefits. Among smokers, within days of quitting, the sense of smell and taste may improve. One year after stopping, there is a substantial reduction in risk for myocardial infarction. Total mortality among former smokers decreases to that of nonsmokers 15 years after quitting. Cessation also reduces the risk for tobacco related cancers, myocardial infarction, cerebrovascular disease and chronic obstructive pulmonary disease.

While many smokers attempt to spontaneously quit, relapse rates are very high and fewer than 5% are able to abstain after the first cessation.

MANAGEMENT

Treatment of nicotine addiction is as cost effective as treatment of hypertension and hypercholesterolaemia. Many patients who visit the physician are especially responsive to advise to stop smoking or chewing tobacco. Guidelines for intervention are provided in **Table 5**. Intervention consists of a tobacco use assessment in every patient who presents to the physician, including a query about chewing tobacco, especially in women. Education about risks of tobacco use and individualised advise should be provided for such patients. Specific intervention includes setting a quit day and stopping suddenly ('cold turkey') or nicotine replacement therapy (NRT) through nicotine gums, nicotine transdermal patches, or sprays. The nicotine gum which is the more easily available NRT comes as 1 mg, 2 mg and 4 mg. The tobacco use must be stopped while using the gum. The gum is used one piece at a time on a fixed schedule. The gum can be prescribed for 4 to 6 weeks and then tapered over 2 to 3 months. The anti-depressant bupropion is also used as first-line therapy in smoking cessation. Its postulated mechanism of action is reduction in craving through its effect on dopamine and noradrenaline. For bupropion treatment, the drug is started while the person is still smoking and the quit date is set about 2 weeks after the initiation of the drug. In doses of 300 mg per day combined with counselling 1 year quit rates of 24% to 33% have been demonstrated. Clonidine may be useful in control of withdrawal symptoms. Individual counselling, group therapy and behaviour therapy strategies, including skills of handling craving, eliminating cues for smoking (e.g. carrying a cigarette or a matchbox or lighter), and other techniques to avoid relapse (e.g. handling stress), are also useful. Co-morbid conditions, such as depression, require treatment. A combination of pharmacological and psychosocial strategies works better than either alone.

Table 5: High Index of Suspicion of Alcohol as a Contributory/ Causative Factor

Adult onset seizure
Young stroke
Poorly controlled hypertension
Young onset or poorly controlled diabetes
Hepatitis, cirrhosis
Peripheral neuropathy
Pancreatitis
Parotid gland enlargement
Cancer
Gastrointestinal symptoms of undermined cause
Sleep disturbances
Unexplained falls or accidents
Poorly controlled gout
Confusion or cognitive impairment
Nonspecific somatic symptoms
Work-related problems such as absenteeism

22.8 Psychiatric Emergencies

JK Trivedi

Emergency psychiatry is a sub-specialty of psychiatry that has evolved over the last few decades and is defined as disturbance in thought, mood and/or action which causes sudden distress to an individual (or to significant others) and/or sudden disability, for which immediate management is required.

Mostly psychiatric emergencies are seen in emergency room of a hospital but these can also present in any psychiatric set up.

Psychiatric emergencies do not mean that patients are suffering from only psychiatric disorder. The consultation may be due to medical conditions or conditions unrelated to medical field, like rape, violence, disaster, etc.

An important task of the attending physician is to determine the cause of the mental disturbance. Thus, the assessment should include an interview, mental status examination, physical and neurological examination and when necessary, relevant laboratory investigations. Psychiatric history should always be obtained from both the patient and the informant(s).

BASIC PRINCIPLES OF APPROACH AND MANAGEMENT

Initial Evaluation

Seriousness of the condition should be assessed and 'TRIAGE' system should be followed in emergency room to prioritise cases like emergency, acute and not acute.

Initial Measures

Many a times the patient is uncooperative. Empathetic, confident and composed attitude shown by the physician can reassure the patient and relatives. A quiet and secluded room is useful. When necessary, restraints may be needed to hold a patient for proper management. Personal safety should be ensured and security staff called when necessary. Hospitalisation should be considered when necessary. Precise psychiatric diagnosis in psychiatric emergency services may be less important than appropriate dispositions. Medico-legal cases need to be registered separately and local police should be informed.

COMMON TYPE OF PSYCHIATRIC EMERGENCIES

Common types of psychiatric emergencies are listed in **Table 1**.

VIOLENT AND AGGRESSIVE BEHAVIOUR

Foreshadowing behaviours or warning signs of impending violent behaviours include increased psychomotor activity, clenching of fists and jaw, pacing, slamming doors, banging their fist on a wall, jumpy and easy to startle, sitting on the edge of the chair and clutching the armrest and verbally abusive patient.

Common psychiatric disorders associated with violent behaviour are listed in **Table 2**.

Table 1: Common Types of Psychiatric Emergencies

- A new psychiatric disorder with acute onset
- A chronic psychiatric disorder with relapse
- An organic psychiatric disorder
- Iatrogenic emergencies
  - Side-effects or toxicities of psychotropic medications
  - Psychiatric symptoms due to toxicity/poisoning
  - Side-effects of non-psychotropic medications presenting with psychiatric symptoms
- Alcohol or other substance abuse
  - Withdrawal
  - Overdose
  - Complication
- Deliberate harm to self or others
- Delirium
- Catatonia
- Prominent anxiety symptoms, like panic attacks
- Dissociative disorder (stupor, hyperventilation, pseudoseizure, trans-possession states)
- An abnormal response to stressful situation
- Seizure disorder

Table 2: Common Psychiatric Disorders Associated with Violent Behaviour

- Psychosis
  - Schizophrenia
  - Delusional disorder
  - Acute psychosis
- Mania
  - First episode
  - Bipolar
- Substance use disorder
- Organic brain disorder
  - Post-ictal states
  - Any systemic condition leading to intracranial pathology and/or delirium
  - As a part of behavioural and psychological symptoms of dementia (BPSD)
- Personality disorder
  - Borderline
  - Anti-social
- Sometimes depression (as murder-suicide)
- Dissociative disorder (trans-possession)
- Acute stress reaction
- Adolescents (behavioural problems)

Management of Aggressive and Violent Patient

The physician should gather maximum information before facing the patient. The physician should be empathic, firm and patient. A direct confrontation may escalate the situation. Some rapport building exercise like addressing the patient by his name should be tried which will help in making the diagnosis. If possible, physical examination should be done without putting oneself in

undue danger. Physical restraint will be necessary if verbal commands are ineffective. Restraint should be done in supine position by at least 5 persons, one for each limb and one for head. Leather restraints are the safest and surest type of restraints. The restraints should be checked periodically for safety and comfort. After the patient is under control, one restraint at a time should be removed at 5-minutes interval until the patient has only 2 restraints on. Both the remaining restraints should be removed at the same time, because it is inadvisable to keep a patient in only one restraint. Intoxicated persons should be restrained in left lateral decubitus position to avoid aspiration.

Pharmacological Intervention

Benzodiazepines (BZD)

Lorazepam is a good choice when treating an acute episode of agitation, especially when aetiology is not clear, such as when a patient with a history of schizophrenia may actually be withdrawing from alcohol.

Doses: 2 to 4 mg slow intravenously (1 to 2 mL), rate 2 mg (1 mL)/min. It may be repeated if necessary up to 10 mg per day. Vital signs should be monitored.

Neuroleptics

Haloperidol 5 to 10 mg intramuscularly can be repeated every half an hour to one hour till the patient is calm (maximum 15 to 30 mg per day). Patient should be monitored for extra-pyramidal side-effects.

Yet another approach is to use a combination of injectable haloperidol and promethazine as they can be mixed in the same syringe. This combination can also be sequentially used with iniectable lorazepam.

Atypical antipsychotics

Olanzapine is effective in reducing acute agitation in patients with schizophrenia, bipolar disorder, schizo-affective disorders and dementia. It exhibits less extra-pyramidal side-effects than haloperidol. Optimal dose in adult is 10 mg intramuscularly. Recommended dose in dementia is 2.5 mg. All the above-mentioned drugs may be given orally if the patient accepts the drug orally. After controlling the acute excitement appropriate long-term management should be started. A combination of injectable olanzapine and lorazipam can also be used in severely agitated patients.

Electroconvulsive therapy as such is not a treatment for excitement or violence *per se*. When used, there should be a clear indication for its use and that should be recorded in the case file.

SUICIDAL ATTEMPTS

Suicide is self-inflicted deliberate self-harm resulting in death with evidence that the person is intended to die.

Suicidal attempt is self-injurious behaviour or unsuccessful suicidal act with non-fatal outcomes. Suicidal patient is one who unsuccessfully attempts suicide or demonstrates suicidal ideation, or harbours suicidal intent, or threatens to commit suicide.

Common Causes of Suicide

Common causes of suicide include depression, schizophrenia, drug dependence, bipolar disorder, adjustment disorder and personality disorder.

Management of Suicidal Patients

It obviously lies in preventing the act. In the emergency room, a patient should be assessed in an empathetic manner. They should be asked about suicidal thinking, intent and plans. A definite diagnosis should be made before starting treatment in such cases.

Hospitalisation

For patients who are at high risk for suicide. They should be regularly monitored and treatment should be started according to the underlying disorder. Patients who are not severely suicidal can be sent home after instituting appropriate medications for the underlying disorder. Relatives of the patient should be informed about the danger and they should be asked to keep a close watch on the patient. The patient should not have access to large amount of medications and drugs should be given under supervision.

Pharmacotherapy

BZDs, non-benzodiazepine hypnotics and quetiapine (in low doses) may be given for sleep disturbance and anxiety symptoms. Anti-depressants are to be given in depression. Lithium may be given when indicated as it has got anti-suicidal role. Anti-psychotics are to be prescribed for psychosis.

Electroconvulsive therapy (ECT)

It is reserved for severely suicidal, with catatonic, symptoms. It acts faster. Any underlying physical disorder should be treated.

Long-term therapy

After the management of acute problem, maintenance therapy and other therapies should be started.

EXTRA-PYRAMIDAL SIDE-EFFECTS OF NEUROLEPTICS

Acute Dystonia

This is an abnormal posture produced by sustained involuntary contraction of muscles of different body parts. It may present as trismus, oculogyric crisis, torticollis, blepharospasm, etc. It is a very painful condition and fatalities may occur if the laryngeal muscles are involved. History should be present of taking a neuroleptic/anti-dopaminergic agent.

Treatment consists of antihistaminics like promethazine: 50 mg intravenoulsy/intramuscularly and anti-cholinergics like benzatropine 1 to 2 mg intravenoulsy/intramuscularly. Oral drugs should be started after the acute crisis is over. Trihexyphenidyl (6 to 10 mg per day in divided doses) may be given for this purpose.

Akathisias

It consists of inability to remain seated and is commonly associated with repetitive shifting of weight, pacing or rocking the trunk when standing. There is an inner sense of restlessness. The treatment is propranolol 40 to 80 mg per day. Benzo-diazepine may be given.

Neuroleptic Malignant Syndrome (NMS)

It is uncommon but potentially fatal. It occurs in 0.5% of patients who are on neuroleptics. It is characterised by mental status changes, confusion, disorientation, rigidity, autonomic instability and temperature dysregulation. Laboratory findings include raised CPK-MM, increased white blood cells, myoglobinuria and altered liver function tests.

Management of NMS

Discontinue the neuroleptic medication immediately. Supportive care (intensive care unit care is preferred) with rehydration should be given to manage vitals. Dantrolene sodium 2 to 3 mg per kg intravenously 3 to 4 times per day or bromocriptine is started with 2.5 mg thrice a day and with gradual increment to maximum daily dose of 60 mg. For management of psychiatric symptoms in such patients after resolution of ICF, depot preparations of anti-psychotics and other high potency conventional anti-psychotics should be avoided.

STATE OF ACUTE ANXIETY AND PANIC

Anxiety is characterised by a feeling of fear accompanied by somatic signs of autonomic nervous system hyperactivity.

Primary psychiatric condition causing anxiety includes generalised anxiety disorder, panic disorder depression, phobia substance abuse, PTSD, acute stress reaction and sometimes schizophrenia.

Medical problem causing anxiety should be differentiated from primary psychiatric disorder. Medical conditions that may present with anxiety symptoms are:

1. Cardiovascular—angina, arrhythmias, valvular diseases
2. Metabolic—hyperthyroidism, hyperadrenalism, hypoglycaemia, hypocalcaemia
3. Haematological—anaemia
4. Respiratory—asthma, COPD
5. Secretory tumours—carcinoid, insulinomas, phaeochromocytoma
6. Iatrogenic—sympathomimetic, stimulants, dopaminergics, anti-cholinergics drugs

Treatment

Provide safe and protective environment and consult physician for medical conditions if any for acute stress, when immediate relief is required lorazepam is given, oral BZDs, alprazolam can also be given.

Primary panic disorder requires maintenance therapy. Serotonin selective re-uptake inhibitors are the treatment of choice. Tricyclic anti-depressants and alprazolam, etc. may be given.

LITHIUM TOXICITY

Lithium toxicity presents with tremor, dysarthria, ataxia, altered sensorium and incoordination. Treatment of lithium toxicity follows the following outlines: stopage of lithium, assessment of serum level of lithium, hydration of the patient, and management of physical complications.

STUPOR

It is defined as a clinical syndrome of akinesis and mutism, but with relative preservation of conscious awareness. It is often associated with catatonic signs and symptoms. Stupor is not a diagnosis but a symptom that is seen in a number of clinical conditions, both psychiatric and physical. The common causes of psychiatric stupor are catatonic schizophrenia, depressive stupor and dissociative stupor. Among the medical disorders, organic cerebral diseases constitute a major cause of stupor. Energetic management is required as the nutrition and hydration are compromised due to poor intake. Stupor accompanied by catatonic symptoms should be treated by ECT.

Hysterical Stupor

This is of sudden onset, preceded by a stressful stimulus.

Treatment

Understanding and resolution of stressful environment factor (remove the attention of relatives) is important. Therapy should be supportive. Medications to treat co-morbid anxiety or depression should be given.

DELIRIUM

It is a disturbance in the state of consciousness; characterised by confusion, disorientation, restlessness, affective lability and perceptual disturbances (visual, auditory). It occurs with relatively acute onset and is associated with distractibility, short-term memory impairment and decreased attention span.

Delirium invariably results from an acute organic disturbance although rarely it may be mimicked by certain psychiatric disorder like brief psychotic episode or mania.

Common Causes of Delirium

Common causes of delirium are given in **Table 3**.

Table 3: Common Causes of Delirium

Infection
High grade fever cerebral malaria septicaemia
Meningitis
Encephalitis
Acquired immunodeficiency syndrome
Metabolic disorders
Electrolyte imbalance
Hypo-/hyperglycaemia
Hepatic encephalopathy
Uraemia
Acidosis
Porphyria
Endocrinal imbalance
Hypothyroidism
Hyperthyroidism
Cushing's syndrome
Addison's disease
Vitamin deficiency
Wernicke-Korsakoff's syndrome
Seizure disorder
Head injury
Substance use disorders
Alcohol (intoxication/withdrawal)
Sedatives
Hypnotics
Drug-induced
Anti-cholinergics
Sympathomimetics
Miscellaneous
Systemic lupus erythematosus
Para-neoplastic syndrome
Hyperviscosity syndrome
Toxins

Management

Agitated patients must be protected from harm. Physical restrains may be necessary in some cases. After safety is ensured, a physical and mental status examination should be done. Relevant laboratory tests should be performed. Identification of cause and its immediate correction; e.g. 50 mg of 50% dextrose intravenously for hypoglycaemia, oxygen for hypoxia, 100 mg of vitamin B1 (thiamine) intravenously for thiamine deficiency; intravenous fluids for fluid and electrolyte imbalance. For agitation, BZDs (diazepam 10 mg or lorazepam 2 mg intravenous) or antipsychotic (5 mg haloperidol intramuscularly) or olanzapine may be given. Supportive medical and nursing care is provided. Specific treatment of the underlying cause of delirium should be initiated once the diagnosis is established.

22.9 Psychotherapy

Vidyadhar Watve

DEFINITION

Strupp defined psychotherapy as 'systematic use of a human relationship for therapeutic purposes of alleviating emotional distress by affecting enduring changes in a patient's thinking, feelings, and behaviour'.

TYPES OF PSYCHOTHERAPIES

Psychoanalysis

Psychoanalysis was introduced by Sigmund Freud.

Principle

To uncover unconscious processes responsible for the problem.

The process lasts for an hour; frequency is 3 to 5 sessions/week, and continues leaning away from the analyst. The patient associates freely narrating anything which comes to his mind, (free association) his fantasies and his dreams. Analyser makes the patient aware of his unconscious processes. The therapy sessions go on for many years. The patient brings about change in his maladaptive behaviour by gaining insight. Intelligent patients with mild-to-moderate psychopathology may benefit from this therapy.

Disadvantage

It is time consuming and expensive. It does not allow simultaneous use of medications.

Psychoanalytically Oriented Psychotherapy

The basic concepts are derived from psychoanalysis. This is less intensive than psychoanalysis. The psychoanalytic psychotherapist is more active and helps patient to understand his inner subjective world to gain understanding of the psychological problem. Each session lasts for an hour, frequency is reduced and may continue for a long time; may or may not allow simultaneous use of medications.

Patients are seen once or twice a week. Patient meets a psychiatrist. The goal is to support the day-to-day problems without leading with unconscious factors; uses various techniques like, ventilation, guidance, environmental manipulation, counselling. Medications are permitted and healthy dependence between patient and the therapist is allowed. However, a greater emphasis is placed on day-to-day reality issues.

These therapies have limitations and have not stood the test of time against other therapies.

Behaviour Therapy

Behaviour therapy (BT) is the application of principles of learning to reduce or culminate maladaptive behaviour and promote desired behaviour in a client. Maladaptive behaviour is reduced by extinction process punishing (punishment, aversion therapy) or by reinforcing desirable behaviour. There are several BT techniques, e.g. aversion therapy, token economy, systematic desensitisation, flooding and assertiveness training. BT is useful in treatment of mental retardation, chronic schizophrenia, agoraphobia, simple phobia, alcoholism and depression.

Cognitive Behavioural Therapy

Cognitive behavioural therapy (CBT), developed by Aaron Beck, is based on the hypothesis that the behaviour is determined by the way in which a person thinks about himself and his role in the society. Maladaptive behaviour is secondary to his distorted thinking which can lead to changes in his mood. The therapy is aimed at changing person's distorted thinking so that it changes his mood and behaviour. CBT is extensively used in depression, substance use disorders, schizophrenia, mild-to-moderate depression, anxiety disorders, personality disorder and bipolar disorder. Sessions are planned and frequency is decided. Therapist actively guides the person to understand and deal with distorted thinking. CBT is scrutinised scientifically and found to be effective in majority of psychiatric disorders.

Interpersonal Psychotherapy

This therapy is based on the concept that psychiatric problems disturb interpersonal relationship and aims to improve interpersonal skills. Patient is seen once weekly for twelve to fourteen weeks. The therapy is used in non-bipolar disorder and non-psychotic depression on outpatient basis. Anti-depressants are used along with this therapy.

Group Therapy

Patients with similar problems or different problems can be treated together to save time and cost. In addition, a patient in group therapy gets immediate feedback from other patients. Group therapy also offers an advantage of observing about his relational abilities and problem behaviour to a variety of people. Sharing emotional problems and learning new skills in a group encourages the coping behaviour. The direct dependency on the therapist is reduced. Alcoholics anonymous (AA) is an example of a large peer-run group for clients who are having alcohol related problems.

Hypnosis

This therapy consists of producing altered state of consciousness through various methods of induction. In these states, the patient is amenable to suggestion, which can bring about change in his behaviour. Hypnosis can be used in many disorders like anxiety disorders, nicotine dependence, sexual disorders and dissociative states.

Biofeedback

A patient is attached to biofeedback machine which gives information through sound or light about his physiologic functions, mainly related to muscular tone, brainwaves (ECT) and autonomic nervous system (e.g. pulse/blood pressure). The goal of treatment is to reduce arousal and anxiety by altering

feedback (sound or light). It is used to manage the tension states associated with migraine, hypertensions and tension headaches.

PERSONALITY DISORDERS

General Considerations

Hippocrates' description of four temperaments is one of the earliest descriptions of personality types and disorders, viz. melancholic (pessimistic), sanguine (optimistic), choleric (irritable) and phlegmatic (apathetic). The term personality is used to describe a person's characteristic behaviour in response to his or her inner and outer experiences.

Definition

A personality disorder is diagnosed when an individual has personality traits, which are inflexible, maladaptive and cause subjective distress and impairment in functioning.

Patient with personality disorders are seen by clinicians in outpatient as well as indoor settings. In the general population, the prevalence is between 10% and 15%.

Aetiology

Earliest theories were mainly psychoanalytic emphasising the contribution of external factors, such as pathological or inadequate parenting.

Subsequent advances in genetic and neurobiology research has identified genetic predisposition in different personality disorders as well as various neurobiological abnormalities such as malfunction of serotonin system.

Available data now suggest that, like other psychiatric disorders, personality disorders result from a complex interaction between all these factors.

Classification of Personality Disorders

At present, 10 individual personality disorders are identified (DSM IV TR). A skilled interview by experienced clinicians is the mainstay of personality disorder diagnosis. The following is the brief description of each of different personality disorders.

Paranoid personality disorder

Persons with paranoid personality disorder are characterised by long-standing suspiciousness and mistrust of persons in general. They refuse responsibility for their own acts and feelings and assign responsibility to others. They are often hostile, irritable, and angry. Persons with paranoid personality disorder are affectively restricted and appear to be unemotional. They pride themselves on being rational and objective, but such is not the case. They lack warmth and are impressed with, and pay close attention to, power and rank. It is more common among men than women.

Schizoid personality disorder

Schizoid personality disorder is diagnosed in patients who display a lifelong pattern of social withdrawal. Persons with schizoid personality disorder seem to be cold and aloof; they display a remote reserve and show no involvement with everyday events and the concerns of others. They appear quiet, distant, seclusive, and unsociable. They may pursue their own lives with remarkably little need or longing for emotional ties, and they are the last to be aware of changes in popular fashion. The life histories of such persons reflect solitary interests and success at non-competitive, lonely jobs that others find difficult to tolerate. Their sexual lives may exist exclusively in fantasy, and they may postpone mature sexuality indefinitely. Men may not marry because they are unable to achieve intimacy; women may passively agree to marry an aggressive man who wants the marriage. Persons with schizoid personality disorder usually reveal a lifelong inability to express anger directly.

Schizotypal personality disorder

Persons with schizotypal personality disorder are strikingly odd or strange, even to laypersons. Patients exhibit disturbed thinking and communication. Although frank thought disorder is absent, their speech may be distinctive or peculiar, may have meaning only to them and may often need interpretation. Like patients with schizophrenia, those with schizotypal personality disorder may not know their own feelings and yet are exquisitely sensitive to, and aware of, the feelings of others, especially negative affects like anger. These patients may be superstitious or claim powers of clairvoyance and may believe that they have other special powers of thought and insight. Their inner world may be filled with vivid imaginary relationships and child-like fears and fantasies. They may admit to perceptual illusions or macropsia and confess that other persons seem wooden and all the same.

Because persons with schizotypal personality disorder have poor interpersonal relationships and may act inappropriately, they are isolated and have few, if any, friends.

Anti-social personality disorder

Anti-social personality disorder is an inability to conform the social norms that ordinarily govern many aspects of a person's adolescent and adult behaviour. Although characterised by continual anti-social or criminal acts, the disorder is not synonymous with criminality. Patients with anti-social personality disorder can often seem to be normal and even charming and ingratiating. Their histories, however, reveal many areas of disordered life functioning. Lying, truancy, running away from home, thefts, fights, substance abuse and illegal activities are typical experiences that patients report as beginning in childhood. Suicide threats and somatic pre-occupations may be common.

These patients are extremely manipulative and can frequently talk to others into participating in schemes for easy ways to make money or to achieve fame or notoriety. These schemes may eventually lead the unwary to financial ruin or social embarrassment or both. Those with this disorder do not tell the truth and cannot be trusted to carry out any task or adhere to any conventional standard of morality. Promiscuity, spousal abuse, child abuse, and drunk driving are common events in their lives. A notable finding is a lack of remorse for these actions; that is, they appear to lack a conscience.

Borderline personality disorder

Patients with borderline personality disorder are characterised by extraordinarily unstable affect, mood, behaviour, object relations, and self-image. They almost always appear to be in a state of crisis. Mood swings are common. Patients can be argumentative at one moment, depressed the next, and later complain of having no feelings. The behaviour of patients with

borderline personality disorder is highly unpredictable and their achievements are rarely at the level of their abilities. The painful nature of their lives is reflected in repetitive self-destructive acts. Such patients may slash their wrists and perform other self-mutilations to elicit help from others, to express anger, or to numb themselves to overwhelming affect.

Because they feel both dependent and hostile, persons with this disorder have tumultuous interpersonal relationships. They can be dependent on those to whom they are close and when frustrated can express enormous anger toward their intimate friends. Patients with borderline personality disorder cannot tolerate being alone and they prefer a frantic search for companionship, no matter how unsatisfactory, to their own company.

Histrionic personality disorder

Persons with histrionic personality disorder are excitable and emotional, and behave in a colourful, dramatic, extroverted fashion. Accompanying their flamboyant aspects, however, is often an inability to maintain deep, long-lasting attachments. Persons with histrionic personality disorder show a high degree of attention-seeking behaviour. They tend to exaggerate their thoughts and feelings and make everything sound more important than it really is. They display temper tantrums, tears, and accusations when they are not the centre of attention or are not receiving praise or approval. Seductive behaviour is common in both sexes. Sexual fantasies about persons with whom patients are involved are common, but patients are inconsistent about verbalising these fantasies and may be coy or flirtatious rather than sexually aggressive. Their need for reassurance is endless. They may act on their sexual impulses to reassure themselves that they are attractive to the other sex. Their relationships tend to be superficial, however, and they can be self-absorbed, and fickle. Their strong dependence needs make them overly trusting and gullible.

Narcissistic personality disorder

Persons with narcissistic personality disorder are characterised by a heightened sense of self-importance and grandiose feelings of uniqueness. Persons with narcissistic personality disorder have a grandiose sense of self-importance; they consider themselves special and expect special treatment. Their sense of entitlement is striking. They handle criticism poorly and may become enraged when someone dares to criticise them, or they may appear completely indifferent to criticism. Persons with this disorder want their own way and are frequently ambitious to achieve fame and fortune. Their relationships are fragile, and they can make others furious by their refusal to obey conventional rules of behaviour. Interpersonal exploitiveness is common place. They cannot show empathy, and they feign sympathy only to achieve their selfish ends. Because of their fragile self-esteem, they are prone to depression. Interpersonal difficulties, occupational problems, rejection and loss are among the stresses that narcissists commonly produce by their behaviour—stresses they are least able to handle.

Avoidant personality disorder

Persons with avoidant personality disorder show extreme sensitivity to rejection and may lead a socially withdrawn life. Although shy they are not asocial and show a great desire for companionship, but they need unusually strong guarantees of uncritical acceptance. Such persons are commonly described as having an inferiority complex. Hypersensitivity to rejection by others is the central clinical feature of avoidance personality disorder, and patients' main personality trait is timidity. When talking with someone, they express uncertainty, show a lack of self-confidence and may speak in a self-effacing manner. They are apt to misinterpret other persons' comments as derogatory or ridiculing. The refusal of any request leads them to withdraw from others and to feel hurt. In the vocational sphere, patients with avoidant personality disorder often take jobs on the sidelines. They rarely attain much personal advancement or exercise much authority but seem shy and eager to please. These persons are generally unwilling to enter relationships unless they are given an unusually strong guarantee of uncritical acceptance. Consequently, they often have no close friends or confidants.

Dependent personality disorder

Persons with dependent personality disorder are characterised by a pervasive pattern of dependent and submissive behaviour. They cannot make decisions without an excessive amount of advice and reassurance from others. They avoid positions of responsibility and become anxious if asked to assume a leadership role. They prefer to be submissive. When on their own, they find it difficult to persevere at tasks but may find it easy to perform these tasks for someone else. Because persons with the disorder do not like to be alone, they seek out others on whom they can depend; their relationships are thus distorted by their need to be attached to another person. In folie a deux (shared psychotic disorder), one member of the pair usually suffers from dependent personality disorder; the submissive partner takes on the delusional system of the more aggressive, assertive partner on whom he or she depends. Pessimism, self-doubt, passivity and fears of expressing sexual and aggressive feelings all typify the behaviour of persons with dependent personality disorder. An abusive, unfaithful or alcoholic spouse may be tolerated for long periods to avoid disturbing the sense of attachment.

Obsessive-compulsive personality disorder

The essential feature of the disorder is a pervasive pattern of perfectionism and inflexibility. Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, orderliness, neatness, details and the achievement of perfection. These traits account for the general constriction of the entire personality. They insist that rules be followed rigidly and cannot tolerate what they consider infractions. Accordingly, they lack flexibility and are intolerant. They are capable of prolonged work provided it is routinised and does not require changes to which they cannot adapt.

Persons with obsessive-compulsive personality disorder have limited interpersonal skills. They are formal and serious and often lack a sense of humour. They alienate persons, are unable to compromise, and insist that others submit to their needs. They are, however, eager to please those whom they see as more powerful than they are, and they carry out these persons' wishes in an authoritarian manner. Because they fear making mistakes, they are indecisive and ruminate about making decisions. Although a stable marriage and occupational adequacy are common, persons with obsessive-compulsive personality disorder have few friends. Anything that threatens to upset their

perceived stability or the routine of their lives can precipitate a great deal of anxiety otherwise bound up in the rituals that they impose on their lives and try to impose on others.

Passive-aggressive personality disorder

Persons with passive-aggressive personality disorder are characterised by covert obstructionism, procrastination, stubbornness and inefficiency. Such behaviour is a manifestation of passively expressed underlying aggression. In DSM-IV-TR the disorder is also called negativistic personality disorder.

Depressive personality disorder

Persons with depressive personality disorder are characterised by life-long traits that fall along the depressive spectrum. They are pessimistic, anhedonic, duty bound, self-doubting and chronically unhappy.

Sadistic personality disorder

Sadistic personality disorder is not included in DSM-IV-TR, but it still appears in the literature and may be of descriptive use. Beginning in early adulthood, persons with sadistic personality disorder show a pervasive pattern of cruel, demeaning, and aggressive behaviour that is directed toward others. Persons with this disorder like to humiliate.

TREATMENT

Personality disorders are evident since adolescence or young adulthood; but they come to the attention of the clinician usually when these individuals develop a psychiatric disorder like major depression, anxiety disorder, schizophrenia or substance abuse. This is mainly because individuals with personality disorder do not recognise their maladaptive traits as undesirable or needing to be changed.

Treatment is difficult, therefore, and unlikely to result in the development of a fully healthy personality. Psychotropic drug therapy is of limited use but psychotherapy, especially cognitive behavioural therapy, has shown encouraging results demean persons in front of others and have usually treated or disciplined persons uncommonly harshly, especially children. In general, persons with sadistic personality disorder are fascinated by violence, weapons, injury, or torture.

22.10 Biological and Somatic Treatments of Psychiatric Disorders

E Mohan Das

The ever-growing knowledge regarding the biological basis of psychiatric disorders has helped in the discovery of new and improved treatment modalities. Following is a brief overview of the common somatic treatments in psychiatry.

ANTI-PSYCHOTICS

The anti-psychotic era began with the discovery of chlorpromazine by Charpentier and its introduction to psychiatry by Delay and Deniker in 1952.

Classification

Anti-psychotic agents are classified as typical and atypical anti-psychotics. The dosage, mode of action and adverse reactions are shown in **Tables 1 and 2**.

Additionally, a recent criterion added to the definition is its efficacy in treating the negative symptoms of schizophrenia. From pharmacologic point of view atypical anti-psychotics are serotonin dopamine antagonists (SDA), multi-acting receptor-targeted anti-psychotics (MARTA), partial dopamine receptor agonists or dopamine system stabilisers, and combined D_2/D_3 receptor antagonists (**Tables 2 and 3**).

Mechanism of Action

Conventional anti-psychotics act by blocking the post-synaptic D_2 receptor. D_2 occupancy of 60% to 75% is needed for anti-psychotic action, and more than 80% or occupancy results in extrapyramidal symptoms EPS. The different dopaminergic pathways explain the effects and side-effects of anti-psychotics (**Table 3**). Mode of action of SDA is shown in **Table 4** (serotoninergic receptor antagonism). In addition to the post-synaptic dopaminergic antagonism, it antagonises the $5HT_{2A}$ serotoninergic receptor.

Therapeutic Indications

Anti-psychotic drugs have multiple uses in psychiatry in different dosages. These are used in treatment of psychosis like acute psychotic episodes; schizophrenia, delusional disorders acute and transient psychotic disorders, and schizoaffective disorders. These groups of drugs are also used in acute manic and hypo-manic states and also in organic brain syndromes with psychosis.

The atypical anti-psychotics are approved by US FDA for treatment of an acute manic episode, and some are approved for the maintenance treatment of bipolar disorders, depression when associated with psychotic symptoms.

Table 1: Typical Anti-Psychotics

	Potency	Dose (mg/day)	Adverse Effects			
			Sedative	Hypotensive	Anticholinergic	EPS
Phenothiazines						
Aliphatic:						
Chlorpromazine	Low	300 to 800	High	High	Medium	Low
Triflupromazine	Low	100 to 150	High	High	Medium	Low
Piperazine:						
Trifluoperazine	High	6 to 20	Medium	Low	Low	High
Fluphenazine	High	1 to 20	Medium	Low	Low	High
Perphenazine	Medium	8 to 40	Low	Low	Low	High
Prochlorperazine	Medium	40 to 150	Low	Low	Low	High
Piperidine:						
Thioridazine	Low	200 to 700	Low	High	High	Low
Mesoridazine	Low	75 to 300	Medium	Medium	Medium	Medium
Thioxanthines						
Chlorprothixine	Low	50 to 400	Medium	Medium	Medium	Low
Thiothixine	High	6 to 30	Low	Low	Low	High
Flupenthixol	High	3 to 15	Low	Low	Low	High
Butyropheraphenones						
Haloperidol	High	6 to 20	Low	Low	Low	High
Trifluperidol	High	1 to 8	Low	Low	Low	Low
Penfluridol	Medium	20 to 60	Low	Low	Low	High
Dihydroindole						
Molindone	Medium	50 to 100	Medium	Low	Medium	High
Diphenylbutylpiperidine						
Pimozide	High	1 to 10	Low	Low	Low	High
Dibenzoxazepine						
Loxapine	Medium	60 to 100	Medium	Medium	Medium	High

The other indications are to use in low dosages in anxiety disorders, borderline personality disorder, eating disorders, impulse control disorders, aggression and self-injurious behaviour in mental retardation and autistic spectrum disorders, and also along with stimulants in attention deficit disorders especially with co-morbid oppositional defiant or conduct disorder. They are used to treat substance-induced psychotic disorders, to control psychotic symptoms in dementia and other organic psychosis and in delirium.

Anti-psychotics are used in the treatment of tic disorders (including Tourette's syndrome), hemiballismus, and Huntington's disease. Anti-psychotics are also used in treatment of Nausea, emesis, intractable hiccups.

Adverse Effects

The common side-effects of anti-psychotics are the extra-pyramidal syndromes that include Parkinsonism, dystonia, akathisia, neuroleptic malignant syndrome (NMS) and tardive dyskinesia (TD) (all these side-effects are minimal with atypical anti-psychotics). The other side-effects include hyper-

Table 2: Atypical Anti-Psychotics

	Dose (mg/day)	Adverse Effects			
		EPS	Anticholinergic	Prolactin	Weight gain
Serotonin dopamine antagonists					
Benzisoxazole					
Risperidone	1 to 16	Low to moderate	Low to moderate	Moderate	Moderate
Benzisothiazolyl					
Ziprasidone	40 to 160	0 to Low	Low	Low	0 to Low
Multi-acting receptor-targeted antipsychotics					
Dibenzodiazepine					
Clozapine	300 to 900	0 to Low	High	0 to Low	High
Thienobenzodiazepine					
Olanzapine	5 to 30	Low	Moderate	Low	High
Dibenzothiazepine					
Quetiapine	300 to 800	0 to Low	Low to moderate	Low	Moderate
Partial dopamine agonist					
Quinolonone					
Aripiprazole	15 to 30	0 to Low	Low	0 to Low	0 to Low
D2/D3 antagonists					
Substituted benzamides					
Amisulpride	400 to 1200	Low to moderate	Low	High	Low
Sulpiride	200 to 1200	Low to moderate	Low	High	Low to moderate

Table 3: Dopaminergic Pathways Targeted by Anti-Psychotics

Pathway	Role	Action
Mesolimbic pathway	Dopaminergic excess in this pathway produces positive symptoms	Reduces dopaminergic transmission to alleviate positive symptoms
Mesocortical pathway	Hypodopaminergic state in this pathway produces negative symptoms	Atypicals potentially increase dopamine content here to alleviate negative symptoms
Nigrostriatal pathway	Involved in the fine tuning of motor function	D_2 blockade causes Parkinsonism Dystonia Akathisia Neuroleptic malignant syndrome Tardive dyskinesia (? dopaminergic super sensitivity)
Tuberoinfundibular pathway	Neuroendocrine regulation	D_2 blockade causes Hyperprolactinaemia Amenorrhoea, galactorrhoea, loss of libido in females, impotence, loss of libido, gynaecomastia, low sperm count, feminisation in males

Table 4: Mode of Action of Serotonin Dopamine Antagonists (SDA)

Post-synaptic dopaminergic mechanism
- In limbic area reduces positive symptoms

5HT2A (serotoninergic) antagonism
- Releases serotoninergic inhibition of dopamine
- In hypodopaminergic state in frontal areas—reduces negative symptoms
- In nigrostriated region reduces SPS

prolactinaemia; anticholinergic effects like dry mouth, visual blurring, and constipation; α_1 adrenergic blockade causing postural hypotension, palpitation; miscellaneous effects like drowsiness, lethargy, confusion, seizures, sialorrhoea (clozapine), corneal/lenticular pigmentation, retinal degeneration (thioridazine), and hypersensitivity reactions like skin rashes, urticaria, photosensitivity, and cholestatic jaundice. ECG changes and cardiac arrhythmias are also seen and QT prolongation is noted with ziprasidone, sertindole, thioridazine and pimozide. Clozapine is reported to cause eosinophilic myocarditis and sudden death. Some of the atypical antipsychotics may cause treatment emergent obsessive compulsive disorder (OCD). Though potentially fatal, the incidence of agranulocytosis with clozapine is very low (0.38%). The atypicals like clozapine and olanzapine run a higher risk of weight gain, elevated blood sugar, and elevated levels of cholesterol, lipoproteins and triglycerides and the risk of metabolic syndrome. There are reports of increased cerebrovascular events in geriatric patient prescribed atypicals especially risperidone and olanzapine.

ANTIDEPRESSANTS

Antidepressants are a heterogeneous group of compounds primarily used for the treatment of depression. The introduction of monoamine oxidase inhibitors and imipramine opened the floodgates for the development of newer drugs in the antidepressant armamentarium.

Classification and Mechanism of Action

The antidepressants are classified based on the neuroreceptor targets on which they act modulating the levels of neurotransmitters like serotonin, norepinephrine and dopamine. There are several different pharmacologic actions for more than two-dozen antidepressants (**Table 5**). The immediate clinical response with most antidepressants is due to the increase in levels of the monoamine neurotransmitters. The antidepressants however exert their full clinical response only in a delayed manner. The delayed therapeutic effect probably is by the desensitisation or down regulation of the neurotransmitter receptors. The final common pathway of action of all antidepressants is probably by gene expression and neuroplasticity through the activation or deactivation of vital genes like the brain-derived neurotrophic factor (BDNF) gene among others.

Therapeutic Indications

Antidepressants are mainly used for the treatment of mood disorders; major depression and dysthymia; bipolar depression (SSRIs and bupropion are preferred to TCAs due to the low risk of switch to mania); depression due to general medical condition, premenstrual dysphoric disorder (PMDD) and substance-induced depression; generalised anxiety disorder (GAD); OCD; panic disorder; post-traumatic stress disorder (PTSD); and social phobia. Other indications include eating disorders, insomnia, parasomnias, neuropathic pain, migrainous and nonmigrainous headache, smoking cessation and cocaine detoxification (bupropion), ADHD (atomoxetine, imipramine) attention deficit hyperactivity disorder, irritable bowel syndrome (IBS), impulse control disorders, borderline personality disorders, paraphilias, premature ejaculation, behavioural disturbances in dementia, autism, nocturnal enuresis (TCA), respiratory disorders (SSRI), peptic ulcer (doxepin), movement disorders, chronic fatigue syndrome.

MOOD STABILISERS

Mood stabilisers are drugs used for the acute and maintenance treatment of bipolar disorder. The major mood stabilisers include lithium, anticonvulsants, and atypical anti-psychotics; though some others like calcium channel blockers (CCB) and omega-3 fatty acids exert mood stabiliser effect (**Table 6**).

Lithium

Lithium has proven efficacy in the acute and maintenance treatment of bipolar illness. About 80% of acute mania responds to lithium and it is 70% to 80% effective in the prophylaxis of manic and depressive episodes. Lithium is also effective in the acute treatment of bipolar depression and is a first-line choice though not approved for the same. Lithium is highly renal toxic. It is effective in serum level of 0.6 to 1.2 meq/litre and a constant blood monitoring of serum lithium level along with renal functions are required in patients where lithium is used.

Anticonvulsants

The anticonvulsants usually used as mood stabilisers include valproate, carbamazepine, lamotrigine, gabapentin and topiramate, of which the latter two drugs have not been approved for acute or maintenance treatment but have some evidence regarding its efficacy as a mood stabiliser. Valproate and carbamazepine are approved for the acute treatment of mania, while lamotrigine is approved for the maintenance treatment of bipolar disorder. Valproate and carbamazepine are preferred to lithium in dysphoric mania and mixed state (carbamazepine nowadays is a second-line choice in mania) and are efficacious in the prophylaxis of bipolar disorder though not US FDA approved for the same. Lamotrigine has more impact on the depressive phase of bipolar and has little antimanic property and is not approved for the acute treatment of mania. It is also used as an off label drug for acute treatment of bipolar depression.

Controlled trials also show that valproate, lamotrigine and lithium are efficacious in rapid cycling bipolar disorder. The other anticonvulsant used as putative mood stabilisers include oxcarbazepine, tiagabine, zonisamide, and levetiracetam.

Anti-Psychotics

Almost all atypical anti-psychotics have shown mood stabiliser action, though clozapine is reserved for refractory bipolar disorder. Risperidone, ziprasidone, olanzapine, quetiapine, and aripiprazole are mood stabilisers approved for the treatment of acute mania. The combination of olanzapine with fluoxetine is the only approved treatment for acute treatment of bipolar depression. Aripiprazole and olanzapine are also approved for the maintenance treatment of bipolar disorder. The typical anti-psychotic chlorpromazine also has received approval for the acute treatment of mania. Haloperidol has shown equal efficacy as atypicals in the control of mania especially as adjuvant.

Table 5: Antidepressants/Therapeutic Indication and Adverse Events

Antidepressant Class (Dosage Range in mg/day)	Therapeutic Indication	Adverse Effects
Tricyclics (TCA) Tertiary amines Imipramine (100 to 300) Amitriptyline (100 to 300) Clomipramine (100 to 250) Doxepin (100 to 300) Dosulepin (dothiepin) Secondary amines Nortriptyline (50 to 200)	Major depression, depression due to general medical condition, generalised anxiety disorder (doxepin), panic disorder, OCD (clomipramine), eating disorder, pain disorder, nocturnal enuresis (imipramine), peptic ulcer (doxepin), narcolepsy, nightmare, PTSD, ADHD, sleep walking, sleep terror, premature ejaculation (clomipramine), movement disorder (clomipramine)	Anti-cholinergic effects, nausea, vomiting, sedation, induction of mania, confusion, autonomic effects, cardiac effects, myoclonus, seizure (clomipramine, amoxapine), parkinsonism and NMS (amoxapine), rashes, weight gain, impotence, SIADH. Rare: hepatitis, jaundice, agranulocytosis, leucopaenia, ataxia, peroneal palsies, and paraesthesia
Tetracyclics Mianserin (30 to 100) Amoxapine (100 to 400)		
Monoamine oxidase inhibitors (MAOI) Irreversible, nonselective Isocarboxazid (30 to 60) Phenelezine (15 to 90) Tranylcypromine (20 to 60) Irreversible, MAO B selective Selegiline (20 to 60) Moclobemide (300 to 600)	Major depression, atypical depression, depression due to general medical condition, panic disorder with agoraphobia, PTSD, social phobia, pain disorder, and eating disorder	Orthostatic hypotension, insomnia, weight gain, sexual dysfunction, tyramine-induced hypertensive crisis, paraesthesia, myoclonic jerks, muscle pains, induction of mania, psychotic symptoms Rare: hepatotoxicity, cardiotoxicity, non-tyramine-induced hypertensive crisis
Selective serotonin reuptake inhibitors (SSRI) Fluoxetine (20 to 80) Fluvoxamine (100 to 300) Paroxetine(20 to 60) Sertraline (50 to 200) Citalopram (20 to 60) Escitalopram (10 to 20)	Major depression, atypical depression, dysthymia, bipolar depression, depression due to general medical condition, OCD, panic disorder, PTSD, GAD, eating disorders, premenstrual dysphoric disorder (PMDD), borderline PD, paraphilias, ADHD, behavioural control in dementias and autism, pain disorder, premature ejaculation and syncope	Sexual dysfunction (50% to 80%), nausea, vomiting, diarrhoea, dyspepsia, weight loss or gain, headaches, anxiety (fluoxetine), insomnia or sedation, nightmares, EPS, seizures, anticholinergic effects, SIADH, increased prolactin levels, serotonin syndrome, apathy syndrome and SSRI withdrawal
Norepinephrine reuptake inhibitor (NRI) Reboxetine (4 to 12) Atomoxetine (0.5 to 1.2)	Major depression, dysthymia, social phobia ADHD, drug of choice of adult ADHD	Urinary hesitancy, headache, dizziness, dry mouth, decreased libido, insomnia Nausea, diarrhoea, vomiting, anorexia, dizziness, mood swings, urinary hesitancy, sexual dysfunction
Serotonin norepinephrine reuptake inhibitor (SNRI) Venlafaxine (75 to 375) Duloxetine (30 to 120) Milnacipran (50 to 250)	Major depression, GAD, panic disorder, OCD, social phobia, agoraphobia, ADHD Major depression, diabetic peripheral neuropathy Major depression, pain disorder	Nausea, somnolence, dry mouth, dizziness, nervousness, constipation, asthenia, anorexia, sexual dysfunction, diastolic hypertension (venlafaxine), and withdrawal syndrome
Norepinephrine dopamine reuptake inhibitor (NDRI) Bupropion (150 to 450)	Major depression, bipolar depression, smoking cessation, cocaine withdrawal	Headache, insomnia, nausea, upper respiratory complaints, seizure, hallucinations, delusions, catatonia and delirium
Noradrenergic and specific serotoninergic antidepressant (NaSSA) Mirtazapine (15 to 45)	Major depression, anxiety disorders	Somnolence, dry mouth, increased appetite, constipation, weight gain, dizziness, nightmares, neutropaenia (0.3%), ALT elevation
Serotonin antagonist/reuptake inhibitors (SARI) Trazodone (75 to 600) Nefazodone (100 to 600)	Major depression, insomnia, PTSD, panic disorder, agitation in elderly Major depression, panic disorder, OCD, PMDD, pain disorder	Sedation, orthostatic hypotension, dizziness, dry mouth, headache, gastric irritation, arrhythmias, neutropaenia, priapism
Selective serotonin reuptake enhancer Tianeptine (12.5 to 37.5)	Major depression	Epigastric pain, dry mouth, anorexia, nausea, vomiting, constipation, flatulence; insomnia, drowsiness, nightmares

Table 6: Mood Stabilizers

	Lithium	Valproate	Carbamazepine	Lamotrigine
Half-life	24 hours	8 to 17 hours	24 hours initially, later 12 to 17 hours	25 hours
Starting dose	300 mg bid or tds	20 mg/kg (250 tds)	200 mg bid	25 mg od
Dose range	900 to 1800 mg	750 to 4200 mg	400 to 1600 mg	100 to 500 mg
Onset of action	5 to 14 days	5 to 14 days	5 to 14 days	5 to 14 days
Metabolism	Nil	Hepatic	Hepatic	Hepatic
Serum level	0.6 to 1.2 meq/L (acute)	45 to 25 µg/mL	4 to 12 µg/mL	Not established
Adverse effects	Nausea, diarrhoea, vomiting, tremor, nephrogenic diabetes insipidus, hypothyroidism, cognitive effects, acne and toxicity	GI irritation, nausea, sedation, tremor, weight gain, alopecia, vomiting, diarrhoea, ataxia, polycystic ovarian disease, hepatotoxicity, and agranulocytosis	Rashes, Steven Johnson syndrome, ataxia, vertigo, GI irritation, diplopia, task performance problems, aplastic anaemia, agranulocytosis, pancreatitis, and hepatic failure	Dizziness, ataxia, somnolence, diplopia, headache, nausea, vomiting, rashes, toxic epidermal necrolysis, and Steven Johnson syndrome
Major indications	Acute treatment of mania, maintenance treatment of bipolar	Acute treatment of mania, seizure disorder	Acute treatment of mania, seizure disorder	Bipolar depression, maintenance treatment of bipolar, seizure disorder

Other Mood Stabilisers

Benzodiazepines (especially clonazepam) are used as adjuvants in the treatment of mania. CCBs are used for the control of mania and ultradian bipolar (mood cycling in less than 24 hours). The omega-3 fatty acids also have putative mood stabiliser action and are used in the treatment of mania.

ANXIOLYTICS

Anxiolytics are drugs specifically used to treat and prevent the various anxiety disorders. They are indicated for short-term treatment and long-term prophylaxis of these disorders.

Classification

The drugs used include benzodiazepines, antidepressants, azapirones, sedative antihistaminics, β-blockers, anticonvulsants, anti-psychotics and miscellaneous agents like inositol.

Benzodiazepines

Benzodiazepines are generally used for the emergency and short-term management of anxiety disorders though of late they are recommended for long-term treatment of anxiety. These drugs are used alongside antidepressants and help in allaying the somatic symptoms of anxiety. These drugs activate all three binding sites of the GABA-BZD receptor (subtype of the $GABA_A$ receptor), which results in chloride influx and decreased neuronal excitability. The other indications of benzodiazepines include mixed anxiety and depressive disorder, insomnia, alcohol withdrawal, depression, bipolar disorder, akathisia, agitation, and seizure disorders. The common adverse effects include drowsiness, dizziness, ataxia, falls and fractures (in elderly), disinhibition and respiratory depression (more if combined with alcohol). They are associated with paradoxical aggression, cognitive impairment, hepatic dysfunction, probable teratogenicity, dependence, tolerance and withdrawal syndrome (**Table 7**).

Azapirones

The azapirones like buspirone, gepirone and ipsapirone act via partial agonism of $5HT_{1A}$ receptors and buspirone is beneficial in the treatment of the cognitive symptoms of anxiety. Buspirone is used in GAD, panic disorder, social phobia, and PTSD. They have a delayed onset (2 to 4 weeks) of action. They lack abuse potential and the side-effects include headache, nausea, dizziness and rarely restlessness and insomnia. Buspirone is usually started 5 mg three times a day and then raised every 2 to 4 days, the effective dose range being 15 to 60 mg per day.

Table 7: Benzodiazepines

Drug	Dosage range (mg/day)	Equivalent dose (mg)	Elimination half-life (hours)
Long-acting			
Diazepam	6 to 80	5	20 to 80
Chlordiazepoxide	10 to 150	10	5 to 30
Clonazepam	1 to 4	0.25	18 to 60
Clobazam	30 to 80	5	12 to 60
Intermediate-acting			
Alprazolam	1 to 4	0.5	12 to 15
Lorazepam	2 to 4	1	10 to 20
Oxazepam	30 to 120	15	5 to 20
Temazepam	10 to 30	10	8 to 22
Short-acting			
Triazolam	0.5 to 2	0.25	1.5 to 5

Other anxiolytics

Hydroxyzine, the H_1 antihistaminic, has shown effect at 50 mg per day dosage in GAD. The β-blocker propranolol is used in social phobia (performance anxiety), panic disorder, GAD and PTSD. The usual approach is to use 10 to 40 mg of propranolol half an hour before an anxiety-provoking situation. Anticonvulsants like valproate, carbamazepine, tiagabine, phenytoin, pregabalin and levetiracetam are used for the treatment of GAD, PTSD, social phobia and panic disorder. The atypical anti-psychotics are used in PTSD and to augment antidepressants in OCD. Inositol has been used in the treatment of panic disorder (**Table 8**).

Table 8: Pharmacotherapy of Anxiety Disorder

Disorder	First-Line	Alternatives
OCD	SSRI Clomipramine	Venlafaxine, clonazepam, mirtazapine, anti-psychotics, buspirone, IV clomipramine, anticonvulsants, pindolol, MAOI
Panic disorder	SSRIBZD (immediate control) Certain TCAs	MAOI, anticonvulsants, venlafaxine, mirtazapine, nefazodone, inositol
PTSD	SSRI Serotonergic TCA	Mirtazapine, venlafaxine, MAOI, anticonvulsants, antipsychotics, clonidine, trazodone, propranolol
GAD	SSRI Venlafaxine BZD (immediate control) Certain TCAs	Buspirone, anti-psychotics, hydroxyzine, propranolol, anticonvulsants
Social phobia	SSRI MAOI	RIMA, clonazepam, venlafaxine, reboxetine, propranolol, anticonvulsants, buspirone

ELECTROCONVULSIVE THERAPY

Cerletti and Bini introduced electroconvulsive therapy (ECT) in 1938. It is one of the safest, most effective and yet the most controversial of all treatment modalities in medicine.

Mechanism of Action and Therapeutic Indications

electroconvulsive therapy uses an electrically-induced generalised seizure activity to treat psychiatric disorders (**Table 9**). A wide variety of mechanisms including neuropsychological, neurophy- siological, neurochemical and neuroendocrine are proposed to explain the therapeutic action of ECT. They are effective in the short-term control of various psychiatric disorders listed in **Table 10**.

Technique and Course

Modified ECT is done under short acting general anaesthesia (thiopentone or methohexital) and muscle relaxation (succinyl choline). Brief pulse stimulation is used to produce seizures and is preferred to sine wave stimulation and a seizure of at least 25 seconds is needed for therapeutic effect. The electrode placement is either unilateral (on nondominant hemisphere) or bilateral (bitemporal or bifrontotemporal). Bilateral placement has more rapid clinical response while unilateral placement has lesser cognitive side-effects. ECT is usually given three times a week and the course of ECT varies with the disorder being treated. In catatonia a course consists of 3 to 5 treatments, in depression 6 to 12 treatments, in mania 8 to 20 treatments and in schizophrenia more than 15 treatments.

Contraindications and Adverse Effects

electroconvulsive therapy has no absolute contraindication but it should be used with caution in cerebral aneurysms, intracerebral haemorrhage, raised intracranial tension, recent myocardial infarction and cardiac arrhythmias. Arrhythmias, severe hypertension, phaeochromocytoma and impending retinal detachment. The mortality with ECT is about 0.002% and the common adverse effects include headache, confusion, delirium, and memory disturbance (returns to normal by 6 months). Other adverse effects include fractures, nausea, vomiting and muscle soreness.

Table 9 : Mechanism of Action of Electroconvulsive Therapy

Neurophysiological mechanism
- Anticonvulsant theory
- ↓ Cerebral blood flow
- ↓ Cerebral metabolism
- ↑ Slow wave activity

Neurochemical changes
- ↑ 5HT2a receptors
- ↑ 5HT1a receptor sensitivity
- ↑ Synthesis and utilisation of NE
- ↓ β-receptor
- ↓ α2 adrenoceptor
- ↑ α1 receptor
- ↑ Synthesis and turnover of DA
- ↑ mRNA of D1 and D2 receptors
- ↓ Glutamatergic activity
- ↑ GABAergic function
- ↑ Endogenous opioids
- ↑ Density of specific opioid receptors
- ↓ Melatonin level

Intracellular
- ↑ Brain derived neurotrophic factor (BDNF)

Neuroendocrine
- ↑ Prolactin, corticotrophin, cortisol, oxytocin, vasopressin, β-endorphin

Neuropeptides
- ↑ Thyrotrophin releasing hormone
- ↑ Neuropeptide Y
- ↑ Somatostatin

Table 10: Therapeutic Indications of Electroconvulsive Therapy

Major depressive disorder
- Suicidal or homicidal ideas/attempts
- Stupor
- Psychotic symptoms
- Marked psychomotor retardation or agitation
- Refusal to take food or fluids

Catatonia
- Psychiatric disorders
- Neurologic disorders

Mania
- Life-threatening physical exhaustion
- Treatment resistance

Acute schizophrenia
- Marked positive symptoms
- Catatonia
- Affective symptoms

Pregnant women with suicidal ideas and depression
Geriatric and medically ill patients who cannot take drugs safely
Atypical psychosis
OCD
Delirium
NMS
Hypopituitarism
Intractable seizures
On-off phenomenon of Parkinson's disease

EMERGING TREATMENTS

The emerging biological treatments include repeated transcranial magnetic stimulation (rTMS), vagal nerve stimulation (VNS), and magnetoconvulsive therapy (MCT). rTMS involves the use of a magnetic field to inhibit cortical neurons. This is being tried in treatment resistant depression, treatment resistant auditory hallucinations and negative symptoms of schizophrenia. In VNS an implanted pulse generator is used to deliver stimulation of vagus and it has shown 40% response in treatment resistant depression. MCT is a method whereby a varying magnetic field is used to induce a more controlled seizure than what is possible by ECT and can help specific targeting for better response and lesser side-effects.

PULMONARY ANATOMY

The lungs perform the main function of gas exchange—the uptake of oxygen and expulsion of carbon dioxide, and several other functions including maintenance of acid-base, water balance, defence against invading foreign particles, micro-organisms and generation of several biological active substances and enzymes, and are also involved in metabolism of certain drugs besides providing a portal for administration of certain drugs.

The lungs are lined by the visceral pleura and separated from the chest wall by the parietal pleura, the pleural space being only a potential space with a little fluid to allow smooth movement. The air passage from the nose up to the larynx is called the *upper respiratory tract* and that below is the *lower respiratory tract*.

Upper Respiratory Tract

The *nose* is lined by ciliated columnar epithelium and is richly supplied by blood and nerve endings. It performs the function of olfaction or smelling and filtration, warming, and humidification of inhaled air. The four *paranasal sinuses*, lined by stratified ciliated columnar epithelium, are air-containing cavities in the skull bones found in relation to the nasal cavity. These reduce the weight of the skull and play a role in the voice resonance and temperature regulation.

The pharynx is located posterior to the nasal and oral cavities and has three parts: nasopharynx, oropharynx, and laryngo-pharynx. The lining mucosa changes from ciliated columnar to stratified in the lower part. It is richly supplied by lymphoid tissue that aggregates to form the adenoids in the nasopharynx and lingual, Eustachian and palatine tonsils. The muscles of the pharynx coordinate the swallowing so that aspiration into the larynx is avoided. The *larynx* consists of three articulating cartilages: the thyroid, cricoid, and the arytenoids. The vocal cords extend from arytenoids posteriorly to the thyroid cartilage anteriorly. These are lined by squamous epithelium and the rest of the larynx is lined by ciliated columnar epithelium. Most of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerves.

Lower Respiratory Tract (Figure 1)

The airways can be divided into conducting, transitional and respiratory passages according to the nature of function performed. The *conducting airways* include the trachea and the larger cartilaginous bronchi and the more distal membranous, non-cartilaginous bronchioles. These do not take part in gas exchange. The *transitional airways*, consisting of respiratory bronchioles and alveolar ducts, provide a passage as well carry out gas exchange while the most distal zone, the *respiratory zone*, consisting of the alveolar sacs and the alveoli, is responsible for gas exchange.

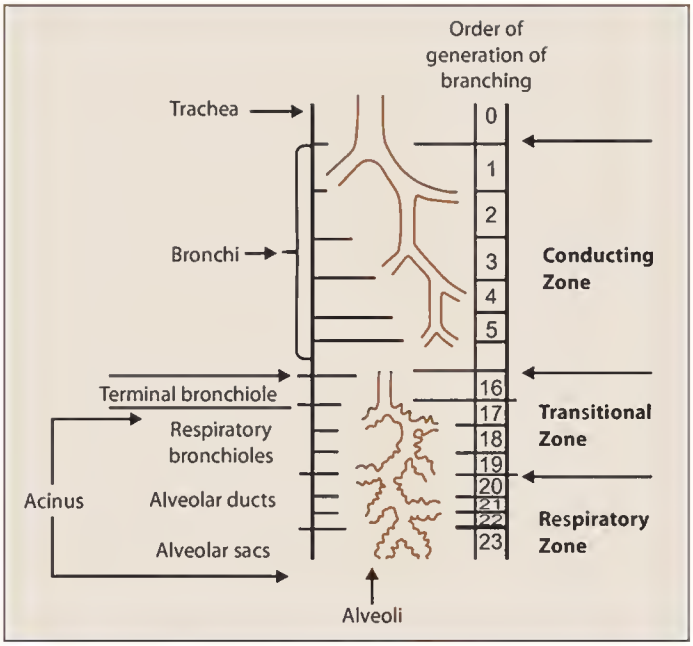

Figure 1: Organisation of the lower respiratory tract.

Conducting Airways (Trachea, Bronchi, and Bronchioles)

The larynx continues as the trachea at the cricoid cartilage enters the thoracic inlet and ends at the carina by dividing into the right and the left main bronchus. Its length varies from 10 to 12 cm; C-shaped cartilages, incomplete posteriorly, encircle it anteriorly and provide stability. It contains rapidly adapting irritant receptors in the epithelium that act as cough receptors and mediate reflex bronchoconstriction. The muscles of the posterior tracheal wall contain slowly adapting stretch receptors that regulate the rate and the depth of breathing. The right main bronchus is wider and is more directly in line with the trachea as compared to the narrower and more horizontal left main bronchus that arises at a sharper angle to the left. The cartilage rings of the bronchi are complete. The two main bronchi give off segmental bronchi (10 on the right and 8 or 9 on the left side) which divide repeatedly finally losing cartilage to become bronchioles, the most distal of which are called the terminal bronchioles (**Figure 2**).

Transitional and Respiratory Zone

The respiratory bronchioles, alveolar ducts, alveolar sacs, and the alveoli constitute the respiratory zone. The respiratory bronchioles, usually up to 3 in order, give rise to up to 9 generations of alveolar ducts. The walls of the respiratory bronchioles contain a little smooth muscle that is also present around the opening of the alveolar ducts. The alveoli are the actual gas exchange area and are present as small outpouchings on the respiratory bronchioles and the alveolar ducts and aggregate to form alveolar sacs at the terminal ends of the alveolar ducts (**Figure 3**). The average number of alveoli is approximately 350×10^6. The total surface area is approximately 40 to 80 m^2.

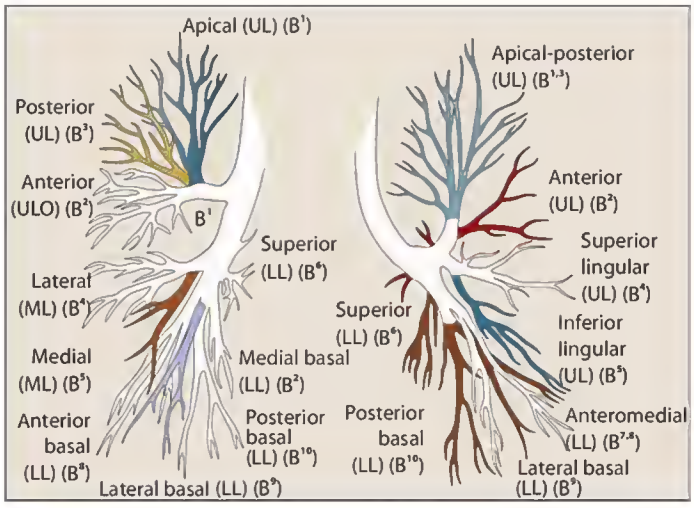

Figure 2: The bronchial tree.

UL = Upper lobe; ML = Middle lobe; LL = Lower lobe.

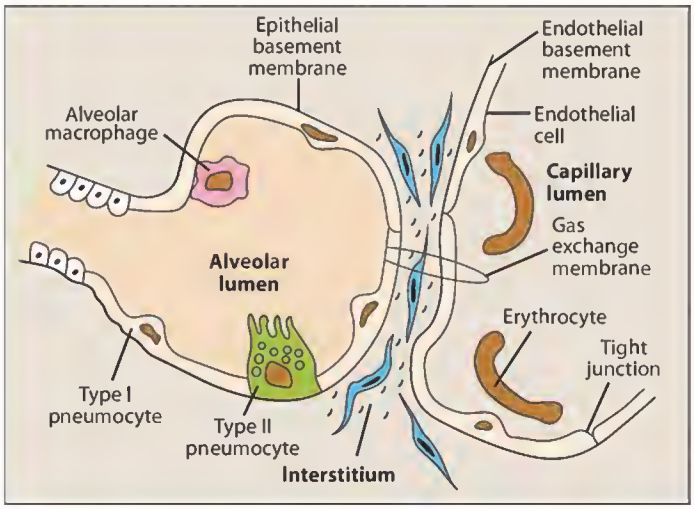

Figure 3: Structure of the alveolus showing the gas exchange membrane and pulmonary interstitium. The alveolar epithelial cells, epithelial basement membrane, pulmonary interstitium, endothelial basement membrane and the endothelial cells constitute the alveolocapillary membrane across which gas exchange occurs.

The part of the lung distal to one terminal bronchiole is called an '*acinus*' and distal to alveolar duct, the '*primary lobule*'. Three to five terminal bronchioles and their acini are bounded by the interlobular septae. This unit is called the '*secondary lobule*'.

Small pores in the alveolar walls, called the *pores of Kohn* provide additional channels of communication between the adjacent alveoli, sometimes even across the segmental boundaries. Additional parallel paths (bronchiolo-alveolar and inter-bronchiolar) or channels may also exist.

Microscopic Anatomy

The trachea is lined by pseudostratified ciliated columnar epithelium rich in goblet cells. The submusoca beneath it contains a few lymphocytes and plasma cells, mast cells (especially in asthmatics), longitudinally arranged elastic fibres and mucosal glands, smooth muscle, nerves and lymphatics. The mucous glands are also present in the larger and medium-sized bronchi. The secretions of these glands contain glycoprotein, lysozyme and lactoferrin.

The mucosa of the main bronchi is similar but becomes thinner and flatter as the airways continue distally. In the respiratory bronchioles, it is cuboidal while in the alveoli, flat and thin cells, the type 1 pneumocytes (90%), provide the surface for gas exchange and have embedded type 2 cuboidal pneumocytes (10%). These latter cells have microvilli and characteristic vacuolar bodies called the lamellar bodies that release the surfactant, a vital lining material that lowers the surface tension of the alveoli at smaller volumes and prevents their collapse. Type 1 cells are more prone to acute lung injury whereas type 2 are more resistant to lung injury and proliferate and differentiate into type1 after lung injury. The mucosa of the large airways contains several types of cells. The *ciliated* cells contain numerous cilia and microvilli on their surface. The cilia move in the direction of the oropharynx providing an escalator for mucous and secretions. The movement of cilia of adjacent cells is co-ordinated to provide an effective wave that moves upwards. The *goblet* cells secrete mucin and are predominantly present in the more proximal airways becoming sparse distally. The *clara* cells with a secretory function and a role in surfactant synthesis are present in larger numbers in the smaller bronchi and the bronchioles. *Serous* cells also perform a secretory function while *basal* cells and *intermediate* cells serve as undifferentiated precursor cells. *Brush* cells are present all over the airways and possibly perform a fluid absorptive function. The *Kulchitsky* or APUD (amine precursor uptake and decarboxylation) cells present in the larger bronchi up to the subsegmental level, may serve a physiological role as chemoreceptors but may also be the precursors for carcinoid and oat cell tumours.

Circulating monocytes migrate into the alveoli traversing the gaps in the capillary endothelial cells to form the alveolar macrophages that provide a phagocytic function as well as an active source of several cytokines and oxidants, and also serve the purpose of antigen-processing.

The alveolocapillary membrane consisting of the alveolar epithelium, its basement membrane, interstitial tissue with a few collagen and elastic fibres and unmyelinated fibres, basement membrane of the capillaries and their endothelium separates the alveolar air from the capillary blood.

Defence, Metabolic and Other Functions

The lungs are equipped with local non-immunological and immunological defence mechanisms that include physical barriers, reflexes including cough and bronchospasm, secretions, and cellular components. The nose and upper respiratory tract filter out large particles in the inhaled air and only particles less than 10 micron manage to reach the lower airways. The mucociliary escalator beats in a coordinated manner to move the trapped particles upwards towards the larynx. The cough and reflex bronchospasm serve to expel inhaled material and limit deeper access.

The bronchial secretions contain substances such as lysozymes, interferon, lactoferrin, etc. having bacteriostatic action as well as the ability to inhibit viral replication. Specific immunological defence mechanisms include lymphocytes, both T and B cells and the macrophages. Lymphocytes are responsible for humoral and antibody-mediated and cell-mediated immunity. Among the immunoglobulins, the predominant are the IgA and IgG. Secretory IgA is of particular importance in respiratory

secretions as it blocks bacterial adherence preventing colonisation and also provides antiviral immunity.

As the lung receives the entire cardiac output, it also serves as a chemical filter for the systemic circulation, protecting against deleterious effects of high levels of several vasoactive substances such as serotonin and norepinephrine. The lung also has a role in the metabolism of bradykinin, endothelin and other peptides.

The lung plays an important role in the maintenance of systemic vascular resistance through the activation of angiotensin II. Other substances that are released from the lung including endothelins and nitric oxide are also involved in the regulation of vascular tone. The lung is a major site for the synthesis and metabolism of eicosanoids.

Blood Supply

The lung receives its blood supply by a dual system, the bronchial arteries supplying oxygenated blood while the pulmonary arteries bring deoxygenated blood for gas exchange. The bronchial arteries are branches of descending aorta but may have other origins. These run along the bronchi and reach as far as the terminal bronchioles. These supply the bronchi, nerves, walls of pulmonary vessels, and intrapulmonary lymph nodes. The veins of the bronchial circulation may drain into the pulmonary veins, left atrium and into the azygous and hemiazygous systems and thence to the right atrium.

The pulmonary artery arises as the outflow of the right ventricle at the pulmonary valve, and divides below the arch of aorta into the right and left branches. These enter the respective hila, although variations are there in the branching pattern, in general these accompany the bronchial tree. The pulmonary trunk and its main branches are elastic arteries and the distal smaller arteries are muscular. The pulmonary circulation is a low-pressure high-capacitance system that accommodates the entire cardiac output. The pulmonary capillaries drain into the pulmonary venous system that finally drains into the left atrium as pairs of pulmonary veins from either lung.

Lymphatics

The lungs are provided with an extensive lymphatic network that maintains fluid balance and provides defence. They drain the fluid from the interstitium. The lymphatic capillaries drain into collecting lymphatics with smooth muscle in their walls and have valves to ensure one-way drainage towards the hilar and the mediastinal lymph nodes. The lymphatics are arranged into a superficial plexus beneath the visceral pleura and a deep plexus in the bronchovascular connective tissue sheath of the airways, the two communicating via lymphatics in the interlobular septa. The branches of the lymphatics accompany the bronchioles and smaller pulmonary arteries and veins. There are no lymphatics in the alveolar walls. The lymph finally flows into the right mediastinal or the thoracic duct. Lymphoid tissue is also present in the lungs along the tracheobronchial tree and also along the vasculature. It participates in antibody and cell-mediated immune responses (**Figure 4**).

Innervation

The afferent pathways originate from sensors in the bronchial epithelium, submucosa, interstitium, and the smooth muscle. Both myelinated and unmyelinated C-fibres are present, the latter being especially prominent in the interstitium where they are thought to be responsible for the J-reflex in response to interstitial oedema. The myelinated fibres serve the stretch and irritant receptors. These fibres travel in the vagus nerve to terminate in the vagal nuclei in the medulla transmitting afferent sensations.

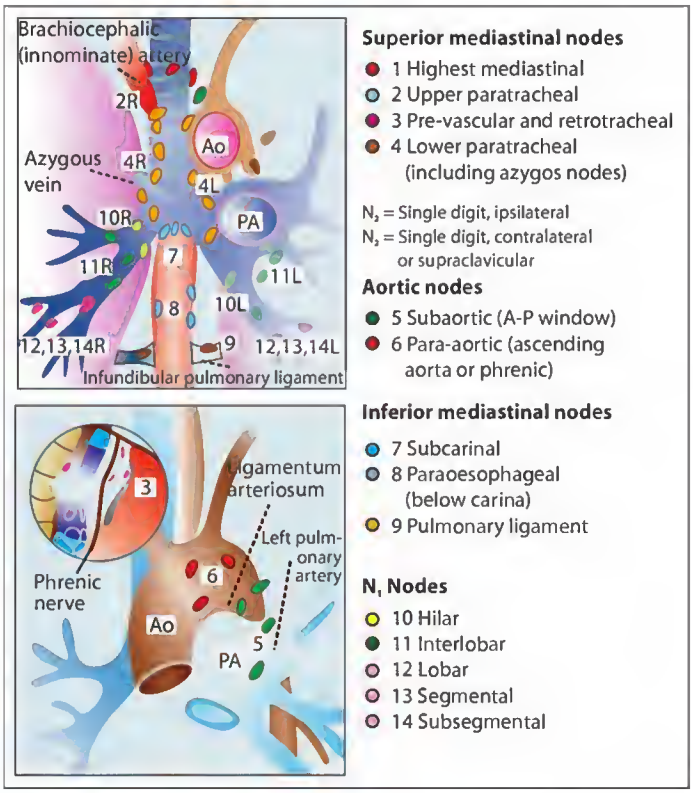

Figure 4: Classification of regional lymph node stations adopted by the American joint committee on cancer (AJCC) and the Union Internationale contre le cancer.

Courtesy: Mountain CF, Dresler CM, Regional lymph node classification for lung cancer staging, Chest 1997; 111: 1718-23.

The efferent pathways reach the lungs through the sympathetic and parasympathetic nervous system. Pre-ganglionic fibres to the sympathetic nerves arise from the upper four or five thoracic paravertebral ganglia while the pre-ganglionic parasympathetic nerves arise from the brainstem motor nuclei associated with the vagus nerve. Post-ganglionic sympathetic fibres terminate near the airway smooth muscle and the glands. The cholinergic activity dominates normally to maintain the bronchomotor tone. Beta-adrenoceptors, mainly the beta-2 subtypes, are present widely throughout the tracheobronchial tree.

ELEMENTARY CONCEPTS IN RESPIRATORY PHYSIOLOGY

Ventilation

The respiratory drive is generated from the medullary centres and transmitted to the diaphragm and the intercostal muscles, the former being responsible for almost 80% of the ventilation. The descent of the diaphragm and expansion of the chest wall create a negative pleural pressure that lowers the alveolar pressure below the atmospheric, thus creating a pressure gradient for air to flow into the lungs. Expiration is a passive process. The upper zones receive more ventilation and the lower zones receive more perfusion.

Airway resistance is the combination of mechanical factors that cause impediment to the flow of air from nose to the alveoli and

back. Due to a tremendous increase in total cross-sectional area, as the bronchial tree divides distally, the resistance is greatest in the larger airways and diminishes distally. Compliance is the property of the lungs to expand in response to an applied change in pressure. Compliance is highest around the resting end-expiratory position and reduces at very high and very low lung volumes. Low compliance indicates a stiff lung.

Gas Exchange

At rest, an adult person utilises 250 mL of oxygen per minute and exhales about 200 mL of carbon dioxide. The diffusion into the blood depends on the pressure gradient across the alveolocapillary membrane and the surface available for gas exchange, as well as the chemical combination rate with haemoglobin, and inversely varies with the length of the passage and the thickness of the membrane. This ability of the lungs to transfer oxygen is called the diffusion capacity (**Figure 5**).

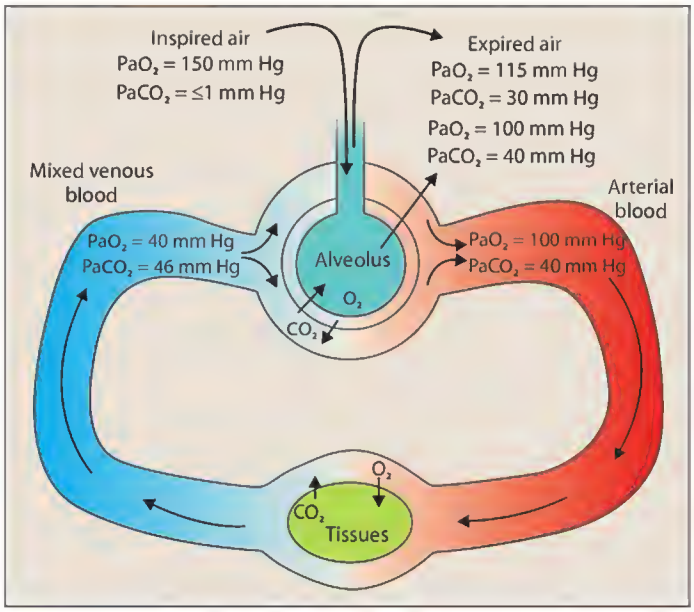

Figure 5: Pulmonary gas exchange.

Gas Transport

Oxygen is transported in blood largely bound to the haem portion of haemoglobin and to a much smaller extent dissolved in the blood, 0.0031 mL per mm PaO_2. The PaO_2 of alveolar air is about 100 mm Hg and that of systemic venous blood is about 40 mm Hg. The extent to which the binding sites on haem are occupied is described as 'saturation' of haemoglobin (SaO_2). When all the sites are occupied, haemoglobin is said to be 100% saturated. The amount of oxygen bound to haemoglobin is determined by the complex relationship between PaO_2 and the degree of saturation and is described by the *oxyhaemoglobin dissociation curve*, which is S-shaped, with the saturation reaching a plateau at the top, indicating that further increase in PaO_2 do not result in an increase in haemoglobin saturation. At a PaO_2 of 60 mm Hg, the haemoglobin is 90% saturated. A PaO_2 of 90% to 100% will result in almost fully saturated haemoglobin. The oxygen dissociation curve shifts to the left with an increase in the pH or a decrease in the $PaCO_2$ or temperature, or 2,3 diphos phoglycerate (2,3-DPG) making it harder to unload (or easier to bind) O_2 for any given PaO_2 while it shifts to the right when the above factors change in the opposite direction making it easier to unload (or harder to bind) O_2 (**Figure 6**).

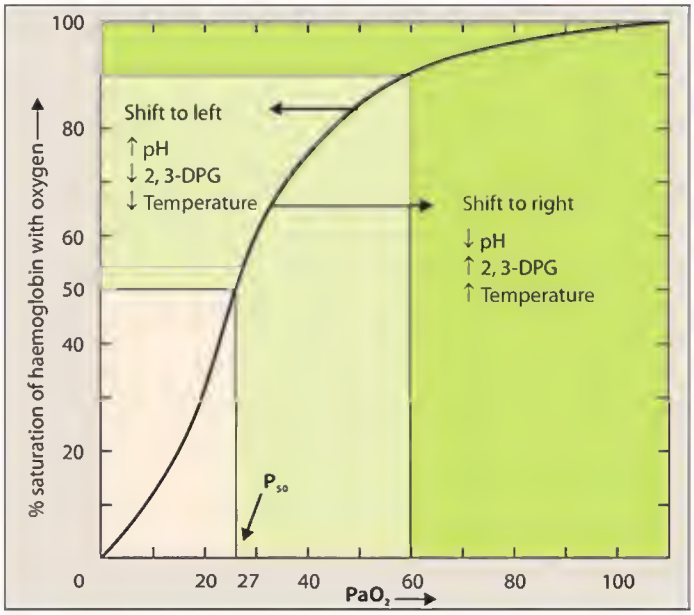

Figure 6: Oxygen-haemoglobin dissociation curve.

The oxygen content of arterial blood (CaO_2) is the sum of the bound and dissolved oxygen. Each gram of haemoglobin can carry 1.34 mL O_2 when fully saturated.

Thus, the CaO_2 = (1.34 × haemoglobin level × SaO_2) + (0.0031 × PaO_2).

The actual delivery of oxygen to tissues is also dependent on the local blood flow that in turn depends on the cardiac output and the local regulation of blood flow in the particular tissue. Disturbances in PaO_2, cardiac output or haemoglobin will thus affect oxygen delivery to the tissues. The PaO_2 falls to approximately 40 mm Hg after O_2 extraction occurs at the tissue-capillary level.

CO_2 is carried in the venous blood in three forms: dissolved (10%), as bicarbonate (60%), and in combination with proteins as carbamino compounds (30%). Combination of CO_2 with water to form carbonic acid (H_2CO_3) in the red cells is catalysed by the enzyme carbonic anhydrase and the latter dissociates into H^+ and HCO_3^-. While HCO_3^- diffuses out, H^+ cannot, as the cell membrane is relatively impermeable to cations. Thus, to maintain electrical neutrality, Cl^- ions move into the cell from the plasma (chloride shift). The deoxygenated haemoglobin has a greater affinity for CO_2 than oxygenated haemoglobin (the Haldane effect). Thus, in the tissues, loading of CO_2 is facilitated.

23.2 Pulmonary Disorders—A Clinical Approach

Jyotsna M Joshi

Clinical approach to a patient with pulmonary disease consists of history taking and clinical examination. A systematic clinical approach is necessary for making an initial clinical diagnosis. A casual approach, on the other hand, results in wasteful investigations or initiation of hasty empirical treatment.

HISTORY

A thorough history can provide 80% of the diagnosis while a poor history results in misdiagnosis or a missed diagnosis. For example, without a history of asbestos exposure, asbestosis may be misdiagnosed as idiopathic pulmonary fibrosis (IPF). Similarly, a case of cough-variant asthma is likely to be subjected to several investigations if history of atopy is not elucidated. Previous treatment history in cases of tuberculosis (TB) is important to request drug susceptibility tests for possible drug resistance. A case with pulmonary symptoms should be questioned about the cardinal symptoms of pulmonary disease (cough, sputum, haemoptysis, breathlessness, wheeze, chest pain) and fever.

Cough

Cough may be characterised as acute (lasting less than 3 weeks), subacute (lasting 3 to 8 weeks), or chronic (persisting beyond 8 weeks).

- Acute cough may develop because of acute respiratory infection (ARI), upper or lower respiratory tract infection (URTI or LRTI) and pneumonia, exacerbation of asthma or chronic obstructive pulmonary disease (COPD) and pneumothorax.
- Sub acute cough most often results from allergic or bacterial rhinosinusitis.
- Chronic cough can have many causes, but airway diseases (asthma, COPD) and interstitial lung diseases (ILDs) account for most cases.

Cough is the only manifestation of asthma (cough variant asthma) in up to 50% of the patients with the disease. Drug [e.g. like angiotensin converting enzyme (ACE) inhibitor]. Induced Post-nasal drip, and gastro-oesophageal reflux disorder (GERD) are other important causes of unexplained cough. ACE inhibitors cause a non-productive cough, which may begin within hours to months after the initiation of therapy and resolution may occur within 1 to 12 weeks after the cessation of therapy. Post-nasal drip syndrome is the most common cause of chronic cough in non-smoking, immunocompetent adults who have a normal chest radiograph. Chronic cough in patients with GERD is likely to be a vagally-mediated reflux mechanism. Heartburn and regurgitation suggest a GERD-induced chronic cough, but these features may be absent in 'silent' GERD.

Sputum

Cough may be associated with sputum (mucoid or purulent). Acute onset cough associated with purulent sputum is seen in ARI like URTI, LRTI, or pneumonia. However, rusty sputum is characteristic of pneumococcal pneumonia. Chronic cough with mucoid sputum (>25 mL/day) is a symptom of COPD while copious mucoid sputum (>100 mL/day) or bronchorrhoea is characteristic of bronchoalveolar carcinoma and rarely asthma. Copious purulent sputum is often foul smelling or blood-tinged with cough is seen in bronchiectasis, lung abscess or broncho-pleural fistula. Cough with anchovy sauce sputum, a feature of pleuro-pulmonary amoebiasis while clear salty or peppery tasting expectoration is characteristic of pulmonary hydatid disease.

Haemoptysis

Haemoptysis is defined as the coughing up of blood derived from the lungs or bronchial tubes. Most cases are minor and treatable or self-limited. Haemoptysis has several causes. However, in up to 30% of the patients, no cause of haemoptysis can be found. Various definitions of the severity of haemoptysis have been proposed. Haemoptysis is conventionally classified as minimal (blood-streaked sputum), moderate less than 200 mL per day and severe if blood loss is greater than 200 mL per day. It is important to recognise massive haemoptysis quickly, because without urgent treatment, up to 80% of the patients may die. The detailed causes and management of haemoptysis is given in chapter 6, section 2.

Dyspnoea and Wheeze

Breathlessness or dyspnoea is the subjective feeling of uncomfortable or difficult breathing. Dyspnoea is most commonly caused by respiratory and cardiac disorders. Causes, such as asthma, congestive heart failure (CHF), COPD, pneumonia, cardiac ischaemia, ILDs, and psychogenic account for 85% of the patients with dyspnoea. Other causes may be upper airway obstruction, a neuromuscular condition or metabolic acidosis. Dyspnoea may be acute or chronic, and with or without associated wheeze. When dyspnoea lasts for more than a month, it is considered as chronic dyspnoea. Dyspnoea associated with wheeze indicates presence of diseases that cause airway obstruction, such as asthma, COPD and bronchiectasis. Dyspnoea may be progressive or non-progressive. The rate of progression can be ascertained by grading dyspnoea at onset and at the time of examination. Various grading systems are used for evaluating dyspnoea but the Modified Medical Research Council (MMRC) grading system is the most commonly used (**Table 1**). Alternatively, effort tolerance (ET) as stated by the patient (e.g. 'one flight of stairs' or 'few feet on flat ground') may be used instead of dyspnoea grade. Paroxysmal nocturnal dyspnoea (PND), orthopnoea (more breathless on lying down), and platypnoea (more breathless on sitting or standing) must also be asked for. PND is associated with CHF, orthopnoea may occur in CHF and all pulmonary disorders except emphysema and hepatopulmonary syndromes, which are associated with platypnoea.

Table 1: Dyspnoea Severity Modified Medical Research Council MMRC Scale

Grade	Level of Activity
0	Not troubled by breathlessness except on strenuous exercise
1	Short of breath when hurrying or walking up a slight hill
2	Walks slower than contemporaries on the level because of breathlessness, or has to stop for breath when walking at own pace
3	Stops for breath after about 100 m or after a few minutes on the level
4	Too breathless to leave the house, or breathless when dressing or undressing

Chest Pain

Chest pain can be a symptom of pulmonary, cardiac, gastro-oesophageal, and musculoskeletal problems. However, chest pain that is localised, sharp stabbing in nature, and worsens on breathing is indicative of pleuritic pain. Pleuritic pain may occur due to pleuritis associated with pleural effusion, pneumothorax, pneumonia, pulmonary embolism and lung cancer. Persistent pleural pain in a case of pleural effusion/thickening indicates malignancy.

Additional History

History of pedal oedema and facial puffiness helps in establishing episodes of right heart failure in chronic pulmonary cases. Rarely, these symptoms may be due to nephrotic syndrome, due to renal amyloidosis in chronic suppurative pulmonary disorders, or anaemia/hypoproteinaemia associated with malnutrition. Additionally, patient must be questioned about history of rhinitis/sinusitis in airway diseases like asthma and bronchiectasis, history of dysphagia/hoarseness of voice in suspected lung malignancy, history of joint pains, skin rashes and Raynaud's phenomenon in connective tissue disorders, etc.

Past history of major medical or surgical illness must be elucidated including previous drug history, particularly ACE inhibitor, beta-blockers, methotrexate, amiodarone, aspirin, and other non-steroidal anti-inflammatory drugs (NSAIDs). Family history of asthma, cystic fibrosis, TB, and cancer must be asked for. Personal history includes occupation, diet, bowel and bladder habits and addictions, particularly tobacco smoking. Smoking history must be quantified; also given in chapter 6, Section 23.

With increased awareness of sleep-related disorders, patients must be specifically questioned about sleep quality, snoring (loud habitual, crescendo decrescendo), nocturnal choking or gasping and excessive day time sleepiness (EDS); all of which indicate obstructive sleep apnoea syndrome (OSAS).

GENERAL EXAMINATION

General examination is important and contributes to diagnostic decision-making in several ways. A crude measure of body fat is the body mass index (BMI), a person's weight (in kilograms) divided by the square of his or her height (in metres). World Health Organization (WHO) defines, underweight as a BMI <20 kg/m^2, normal 20 to 25 kg/m^2, overweight ≥25 kg/m^2, and obesity as a BMI of >30 kg/m^2 and extreme obesity if BMI >40 kg/m^2. Over weight or obesity is common in patients with OSAS. Low BMI in COPD indicates the presence of 'pulmonary cachexia' or 'pulmonary sarcopaenia', a systemic manifestation of COPD.

Pulse, respiratory rate, temperature, and blood pressure have been traditionally considered as the vital signs. Pulse oximetry is now viewed as 'the fifth vital sign'. It is useful to record the baseline saturation of a patient as it may warn the clinician of significant desaturation during an acute illness later. Baseline or exercise desaturation can also aid in diagnosis and oxygen therapy in chronic respiratory disease, like ILD and COPD. Exercise test for this purpose is performed under supervision while the patients are encouraged to walk at their own pace on a flat surface for 6 minutes, alternatively till the target heart rate (200-age) is reached or until limited by shortness of breath or fatigue. Clinically significant desaturation is considered to be any saturation decrease of 4% or more or to a *nadir* of 88%.

General examination findings, like clubbing and pallor, point towards chronic inflammatory diseases and malignancies. Elevated jugular venous pressure (JVP) and pedal oedema in chronic pulmonary cases help to diagnose cor pulmonale with right heart failure. Clubbing is an important clinical finding in a pulmonary case (**Figure 1**). Clubbing is described in 4 grades (**Table 2**). The common causes for finger clubbing are shown in **Table 3**. Presence of enlarged cervical lymph nodes is an important finding, particularly in cases of lung cancer and mediastinal masses. These provide accessible site for fine needle aspiration cytology or biopsy (FNAC/B). Cervical and axillary lymph nodes must be meticulously examined before embarking on expensive and invasive procedures, like computed tomography (CT) and bronchoscopy. The finding of crepitus in the neck is a pointer to the presence of pneumo-mediastinum, engorged neck veins to superior vena cava (SVC) obstruction, and an enlarged thyroid gland explain symptoms of upper airway obstruction. Associated hypothyroidism may explain OSAS and hyperthyroidism may be responsible for worsening asthma control.

Table 2: Grades of Clubbing

Grade	Description
Grade 1	Nail may seem to be loose within the soft tissue (increased bogginess) when palpating the fingernail
Grade 2	Nail extends from the bed (the profile angle) at 180 degrees or greater (normal 160 degrees) demonstrated by 'window sign' or Schamroth sign
Grade 3	Increased curvature of nails with grade 1 or 2 changes, appear like 'parrot beak' or 'drum stick'
Grade 4	Osteoarthropathy (pain and swelling of ankle/wrist joints, elbow/knee joints and hip/shoulder joints with finger clubbing). Osteoarthropathy may be confirmed by showing periosteal new bone formation of long bones.

Table 3: Causes of Finger Clubbing

Respiratory
- Chronic suppurative pulmonary disease—bronchiectasis, lung abscess, empyema
- Malignant lung cancer, malignant mesothelioma
- Idiopathic interstitial pneumonia (IIP) (especially, idiopathic pulmonary fibrosis)
- Pleural fibroma

Cardiac
- Cyanotic heart disease
- Subacute infective endocarditis
- Atrial myxoma

Gastrointestinal
- Inflammatory bowel disease
- Hepatic cirrhosis

Neurological
- Hemiplegic stroke

Metabolic Disease
- Thyroid acropachy

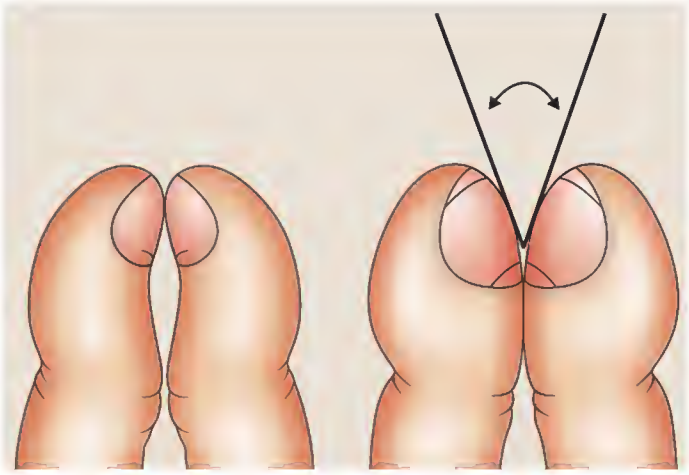
Other
- Familial
- Idiopathic

RESPIRATORY SYSTEM EXAMINATION

Respiratory system examination includes: (a) respiration rate, rhythm and accessory muscles use; (b) upper respiratory tract-nasal discharge, sinus tenderness and examination of the oral cavity; and (c) examination of the chest. Suitable chest examination requires the patient's chest, neck and abdomen to be appropriately exposed. Chest examination is best performed in the sitting or standing position. In patients who have difficulty in sitting, support can be given by someone standing in front and holding his/her hands. In those who are too sick to stand or sit, rolling on one side and then the other for examination of the back helps. Chest examination is performed under the headings of inspection, palpation, percussion, and auscultation (IPPA). The clinical findings are described in terms of areas over the chest (anteriorly—supraclavicular, clavicular, mammary and inframammary, axilla-axillary and infra-axillary, and posteriorly—suprascapular, interscapular, scapular and infrascapular). The corresponding areas of various lung lobes are shown in surface marking in **Figures 2A and B** and help in localising the diseased lobe.

Inspection and Palpation

Inspection and palpation of the chest are performed to assess where disease is bilateral—indicated by equal chest movements (asthma, COPD, ILD) or unilateral—indicated by reduced chest movements and if unilateral; whether associated with increase in hemithoracic volume (bulging of the chest, elevated shoulder, increased spino-scapular distance and shift of the trachea and cardiac impulse/apex beat to opposite side) found in pleural effusion, pneumothorax, hydropneumothorax; reduction in hemithoracic volume (flattening of the chest, depressed shoulder, reduced spino-scapular distance and shift of trachea and cardiac impulse/apex beat to same side) found in collapse, cavity, pleural thickening and no change in volume (no bulging or flattening, both shoulders at same level, equal spino-scapular distance, central trachea, and cardiac impulse/apex beat in the 5th intercostal space in the mid clavicular line) noted in consolidation.



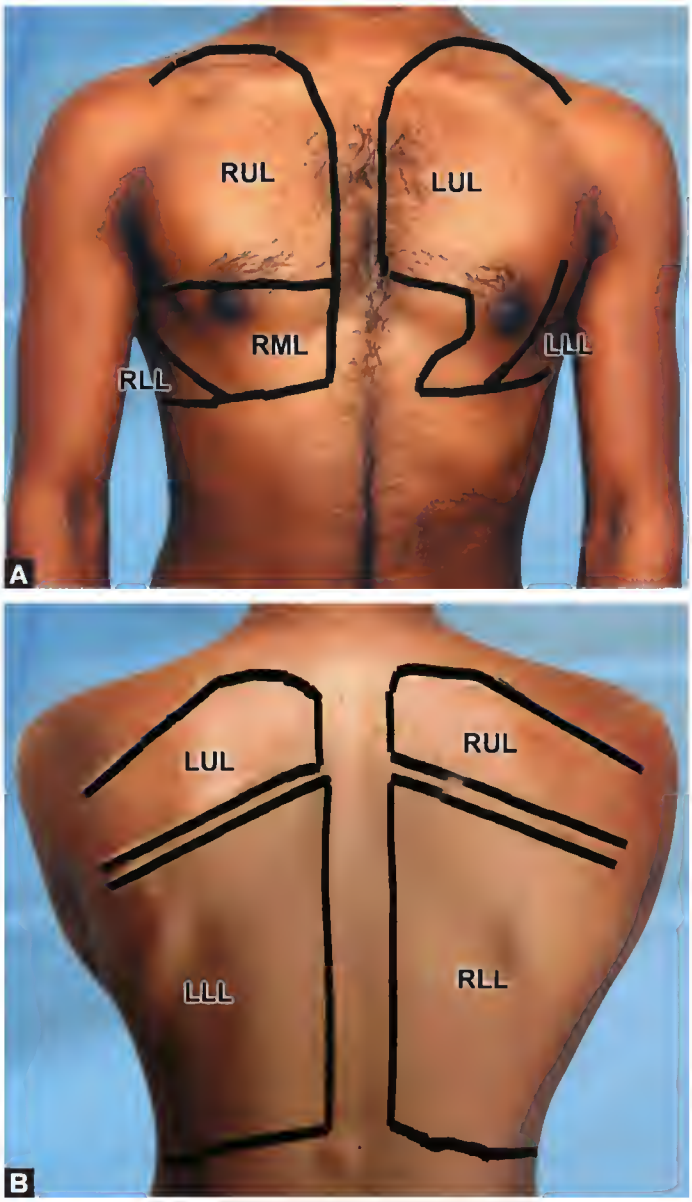


Figure 1: Shamvoth schematic diagram showing a normal finger showing a 'diamond-shaped window' when the dorsal surfaces of the terminal phalanges on opposing fingers are placed together, while the clubbed finger will show no space visible between the opposing nails.

Figures 2A and B: Surface marking of lung lobes over the anterior and posterior chest.

RUL = Right upper lobe; LUL = Left upper lobe; RML = Right middle lobe; RLL = Right lower lobe; LLL = Left lower lobe.

Percussion and Auscultation

Percussion adds to the findings of inspection and palpation. The technique of digital percussion was described by Barth and Roger (1865). The percussion notes vary from tympanic (over the stomach gas bubble—'Traube's space') to dull (over the heart and liver). In pathological cases, hyper-resonant notes are heard in cases of pneumothorax and emphysema, whereas dull notes are produced over consolidation, collapse or pleural effusion. Auscultation via a stethoscope is an integral part of chest examination. Auscultation terms simplified by Forgacs (1978) are established by the International Lung Sounds Association (ILSA). The sounds heard at auscultation are breath sounds (normal or bronchial) and voice sounds (increase vocal resonance/bronchophony or aegophony) and adventitious sounds; continuous sounds (wheezing and rhonchi) and intermittent sounds (coarse and fine crackles). Other adventitious sounds are those that originate in the upper airways (stridor) or in the pleura (friction rub) and interstitium (squawk—inspiratory squeaking sound). The normal breath sounds are the result of turbulent airflow through the larger airways. At the chest wall, the higher frequencies are attenuated by the lung parenchyma resulting in vesicular breath sounds. In the presence of consolidation or collapse with a patent bronchus, these higher frequencies are transmitted, leading to 'bronchial breathing'. Bronchial breathing is usually high pitched (tubular) and heard over consolidation; collapse with a patent bronchus and just above the level of pleural effusion due to collapse (relaxation or passive collapse) of lung. Bronchial breathing may be low pitched (cavernous), heard over an irregular walled cavity or high pitched with metallic intonation (amphoric) heard over smooth walled cavity or broncho pleural fistula. The same mechanism that produces bronchial-breathing allows spoken sounds to be transmitted well as increased vocal resonance (VR)/bronchophony (loud and clear)/aegophony (with a nasal twang) and also whispered sounds 'positive whispering pectoriloquy (WP)'. The breath sounds (and spoken sounds-VR) are reduced or absent when the lung and chest wall is separated by fluid or air, as in pleural effusion or pneumothorax and due to inability of breath sounds to reach the lungs in collapse with obstructed bronchus. **Figure 3** briefly depicts the flow chart of respiratory examination.

MAKING A CLINICAL DIAGNOSIS

The findings of history and clinical examination are analysed to make a clinical diagnosis (**Figure 3**). A summary of findings in various pulmonary disorders is shown in **Table 4**.

A clinical diagnosis must consist of:

1. Pathological diagnosis (What is the lesion?)
2. Anatomical diagnosis (Where is the lesion?)
3. Guess to aetiology (What is the likely cause?)
4. Additional diagnosis (e.g. cor pulmonale, anaemia, jaundice, goitre, etc.)

For example

Left lower lobe collapse due to lung cancer with anaemia, where:

Pathological diagnosis (What is the lesion?): *collapse*

Anatomical diagnosis (Where is the lesion?): *left lower lobe*

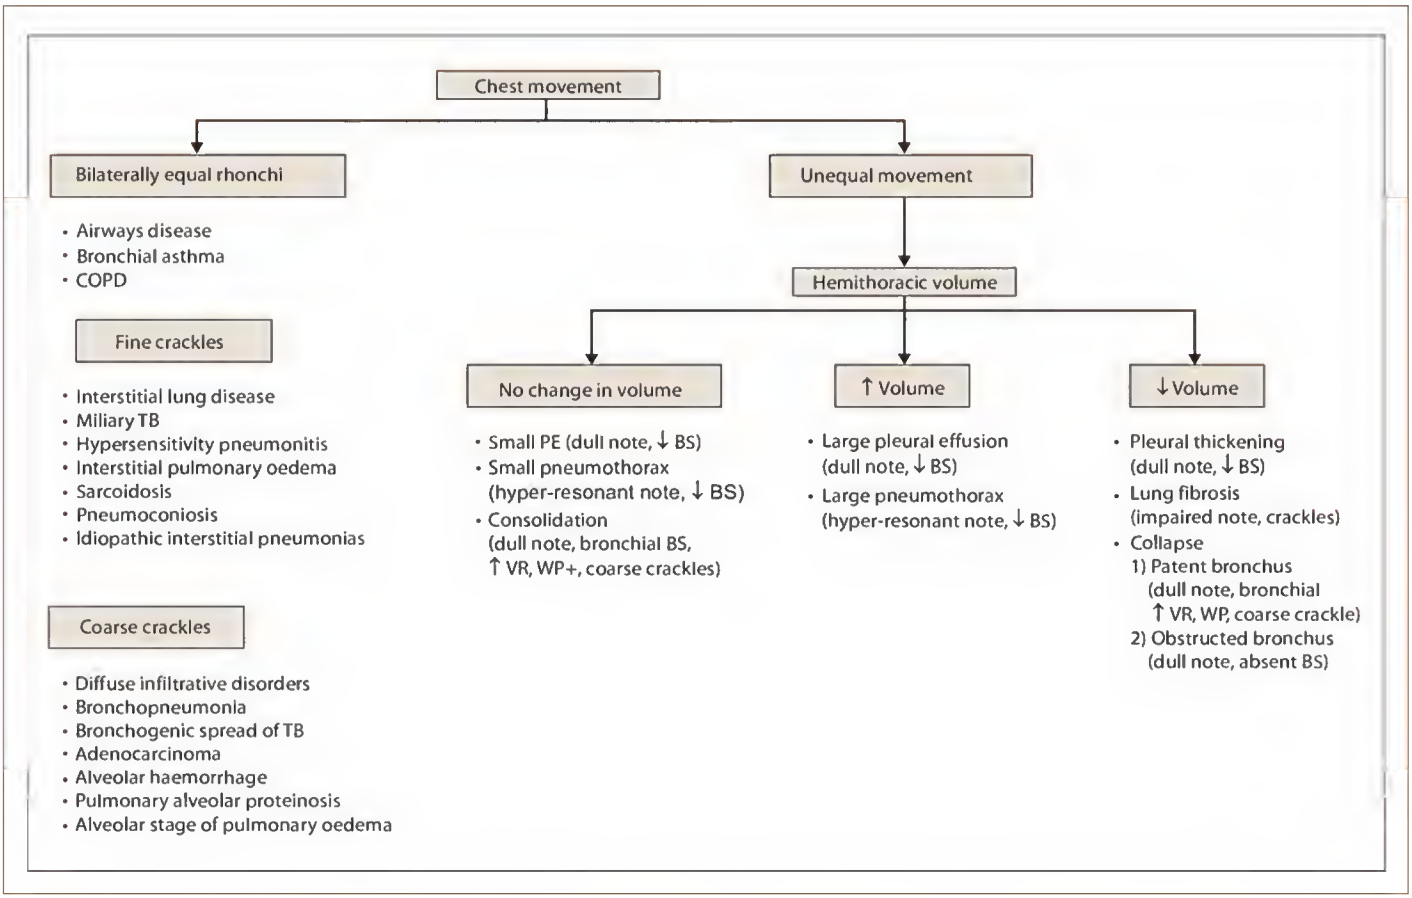

Figure 3: Flow chart of respiratory examination.

COPD = Chronic obstructive pulmonary disease; TB = Tuberculosis; PE = Pulmonary embolism; BS = Breath sounds; VR = Vocal resonance; WP = Whispering pectoriloquy.

Table 4: Clinical Findings in Various Pulmonary Disorders

Disorders	Symptoms	General Examination	Respiratory Examination
Diffuse lung disorders			
Asthma	Dyspnoea, cough, wheeze		Rhonchi
COPD	Cough, mucoid sputum, dyspnoea, wheeze		Emphysematous chest, rhonchi, crackles
Bronchiectasis	Cough, copious mucopurulent sputum, dyspnoea, haemoptysis	Clubbing	Coarse crackles, rhonchi
ILD	Dry cough, dyspnoea, no wheeze	Clubbing	Fine end inspiratory crackles, squawks
Localised lung disorders			
Consolidation	High fever, cough, purulent sputum, chest pain		NCV, dull note, bronchial BS, ↑ VR, WP+, coarse crackles
Collapse (patent bronchus) (also fibrotic/cicatricial collapse)	Cough, sputum, haemoptysis, dyspnoea		↓ Volume, dull note, BS bronchial, ↑ VR, WP+, coarse crackles
Collapse (obstructed bronchus)	Cough, sputum, haemoptysis, dyspnoea		↓ Volume, dull note, BS absent, ↓ VR
Fibrosis	Dry cough		↓ Volume, impaired note ↓ BS, crackles
Pleural effusion	Dry cough, pleuritic chest pain		Dull note, ↓ BS, ↓ VR, shifting dullness +, (initially NCV, subsequently ↑ volume)
Pneumothorax	Dyspnoea, dry cough, pleuritic chest pain		↑ Volume, hyper-resonant note, absent BS, ↓ VR
Hydropneumothorax	Cough (dry or with sputum), dyspnoea, pleuritic chest pain		Hyper-resonant note followed by dull note, shifting dullness, ↓ BS, ↓ VR, succussion splash
Hydropneumothorax with bronchopleural fistula	Cough with copious purulent sputum, posture dependent, dyspnoea, chest pain	Clubbing	Hyper-resonant/dull note shifting dullness, BS-amphoric, ↓ VR, WP+, succussion splash
Pleural thickening (fibrothorax)	Dry cough, dyspnoea		↓ Volume, dull note, ↓ BS, ↓ VR

COPD = Chronic obstructive pulmonary disease; ILD = Interstitial lung disease; NCV = No change in volume; BS = Breath sounds; VR = Vocal resonance; WP = Whispering pectoriloquy.

Guess to aetiology (What is the likely cause?): *lung cancer*

Additional diagnosis: *anaemia*

Based on the clinical diagnosis, further imaging and laboratory tests are performed to make a final diagnosis.

23.3 Pulmonary Disorders—Diagnostic Procedures

Gautam Ahluwalia, Surendra K Sharma

INTRODUCTION

In patients with pulmonary disorders, investigations play a very important role in narrowing down the diagnostic possibilities. Broadly, the procedures can be divided into invasive and non-invasive methods (**Table 1**). Though there may be an overlapping between non-invasive and invasive procedures, this classification, to a large extent, helps in improving the understanding about various diagnostic procedures used in pulmonary disorders. In fact, the gold standard for any diagnosis is histopathology, cytology or microbiologic confirmation of the disease. In the last two decades, the use of various diagnostic modalities for obtaining tissue specimens for confirmation of diagnosis in various respiratory disorders has been a very major development in pulmonary medicine.

Table 1: Diagnostic Procedures in Pulmonary Disorders

Non-invasive

- Imaging studies like chest radiograph, ultrasonography (USG) and computed tomography (CT) to assess the anatomy
- Pulmonary function tests to assess physiology and gas exchange
- Microbiological isolation
- Serum markers
- Arterial blood gas (ABG) analysis
- Overnight polysomnography

Invasive

- Fibreoptic bronchoscopy, endobronchial USG
- Thoracoscopy, video-assisted thoracoscopy (VATS)
- Mediastinoscopy
- Definitive tests to confirm the diagnosis by obtaining tissue during bronchoscopy/thoracoscopy/USG and CT-guided procedures

The following sections represent an overview of the various investigative procedures in pulmonary disorders.

NON-INVASIVE DIAGNOSTIC PROCEDURES

Chest Radiography

Chest radiography is the sheet anchor for diagnosis in pulmonary disorders as it is easily available as well as economical. In fact, some clinicians may like to call it an extension of the stethoscope. However, it is important to appreciate that a good clinical examination cannot have any replacement and radiology is complementary and not a substitute for clinical examination.

In the last few years, digital radiography has revolutionised the quality of radiography as compared to the conventional film-based radiography. Normally, a chest radiograph with a postero-anterior (PA) projection is the standard protocol, where the film cassette is placed against the anterior chest wall. However, the patient should be able to sit or stand for the PA view. In critically ill patients or those who are not able to sit up, an antero-posterior (AP) view is performed where the film cassette is placed behind the back. While interpreting the AP view, there is a word of caution; the heart size may be falsely enlarged as the distance between the heart and the cassette increases. Therefore, cardiomegaly on an AP view need not be 'true' cardiomegaly.

The clinicians should analyse the chest radiograph in a systematic order to avoid missing an abnormality and gain maximum information from a standard PA radiograph. One should start with the quality of chest radiograph and positioning of patient, then comment on soft tissues, bony cage, followed by tracheobronchial tree, hilum, mediastinum, lung parenchyma, and costophrenic angles. This should be followed by a comment on cardiac size. The quality of the radiograph is very important. A technically sound radiograph should demonstrate the entire dorsal spine with mid point of right diaphragm at the level of the anterior end of the 6th rib, implying that it is a deep inspiration film, which is very important. A correct positioning of the patient is indicated when medial end of both clavicles is equidistant from the vertebral spinous processes.

It is essential to appreciate that history of the patient, for which the chest radiograph has been performed, is very important. One should always ask for an old chest radiograph for comparison. This also results in avoiding many expensive investigations for a 'lesion' which has been present for many years like the presence of fibrotic strands in the apex in a patient with previous history of tuberculosis (TB).

A few of the common abnormalities on the chest radiograph are pulmonary nodules/masses, cavitary lesions, pneumonia/consolidation, and pleural effusion.

Pulmonary nodules/masses

These could be solitary or multiple. In a solitary lesion, the doubling time is very important. Most malignant lesions have a doubling time between 4 weeks and 24 weeks. In other words, a lesion which has doubled in less than 2 weeks or after 24 weeks is unlikely to be of malignant aetiology. The increase in diameter of more than 25% on the chest radiograph signifies a pathological doubling of the lesion. The other soft pointers toward a benign solitary nodule are significant calcification and smooth margins. However, it is important to note that these soft markers can be deceptive. A nodule in a patient with history of smoking should always necessitate further evaluation. A comparison with old radiographs (if available) is very helpful.

Multiple pulmonary nodules are mainly due to malignant deposits of varied aetiology. Another important term is miliary mottling. These are small nodules of less than 5 mm in diameter. The commonest cause in India is miliary TB. However, the differential diagnosis of miliary mottling includes metastasis, fungal infections, pneumoconiosis, and sarcoidosis.

Cavitary lesions

The two important differential diagnosis are bronchial carcinoma and lung abscess. The common aetiologies of infections in a lung abscess are *Mycobacterium tuberculosis*, *Klebsiella*, *Staphylococcus*, and anaerobes. The presence of air-fluid level suggests the diagnosis of a cavitary lesion (**Figure 1**).

Figure 1: Chest radiograph (PA view) showing a cavitary lesion with an air-fluid level in the right lung.

Pneumonia/consolidation

The important radiological sign of a pulmonary consolidation is air bronchogram, which is a radiolucent bronchi (black) in the background of an opaque lung (white). The other important sign is the opacification of the lung with undulating margins obscuring the underlying blood vessels. A lobar consolidation follows the contours of the lobe and has a sharp margin in the corresponding fissure.

Infections are the commonest cause of consolidation. However, the unusual differential diagnosis including fluid overload, bronchioloalveolar carcinoma, collagen vascular diseases, and pulmonary haemorrhage should also be considered in the appropriate clinical setting.

Pleural effusion

The earliest sign of pleural effusion on the chest radiograph (PA view) is blunting of the lateral costophrenic angle. A minimal amount of fluid (approximately 200 mL) is required to produce appreciable blunting. A large free pleural effusion appears as a dependent opacity with lateral upward sloping of a meniscus-shaped contour. A massive pleural effusion appears as an opaque hemithorax with mediastinal shift to the opposite side. The lateral decubitus view was very important in diagnosing minimal pleural effusion (less than 100 mL), which is not picked up on a routine PA view. With technologies like ultrasonography (USG) and computed tomography (CT) becoming more freely available, this view is used infrequently. However, it is very important to know the importance of this projection, especially in resource-limited setting areas like India where the newer technology is still lacking in the underdeveloped regions of our country.

Intensive care unit (ICU) imaging

With the evolution of advanced critical care in our country, the role of the chest radiograph in this setting needs special mention. In a resource-limited setting like India, chest radiograph is an economical modality to evaluate patients in the ICU. In fact, chest radiograph has become an important diagnostic armamentarium in the ICU setting. It is used to evaluate the position of the monitoring and support equipment like central venous catheter, endotracheal tube, tracheostomy tube, chest tube, pulmonary artery catheter, enteric tube, and intra-aortic balloon pump. The chest radiograph is also an important tool to diagnose pneumothorax, pneumonia, pulmonary oedema, atelectasis, and pleural effusion, which are frequently encountered complications in the management of patients on ventilators and other life-saving devices.

Ultrasonography and Computed Tomography

These techniques have improved the diagnostic armamentarium in respiratory diseases tremendously.

Ultrasonography is a good investigative modality for the peripherally placed lesions in the lung. USG guided procedures help to secure biopsy specimens for tissue diagnosis. The major indication of USG is to detect minimal pleural effusion which is not picked up on PA view and to differentiate between pleural thickening *vis-à-vis* an effusion. The presence of septation in the fluid is a pointer that the effusion is exudative, though final confirmation is obtained on examination of the fluid. A large collection of fluid or pus in the pleural cavity can be drained with USG guidance. Similarly, USG is most useful to drain multiple localised collections of fluid in the pleural cavity.

Computed tomography is another very important investigation which is far superior to the conventional chest radiograph, though the basic principles of physics are the same as in chest radiography. One needs to have a clear understanding of the various terminologies used like spiral CT, high resolution CT (HRCT), lung window, and mediastinal window. The mediastinal window helps in assessing the lesions in the major tracheobronchial tree and in the mediastinum like lymph nodes and great vessels. The mediastinal window also helps in commenting on density difference like calcification as well as caseation in intrathoracic lymph nodes (**Figure 2**). The lung window helps in assessing the parenchymal abnormalities in the lung (**Figure 3**).

The problem with the conventional CT is that the patient needs to hold his breath for a clear image on the CT, otherwise there

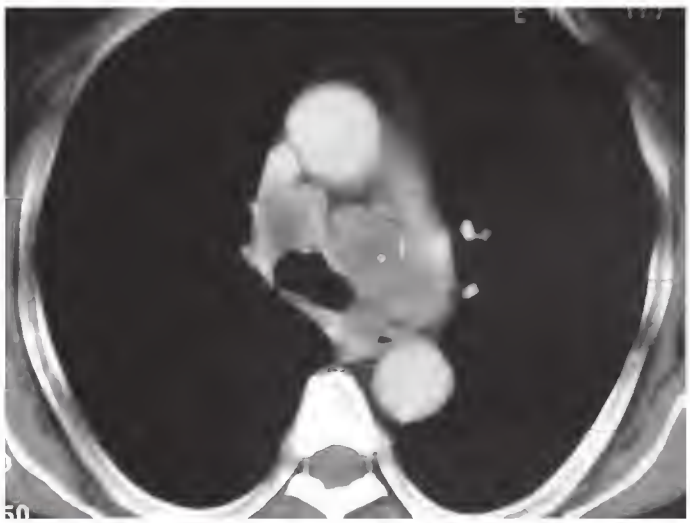

Figure 2: Mediastinal window showing intrathoracic lymph nodes with necrosis.

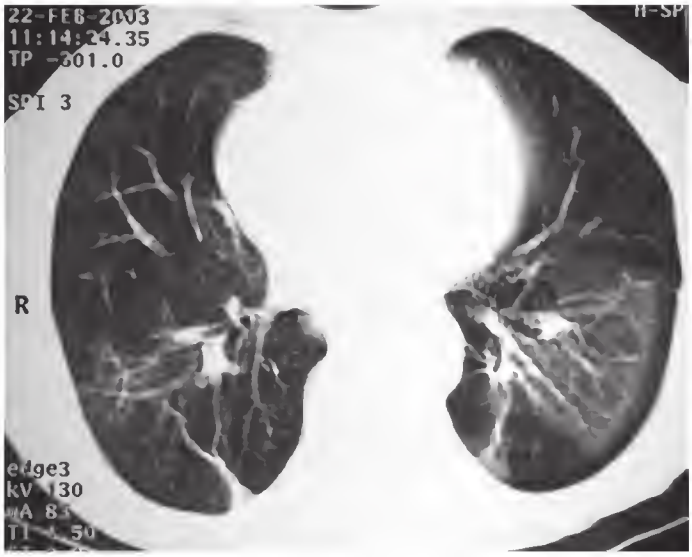

Figure 3: Lung window showing bilateral ground glass opacification.

is blurring of image due to respiratory movement. Moreover, due to respiratory movement, small lesions may be missed. This problem has now been overcome by spiral CT. Spiral CT is a technological evolution where the entire thorax is imaged by holding the breath once only for a few seconds. In fact, even in a dyspnoeic patient, fairly clear images can be obtained, which is not possible on conventional CT machines. As the image acquisition is faster, the amount of contrast required is also less.

A technical advancement over single slice spiral CT is multi-detector row CT (MDCT) or earlier known as multi-slice spiral CT. In MDCT, multiple slices are acquired at the same time. Consequently, the speed of scanning as well as resolution is enhanced significantly. In fact, MDCT allows coronal, sagittal, and oblique imaging at higher spatial resolution as compared to conventional CT. Dynamic MDCT with intravenous contrast or CT pulmonary angiography (CTPA) is becoming the investigation of choice for pulmonary emboli phasing out ventilation-perfusion (V/Q) radionuclide scans. Moreover, three-dimensional anatomy of the tracheobronchial tree can also be constructed using MDCT unlike conventional CT. In fact, the tracheobronchial tree is visualised as clearly as bronchoscopy. This is called virtual bronchoscopy. Research tools are also being developed to employ xenon gas to enhance regional ventilation of lungs using MDCT (Xenon enhanced MDCT or XE-MDCT).

The modality of HRCT (thin transverse slice of 1 to 2 mm *vis-à-vis* the normal slice thickness of 10 mm) is extremely helpful in diagnosis of diffuse lung parenchymal disease. These scans can be performed on both conventional and MDCT. Therefore, it is important to appreciate that HRCT and MDCT are not synonymous.

To summarise, the broad diagnostic indications for CT include further evaluation of lung, mediastinal, and hilar abnormalities in the presence of non-diagnostic radiographs. It is also important in evaluation of mediastinal lymphadenopathy, diffuse lung disease, lung tumours, haemoptysis with non-localising chest radiograph, and pulmonary embolism.

The only limitation is its cost in a resource-limited setting like India. The hazards of radiation exposure to the patient should also be kept in mind, especially in a pregnant woman.

Magnetic Resonance Imaging

The primary advantage of MRI over CT is the lack of ionising radiation. It is also important to realise that as far as respiratory imaging is concerned, MRI offers no diagnostic advantage over CT. In fact, MRI is an inferior modality to assess lung parenchyma as compared to CT. However, the evolution of newer MRI scanners with dynamic gadolinium-enhanced imaging and ultrafast proton will result in increased utility of MRI in evaluation of lung diseases, especially in perfusion abnormalities like pulmonary embolism in pregnant females. The use of hyperpolarised gas imaging with helium and xenon are also being evaluated in malignant lung pathology. The assessment of diaphragm abnormalities, chest wall motion assessment, and breathing mechanics is potentially feasible for clinical usage in future with the advent of advanced ultrafast proton imaging MRI scanners.

Pulmonary Function Tests

Pulmonary function tests are important to assess the physiological function of the lungs. These include tests of respiratory mechanics and pulmonary gas exchange. The standard protocol involves a computerised spirometer and additional facilities for measuring carbon monoxide (CO) diffusion as a measure of diffusion capacity reflecting gas exchange. Of course, the acid-base disorders also reflect on the physiological function of the lungs, but they are outside the purview of this chapter. Ideally, PFT values have to be compared with the predicted values in a population which need to be epidemiologically established in every country. In India, most centres with PFT machines have to depend on the western data for normal values, which may not be representative of our country due to different body habitus.

Basically, respiratory mechanics involve compliance of lung and chest wall on one hand and airway resistance on the other. The direct measurements of lung compliance and airway resistance involve estimation of oesophageal pressure, pleural pressure and trans-diaphragmatic pressure, which is not feasible for day-to-day clinical practice. The practical measure of lung compliance in PFT is measurement of lung volumes, whereas the practical corollary for airway resistance is based on forced expiration manoeuvres by patients. In restrictive lung diseases, PFT demonstrates decreased vital capacity (assumed to be same as forced vital capacity (FVC) for practical purposes), whereas obstructive disease is reflected by decreased forced expiratory volume in one second (FEV1).

For interpretation, we look at the ratio of FEV1/FVC to differentiate between restrictive and obstructive lung disease rather than FEV1 alone. The reason is simple. In a patient of restrictive lung disease as FVC is reduced, consequently FEV1 is also reduced as the lungs have 'less air to be expelled'. Therefore, if one looks at FEV1 only, PFT of a patient with restrictive airway disease may give a false impression of obstructive airway disease due to reduced FEV1. However, when we look at the ratio of FEV1/FVC; as both values are reduced, the FEV1/FVC ratio is normal. On the other hand, in obstructive airway disease, there is air trapping and FVC is increased whereas due to obstruction in the airways, FEV1 is decreased; hence FEV1/FVC ratio is reduced.

Another important difference to understand is between peak expiratory flow rate (PEFR) and FEV1. PEFR can be easily

measured at home and is a very important objective parameter for asthma patients to know whether the disease is under control or is worsening so that they can report to the hospital at the right time. However, PEFR is always effort dependent, and hence, the patient should do it 2 to 3 times and note the best value. However, FEV1 done as part of PFT is relatively effort independent and gives a better reflection of the airway obstruction.

The assessment of respiratory muscle function is important to diagnose neuromuscular disorders affecting the respiratory system and occasionally in restrictive lung disease patients when restriction is extraparenchymal in the chest wall. Briefly, the respiratory muscle function is measured as PE_{max} (indicating maximum expiratory muscle pressure) and PI_{max} (indicating maximum inspiratory muscle pressure). Though expiration is a passive process, abdominal muscles play an important role. On the other hand, inspiration is an active process and the diaphragm is an important inspiratory muscle. Logically, expiratory muscles are most active at end-inspiration (PE_{max}) when the lung volume is maximum; whereas inspiratory muscle act at lower lung volumes, i.e. end-expiration (PI_{max}).

The pulmonary gas exchange parameter practically used in day-to-day clinical practice is carbon monoxide diffusing capacity (DLCO). It is a sensitive test to assess the integrity of the alveolo-capillary membrane. It is classically reduced in interstitial lung disease. However, it is also dependent on the surface area of the alveolo-capillary membrane. In other words, if patient has significant reduced surface area as in emphysema or pneumonectomy, DLCO would be reduced. Therefore, to remove this confounding factor, transfer coefficient (K_{CO}) is a more reliable parameter which represents the uptake of CO per litre of effective alveolar volume.

A more detailed assessment of the physiology of compliance of respiratory apparatus as well as the exact level of airway obstruction (from larynx to terminal airways) can be performed by studying the flow-volume curves or loops and measurements of static and dynamic compliance and airway resistance (R_{aw}) which is readily determined by body plethysmography and specific conductance (SG_{aw}) which is inverse of R_{aw} divided by lung volume at which the measurement was made. Another modality of assessment of respiratory function is the exercise test, which helps to quantify the exercise performance and objective assessment of disability due to disease, where clinically a patient may have recovered. For example, in miliary TB even after complete clinical and radiological recovery, a proportion of patients, despite successful treatment, develop exercise limitation that is detected on exercise test. These tests need a detailed understanding of the respiratory physiology and mechanics for a correct interpretation and their day-to-day use is quite limited. Nevertheless, they are very important for operational research to understand the basic pathophysiology of various respiratory disorders.

Microbiological Techniques

These techniques have a very important role in the diagnosis of infections of the respiratory system. However, it is very important to understand that in our country all microbiology laboratories may not be equipped with facilities for some of the advanced microbiological investigations; therefore the treatment of a critically ill patient should not wait for the outcome of these investigations. The clinicians should empirically cover for the prevalent organisms. On the other hand, if the clinical setting does not support the results of a microbiological investigation, we need to re-check for any contamination of the sample.

Sputum is the most commonly accessible material for a microbiological investigation. The collection of the sputum is very important, otherwise the report may be non-contributory and only add to the cost of care to the patient. It is very important to differentiate sputum from saliva. Grossly, a good sputum sample is thick (semi-solid), which is coughed out deeply from the lungs and is at least 2 mL. Microscopically, a good sputum sample should have less than 10 squamous epithelial cells and more than 25 neutrophils per low power field. If the patient is unable to produce adequate sputum, then it should be 'induced' with hypertonic saline given through a nebuliser mask. The transportation of the sample to the laboratory is equally important and should be done as early as possible.

The role of blood culture is also very important, but again the collection of blood for culture is more vital. All clinicians should be conversant with the correct technique of collecting a blood sample; otherwise the results can be misleading in the management of patients.

There are newer antigen markers in sera/sputum for atypical pneumonia organism like *Mycoplasma*, *Legionella* which can rapidly diagnose these infections.

The role of Ziehl-Neelsen (carbol-fuchsin) staining in the sputum smear for diagnosis of *M. tuberculosis* has been well established over the years. However, newer staining techniques like fluorochrome (auramine-rhodamine) staining are more sensitive as well as time conserving for identifying the mycobacteria.

The culture of mycobacteria on Lowenstein-Jensen medium is a time consuming process and is not of much value as far as immediate patient management is concerned. It takes 6 to 8 weeks for the culture to be reported. Newer culture methods like BACTEC radiometric system yield relatively earlier results.

Polymerase chain reaction

M. tuberculosis ribosomal RNA in respiratory tract specimens can now be identified within 24 hours. In fact, the rapid tests do not replace acid-fast staining, which provides an index of contagiousness, or mycobacterial cultures, permit drug susceptibility testing.

Tuberculin skin test

Tuberculin skin test (TST) (Mantoux test) is another investigation which is frequently done to diagnose latent TB infection (LTBI). However, its diagnostic reliability is always in relation to the clinical context and a positive TST (more than 10 mm induration) in the absence of clinical symptoms should not be considered diagnostic of active TB in our country because of false positivity due to Bacillus Calmette-Guérin (BCG) immunisation. A lower threshold of 5 mm is used to diagnose LTBI in human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).

Interferon gamma release assays

Interferon gamma release assays are used to diagnose LTBI. Their diagnostic utility in active TB has not been established. These tests include quantiferon-TB Gold (QFT-G), quantiferon-TB Gold in- tube test (QFT-GIT) and T-spot TB test. Early secreted antigen target-6 kDa protein (ESAT-6), culture filtrate protein-10 (CFP-10) and TB7.7 are three antigens used in these tests. The patient makes one visit to the health care facility and results are available in 24 hours.

Nuclear Medicine Imaging

The role of positron emission tomography (PET) and PET-CT using radiopharmaceutical fluoro-2-deoxy-D-glucose (FDG-PET) in the evaluation of focal lung lesions, especially solitary pulmonary nodule is emerging. The low false-negative rate of FDG-PET helps in excluding malignancy and allows follow-up of benign lesions as compared to CT.

Serum Markers

There are some serum markers which are helpful in the diagnosis of pulmonary disorders. Increased angiotensin-converting enzyme (ACE) levels in blood are most frequently used in the evaluation of sarcoidosis. However, increased ACE levels are not specific for sarcoidosis. Some of the other pulmonary conditions with increased ACE levels include emphysema, occupational lung diseases, and lung cancer.

Other serum markers useful in the diagnosis of pulmonary disorders include anti-neutrophil cytoplasmic antibody (ANCA) levels in blood for the diagnosis of Wegener's granulomatosis (WG). Proteinase 3 ANCA (PR3 ANCA) is more specific for WG.

Alpha 1-antitrypsin deficiency resulting in early-onset panacinar emphysema is diagnosed by estimating serum levels of alpha-1-antitrypsin. The presence of high levels of immunoreactive trypsinogen (IRT), a pancreatic protein is being used as a screening modality in infants with cystic fibrosis (CF). The mutation observed in CF patients result from deletion of three base pairs in CF transmembrane conductance regulator nucleotide sequence. This deletion causes loss of the amino acid phenylalanine located at position 508 in the protein. This mutation is referred to as ÄF508, which signifies severe clinical manifestations in patients of CF.

The role of tumour markers is also evolving in patients with lung cancer. Tissue polypeptide specific antigen (TPS) and cytokeratins CYFRA 21-1 are useful serum markers for the diagnosis of non-small cell lung cancer. Neuron specific enolase (NSE) is a useful tumour marker for monitoring course of patients with small cell lung cancer.

Arterial Blood Gas Analysis

The measurement of arterial blood gas analysis (ABG) is an extremely important tool to assess the pH, oxygen, carbon dioxide, and bicarbonate levels in blood. These parameters reflect the exact gas exchange occurring in lungs and integrity of the ventilatory control mechanism. Arterial blood gas analyses also reflects the various pulmonary-renal interactions occurring to maintain the normal acid-base physiology in the body.

Polysomnography

This is an overnight test performed in the sleep laboratory to diagnose apnoea. Cardio-respiratory, thoraco-abdominal, and electroencephalography parameters and oxygen saturation are recorded. Apnoea-hypopnoea index (AHI) > 5 events per hour are used to diagnose obstructive sleep apnoea.

INVASIVE DIAGNOSTIC PROCEDURES

Pleural Fluid Analysis

Diagnostic thoracocentesis and analysis of the pleural fluid is an essential procedure in the evaluation of a patient with pleural effusion. The evaluation includes biochemical, microbiological, and cytopathological analysis.

Enzymes and Cytokines

In recent years, adenosine deaminase (ADA) and interferon-gamma (IFN-γ) have emerged as important diagnostic tools in the diagnosis of tuberculous pleuritis. In a patient with pleural effusion, an elevated level of ADA (> 36 IU/L) in the pleural fluid is suggestive of TB. In fact, there are two isoenzymes of ADA: ADA1 and ADA2. The pleural fluid in tuberculous pleurisy primarily contains ADA2. However, for all practical purposes, the total level of ADA is measured in the fluid. Among the cytokines, studies have suggested that elevated pleural fluid IFN-γ can be used as a marker for the diagnosis of TB. In fact, it is now well documented that significantly higher IFN-γ: interleukin lukin-4 ratio in the pleural fluid compared to peripheral blood in patients with pleural tuberculosis.

Though elevated levels of IFN-γ in the pleural fluid are more sensitive for TB, ADA estimation is a cost effective investigation in the resource-limited setting of our country where the prevalence of TB is high.

Bronchoscopy

Fibre-optic bronchoscopy (FOB) is an outpatient procedure and is used to visualise the tracheobronchial tree. The role of FOB has also been established in diffuse lung disease. Fibre-optic bronchoscopy is also useful in obtaining histopathological, microbiological (Gram's stain, acid-fast bacilli stain, fungal stain, cultures), and cytological samples for the confirmation of diagnosis. The various techniques used with FOB are endobronchial brushings, washings, and biopsy. This technique is important in a proximal lesion of the tracheobronchial tree-like bronchogenic carcinoma. On the other hand, broncho-alveolar lavage (BAL) provides samples from the peripheral airways and alveoli. In patients with miliary TB, it has been shown that significantly higher levels of IL-4 are present in the peripheral blood as compared to BAL.

In patients with diffuse lung disease, BAL is an important tool in association with transbronchial lung biopsy. A newer technique is transbronchial needle aspiration to sample the sub-carinal mediastinal lymph nodes.

Endoscopic bronchial ultrasonography (EBUS) is also becoming a very useful adjunct to evaluate mucosal and sub-mucosal lesions in the tracheobronchial tree. Endoscopic bronchial ultrasonography also increases the diagnostic sensitivity in obtaining fine needle aspiration cytology (FNAC) or biopsy of suspicious lesions.

The use of rigid bronchoscopy had become restricted to the management of exsanguinating haemoptysis or in small children. However, with the advent of tracheobronchial stents, the use of rigid bronchoscopy is again gaining ground. The other

newer therapeutic uses of bronchoscopy include cryotherapy and laser therapy for bronchogenic carcinoma. Another important therapeutic procedure is removal of aspirated foreign body from the tracheobronchial airways.

Radiologically Guided Procedures

The role of USG/CT-guided FNAC and biopsy of various pulmonary abnormalities is a relatively less invasive modality to establish the diagnosis in these disorders. These procedures are quite safe and can be performed on an outpatient basis by experienced radiologists.

Thoracoscopy and Mediastinoscopy

Just as bronchoscopy is used for the tracheobronchial tree, thoracoscopy is used to visualise the pleura, and mediastinoscopy is used to visualise the structures of the mediastinum. The main advantage is obviously a direct visualisation of the suspicious tissue which can be biopsied for further analysis.

However, these are invasive surgical procedures performed under general anaesthesia with consequent morbidity and mortality. These procedures are generally performed when one has exhausted relatively less invasive means of establishing a diagnosis. In recent years, video-assisted thoracoscopic (VATS) procedures have further improved this technique. The main diagnostic indication of thoracoscopy and VATS are pleural biopsy for undiagnosed pleural effusions and wedge lung biopsy for diffuse lung disease. At the same time, therapeutic procedures in the form of pleurodesis for intractable pleural effusion, bullectomy for large bullae and lung volume reduction surgery for chronic obstructive pulmonary disease can also be performed. Mediastinoscopy is very useful to appropriately stage the lung cancers pre-operatively as the hilum is best visualised by this procedure.

23.4 Upper Respiratory Tract Infections

DG Jain

INTRODUCTION

Upper respiratory tract infections (URTIs), amongst the most common acute conditions presenting in the outpatient setting, is an important cause of morbidity and economic loss globally. Disease transmission occurs via the inhalation route and direct contact. Viruses are the most frequently implicated aetiological causes but URTIs due to primary bacterial infection or super-infection are also frequently encountered. Viral infections need to be distinguished from bacterial URTIs, as targeted treatment is available for bacterial infections.

COMMON COLD AND INFLUENZA

'Common cold' is an upper respiratory tract infection (URTI) caused by viruses (**Table 1**). The term 'influenza' refers to a severe form of the common cold caused by the influenza virus. A new subtype of swine-origin influenza A (H1N1) virus, which has now taken the form of a pandemic, has segments from four influenza viruses, i.e. North American swine, North American avian, Human influenza, and Eurasian swine. Its incubation period is 1 to 7 days.

Table 1: Five Groups of Viruses Causing Common Cold and Influenza

Influenza viruses
Picornaviruses (Coxsackie, Reo, Echo, and rhinovirus)
Respiratory syncytial virus
Parainfluenza virus
Adenovirus

Clinical Features

Sneezing, rhinorrhoea, nasal congestion, sore throat, non-productive cough, pain in the eyes, and headache are the usual symptoms. Sometimes, constitutional symptoms such as malaise and myalgias may be prominent (influenza or para-influenza virus). Fever is uncommon in adults. Occasionally, conjunctivitis (adenovirus), laryngitis (parainfluenza virus), and skin rash (enteroviruses) may also be present. Physical examination reveals post-nasal discharge, erythema around the nose, and glossy nasal mucous membranes. The pharynx may appear congested and exudates could be present on the tonsils. Jugulodigastric lymph nodes may be enlarged and tender. In influenza, extremes of age and pre-existing medical conditions attract a higher risk of complications like sinusitis, otitis media, croup, bronchiolitis, status asthmaticus, pneumonia, myositis, myocarditis, pericarditis, rhabdomyolysis, seizures, encephalitis, toxic shock syndrome, secondary bacterial pneumonia with or without sepsis.

Diagnosis

Real-time polymerase chain reaction (RT-PCR), or isolation of the virus in culture, or a four-fold rise in virus specific neutralising antibodies are used for confirmation of the diagnosis (before administration of antiviral drugs) from clinical specimens, i.e. nasopharyngeal swab, throat swab, nasal swab, wash or aspirate or tracheal aspirate in case of intubated patients.

Management

Common cold is usually treated empirically due to the non-availability and cost involved in laboratory testing. The mainstay of management is symptomatic and supportive treatment directed at alleviating the symptoms of common cold rather than addressing the aetiological causes. Bed rest, adequate fluid intake, anticholinergic nasal sprays (e.g. ipratropium nasal spray) for rhinorrhoea, saline nasal drops, nasal decongestants (e.g. xylometazoline nasal spray) for nasal obstruction are used for symptomatic relief.

In case of influenza, nosocomial and household spread of disease can be minimised by early institution of infection control measures and isolation of the patient in a well-ventilated isolation room/ward with beds kept at least one metre apart. Prompt treatment should be instituted with a generally well-tolerated antiviral drug (e.g. oseltamivir) to prevent severe illness and death. Antiviral prophylaxis should be provided to health care personnel managing the patient. Supportive therapy includes intravenous fluids, parenteral nutrition, oxygen therapy, ventilatory support, antibiotics for secondary infection, vasopressors for shock, paracetamol or ibuprofen for fever, headache, myalgia. Aspirin/salicylate medication is contra-indicated in influenza as it may cause Reye's syndrome. Patients should be monitored for lower respiratory tract infection and for hypoxia. Close contacts of suspected, probable, and confirmed cases should be advised voluntary home quarantine for at least 7 days after the last contact with the infected person.

RHINITIS

It is defined as inflammation of the membranes lining the nose. Rhinitis is characterised by nasal congestion, rhinorrhoea, sneezing, itching, and/or postnasal discharge. It is classified as allergic and non-allergic (**Table 2**).

Allergic Rhinitis

The inflammation in the nose is immunoglobulin E (IgE)-mediated in allergic rhinitis and is due to acute exposure to the inciting allergens which induce the early symptoms such as sneezing, itching, and clear rhinorrhoea within minutes of exposure. Late phase symptoms (nasal congestion and obstruction) appear 4 to 6 hours after exposure. The nasal mucous membrane appears boggy and pale. Acute infectious rhinitis is usually viral in origin. Secondary bacterial infection involving the sinuses is a common complication in which patients have mucopurulent or purulent nasal discharge, facial pain and pressure, and fever may be present.

Non-Allergic Rhinitis

Patients with non-allergic, non-infectious rhinitis without eosinophilia, and some with vasomotor rhinitis, present with nasal obstruction, rhinorrhoea, and congestion that may be precipitated or exacerbated by certain odours, alcohol, spicy foods, emotions, and environmental factors such as temperature, barometric pressure changes, and bright lights. Chronic nasal obstruction is frequently associated with sleep-disordered breathing.

Table 2: Aetiological Causes of Rhinitis

- **Allergic rhinitis**
  - Seasonal (e.g. pollens)
  - Perennial (e.g. house dust mite)
  - Occupational (e.g. animal antigens)
- **Non-allergic rhinitis**
  - Infectious rhinitis
    - Acute (viral, bacterial)
    - Chronic
      - Specific: bacterial, fungal
      - Non-specific: immune deficiency
    - Atrophic rhinitis (*Klebsiella ozaenae*)
  - Non-allergic, non-infectious rhinitis without eosinophilia
  - Non-allergic rhinitis with eosinophilia syndrome
  - Vasomotor rhinitis
    - Runners (rhinorrhoea predominates)
    - Dry patients (nasal obstruction and airflow resistance predominate)
  - Hormonal
    - Menstruation
    - Pregnancy
    - Hypothyroidism
  - Occupational (e.g. wood dust)
  - Food-induced and gustatory rhinitis
  - Drug-induced rhinitis
  - Antihypertensives
    - ACE-Inhibitors
    - Reserpine
    - Phentolamine
    - Alpha-methyldopa
    - Beta-blockers
  - Chlorpromazine
  - Aspirin and other NSAIDs
  - Oral contraceptives
  - Rhinitis medicamentosa
    - Alpha-adrenergic vasodilators
    - Oxymetazoline
    - Phenylephrine

ACE = Angiotensin converting enzyme; NSAIDs = Non steroidal anti-inflammatory drugs.

Diagnosis

Identification of the aetiological causes is based on the pattern, chronicity, and seasonal variation of symptoms (or the lack of these), history of medication, presence of co-existing conditions, occupational exposure, environmental history and identification of the precipitating factors. Physical examination should also focus on identifying surgically correctable conditions such as deviation of the nasal septum (DNS), polyps, or enlarged turbinates. Allergen skin or *in vitro* testing is useful in detecting allergic rhinitis.

Management

Management of rhinitis includes antihistamines, topical corticosteroids, and avoidance of inciting factors. Second generation, non-sedating oral antihistaminics (e.g. loratadine, cetirizine, fexofenadine) are effective in reducing symptoms of itching, sneezing, and rhinorrhoea. The World Health Organization (WHO) recommends using a combination of a non-sedating anti-histamine with anti-leukotriene for treating allergic rhinitis. Intranasal anti-histaminics (e.g. azelastine), while useful in relieving rhinorrhoea, have a bitter taste and may cause sedation due to systemic absorption. Topical corticosteroids (e.g. budesonide, mometasone furoate, beclomethasone) provide ample relief in patients with allergic rhinitis. Other useful drugs for rhinorrhoea include anti-cholinergic agents (e.g. ipratropium bromide), nasal decongestants (e.g. oxymetazoline). Oral corticosteroids and allergen immunotherapy may be helpful in some patients.

PHARYNGITIS

Pharyngitis is defined as the inflammation of the pharynx, hypopharynx, uvula and tonsils. It is usually infectious in aetiology and majority of the cases are of viral origin. Other causes of pharyngitis include allergy, trauma, toxins and neoplasia. Pharyngitis caused by group A β-haemolytic *Streptococci* is more common in children aged 4 to 7 years. In persons with orogenital contact, gonococcal pharyngitis can occur. Oral thrush caused by *Candida* may develop in immunosuppressed persons.

Clinical Features

Pharyngitis may present with throat discomfort, odynophagia, cough, and constitutional symptoms such as fever, headache, malaise and myalgias. Clinical examination reveals tonsillopharyngeal erythema, exudates and rarely foul smelling grey-white pharyngeal membrane (diphtheria). Swollen tender cervical lymphadenopathy, conjunctivitis (adenovirus), maculopapular rash (infectious mononucleosis) may also be present. Cough, rhinorrhoea, and conjunctivitis are frequently associated in viral pharyngitis. Differential diagnosis includes more dangerous conditions, such as epiglottitis, laryngitis, laryngotracheitis, and peritonsillar abscess.

Diagnosis

Diagnosis is established by throat swab culture and serological testing. Prompt recognition and treatment of group A β-haemolytic streptococcal pharyngitis is of paramount importance as this is associated with the development of rheumatic heart disease.

Management

Treatment of pharyngitis is mainly symptomatic and supportive. Some patients may require antibiotic treatment. Empiric antimicrobial therapy should cover all likely pathogens in the given setting and should be tailored as per the culture and sensitivity report. Anti-fungal and anti-viral agents may be required in certain cases. Viral pharyngitis is mostly a self-limiting disease which resolves spontaneously. However, the clinician should be aware of the potential complications of pharyngitis (**Table 3**).

Table 3: Complications and Sequelae of Pharyngitis

Suppurative
- Sinusitis
- Otitis media
- Epiglottitis
- Mastoiditis
- Peritonsillar abscess
- Retropharyngeal abscess
- Suppurative cervical lymphadenitis
- Pneumonia

Non-suppurative
- Airway obstruction
- Acute inflammatory demyelinating polyneuropathy
- Thrombocytopaenia
- Myocarditis, pericarditis
- Encephalitis, meningitis
- Streptococcal toxic shock syndrome
- Acute rheumatic fever

SINUSITIS

Inflammation of the paranasal sinuses results in sinusitis. Numerous factors predispose to the development of sinusitis (**Table 4**).

Table 4: Conditions Predisposing to the Development of Sinusitis

Anatomic abnormalities of the osteomeatal complex (e.g. deviated nasal septum, concha bullosa, bone spurs)
Allergic rhinitis
Vasomotor rhinitis, rhinitis medicamentosa, cocaine abuse
Nasal polyps
Nasotracheal, nasogastric intubation
Tumours causing obstruction
Dental disease/surgery
Recurrent upper respiratory infections
Immune deficiency (e.g. common variable immunodeficiency)
Cystic fibrosis
Kartagener's syndrome and other immotile cilia syndromes
Tobacco smoking
Environmental pollution

Clinical Features

Patients with acute sinusitis present frequently with persistence of symptoms even after the common cold has subsided, with nasal congestion, mucopurulent or purulent nasal discharge, headache, facial pain or heaviness, and fever. Pain increases in bending forwards. Localised tenderness indicates involvement of a group of sinuses. Maxillary sinuses are more commonly affected. The nasal mucosa appears oedematous with copious secretions. In chronic sinusitis, pain and fever are seldom present and the predominant symptoms are nasal obstruction, purulent nasal discharge, postnasal drip, chronic cough, hyposmia and halitosis. Clinical examination reveals an inflamed, thickened mucosa with polypoidal changes.

Diagnosis

Nasal endoscopy is useful for direct visualisation and for obtaining samples for microbiological and histopathological study. Radiographs of the paranasal sinuses [occipitomental (Water's) view and submentovertical view] and computed tomography are useful to demonstrate sinusitis radiographically. Magnetic resonance imaging is a superior modality for evaluating neoplasms, orbital and intracranial complications, and fungal sinusitis.

Management

Sinusitis is treated by controlling the predisposing factors (**Table 4**), analgesics for fever and pain relief and appropriate antibiotics. Nasal saline spray, topically administered decongestants (xylometazoline), steroids (fluticasone, beclomethasone), and cromolyn sodium, may be used for symptom relief. Surgery is indicated in patients with chronic sinusitis refractory to medical treatment, recurrent sinusitis, large obstructing polyps (**Figure 1**), suspicion of tumour, sinus mucocele, pyocele, intracranial extension, cavernous sinus thrombosis, and fungal sinusitis. Surgical options include functional endoscopic sinus surgery, and Caldwell-Luc operation.

23.5 Bronchial Asthma

Virendra Singh, Ajeet Singh

DEFINITION

Bronchial asthma is a chronic airway disorder which can affect people of all age groups. According to the *global initiative for asthma* (GINA), asthma is defined as a chronic inflammatory disorder of airways which is associated with airway hyper-responsiveness. It leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night or early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lungs that is often reversible either spontaneously or with treatment. In asthmatic patients, airway inflammation usually persists even during asymptomatic periods. Though symptoms and bronchospasm are intermittent, airway inflammation is persistent. Based on the concept of persistent airway inflammation, two important principles have emerged. First, the disease is chronic, often life-long; second, its severity fluctuates and sometimes there may be prolonged remissions.

EPIDEMIOLOGY

Prevalence of asthma varies considerably within countries and between countries. It is more prevalent in developed countries than developing ones, more in children (15%) than adults (10% to 12%), more in urban than rural areas, reasons of which are not fully understood. Nearly 8% to 10% of the total population suffers from it. In India, the prevalence of asthma has been found to be around 7% in the majority of surveys done. However, it has been reported to vary from 2% to 17% in different study populations, the disease can start at any age, but in a majority it starts before 10 years of age. It is twice as common among boys than girls, whereas in adults the male to female ratio is usually equal.

AETIOPATHOGENESIS

Aetiologic factors of asthma are divided into two groups: inducing factors and trigger factors. Inducing factors induce asthma in susceptible persons and these include genetic factors, obesity, viral infections in early life and exposure to tobacco smoke. Trigger factors such as allergens, vigorous exercise, viral infections, etc. can provoke symptoms in subjects already having asthma. Some factors such as viral infection and occupational sensitisers act as both inducer and trigger factors.

Inducing Factors

Asthma occurs more commonly in relatives of atopic individuals, and therefore, atopy has been recognised as an important risk factor for developing asthma. A distinct gene for atopy on chromosome 11q has been identified. Similarly, a gene at chromosome 5q has been linked to the synthesis of immunoglobulin (Ig)E. Tobacco smoke, maternal smoking during pregnancy or infancy, rhino-syncytial virus infections and exposure to high concentration of allergens during infancy can also induce bronchial asthma.

Trigger Factors

Wide range of factors can trigger symptoms in a patient with asthma, important among these are as follows:

Allergens

Inhaled allergens are the common triggering factors responsible for provoking symptoms of asthma. House dust mite is the commonest allergen. Pollen, mold, animal dander and cockroaches are other common allergens provoking asthma.

Environment

Asthma is usually worse on a cold and dry day, especially when there is a strong wind. Traffic pollution can aggravate symptoms in asthmatic patients. Air pollutants such as sulphur dioxide, ozone, diesel particles can also precipitate asthmatic symptoms. Indoor air pollution is also an important trigger factor. Cooking gas fumes and even passive cigarette smoking can trigger symptoms in asthmatic subjects. Paints, sprays and fumes can also precipitate severe symptoms in patients with asthma.

Infections

Patients often give history of an upper respiratory tract infection before an attack of asthma. These symptoms are usually due to rhinovirus infection. Viral infections are the major triggering factors for asthma exacerbations, but it is uncertain that they play an important role in aetiology of bronchial asthma. Recently, atypical micro-organisms like *Mycoplasma* and *Chlamydia* have also been identified in the mechanism of severe asthma.

Drugs

Beta-blockers and cholinergic drugs used for *Myasthenia gravis* and prostaglandins-2 (PGF-2) used for inducing abortion are known to cause bronchoconstriction in patients with bronchial asthma. Aspirin and nonsteroidal anti-inflammatory drugs are known to trigger asthma in almost 5% of the patients. Aspirin-sensitive asthma is more common in intrinsic variety of asthma, especially those having nasal polyps. Majority of aspirin-sensitive patients tolerate paracetamol quite well.

Food

Food allergens are not so common triggers of asthma. Egg, milk, and wheat are implicated in causing asthma in a few cases. The yellow colouring agents of food such as tartrazine and food preserving agents such as sulphites can also aggravate asthma in some patients, often those who are sensitive to aspirin. Physical characteristics of food such as cold edibles are usually not implicated in aggravation of asthma. However, Indians are reported to be more sensitive and they exhibit bronchoconstriction to edibles such as ice. Diet rich in anti-oxidants such as vitamin C and vitamin A, selenium, magnesium and omega-3 polyunsaturated fats or high in sodium and omega-6 polyunsaturated fats are associated with increased risk of bronchial asthma. Some asthmatics may show aggravation of symptoms to sea food items.

Exercise

Vigorous exercise, particularly on a cold and dry day, will cause symptoms in 80% of the patients with asthma. Exercise related exacerbation is also termed as exercise-induced asthma.

Psychological factors

Stress can influence asthma in some patients. However, it is rarely a major contributor to the severity of asthma.

Occupation

Occupational asthma is caused by a specific agent present at the work place. Occupational asthma affects almost 10% of the young adults. More than 200 agents have been linked with triggering of asthma at work places. Chemicals such as isocyanates, platinum, chrome, nickel, reactive dyes of diazonium salt, pharmaceutical agents, wood dust and cotton dust are among the common causes of occupational asthma.

Gastro-oesophageal reflux

Gastro-oesophageal reflux has been associated with triggering of asthma. Microaspirate of gastric contents and nervous reflex causing bronchoconstriction are common mechanisms proposed to explain GER-induced asthma.

PATHOLOGY

Gross Appearance

Patients dying from acute episodes of asthma have bulky and over distended lungs which fail to deflate when the chest is opened. The airways are thickened and plugged with sticky secretions.

Microscopic Appearance

The main features of asthmatic airways include marked thickening of basement membrane, bronchial smooth muscle hypertrophy and damaged epithelium, much of which is shaded. The bronchial wall contains inflammatory cells and the most important cell is eosinophil. Other cells include neutrophils, lymphocytes and plasma cells. The mucous or bronchial secretions of an asthmatic patient contain eosinophils, eosinophil cationic protein, desquamated airway epithelial cells termed as creola bodies, Charcot-Leyden crystals, and thick thread-like sputum called Curschmann's spirals. The mucus is often impacted in the small airways in severe asthma.

PATHOGENESIS OF ASTHMA

Initial Sensitisation

It is now clear that T-lymphocytes play a key role in asthmatic airway inflammation and sensitisation. There are two types of T-lymphocyte helper (Th) cells. Th1 controls synthesis of Igs such as IgA and IgM whereas Th 2 controls IgE production. Usually, there is a balance between Th1/Th 2 switch.

Exposure to an inducing factor sensitises T cells of a person with genetic susceptibility with bronchial asthma, and it shifts the Th1/Th 2 switch in favour of Th 2 dominance. Once sensitised, these Th 2 cells get into airway mucosa and governs IgE-mediated responses of allergic reaction (**Figure 1**). In a normal individual, when a noxious allergic substance enters the airway, IgA is released. However, in a sensitised person IgE is released. Once sensitised, the dose of the noxious agent that provokes asthma on subsequent exposure is much less.

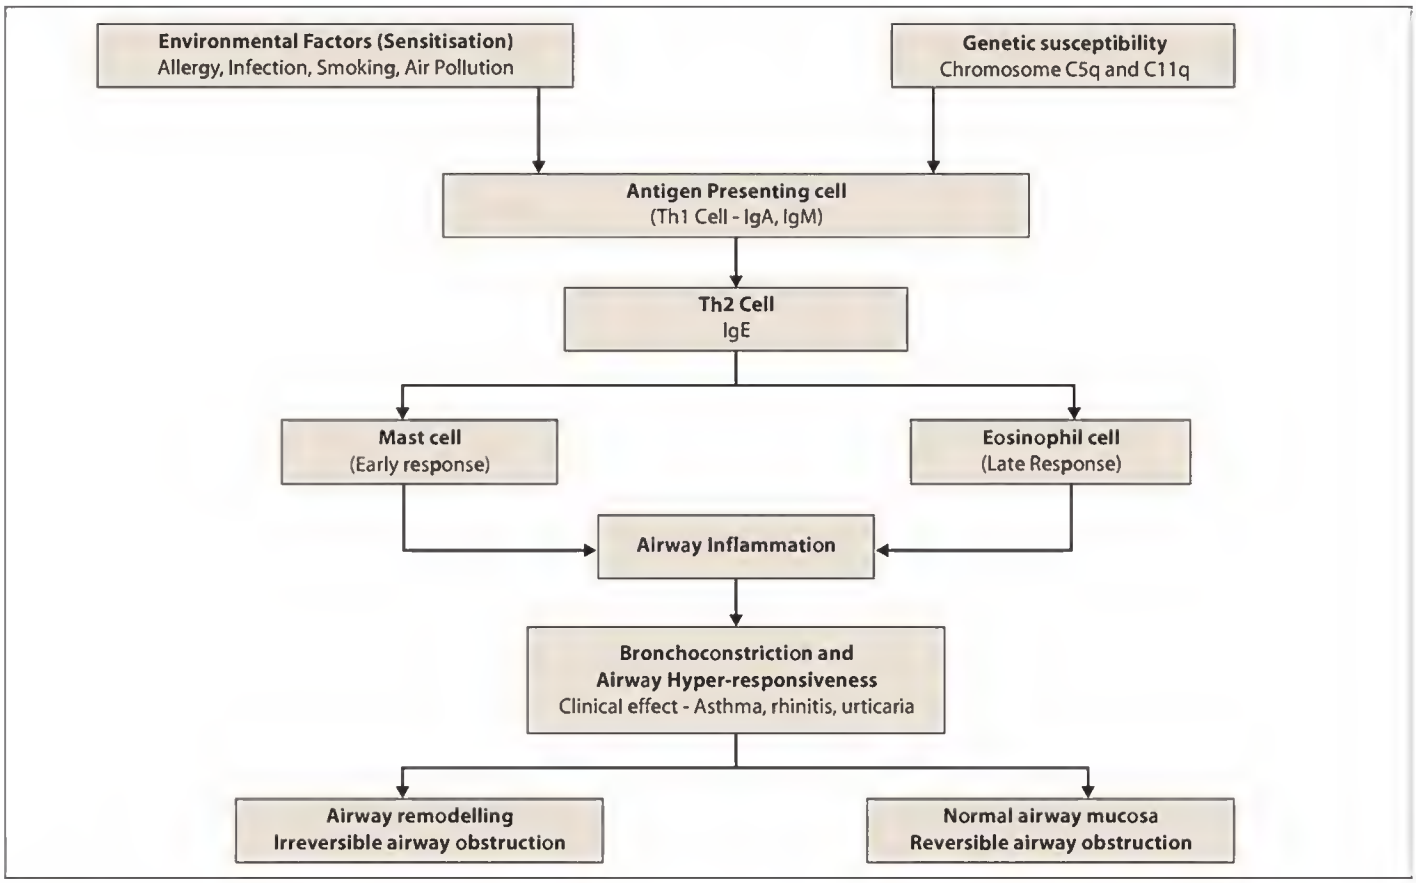

Figure 1: Pathogenesis of asthma.

Ig = Immunoglobulin.

Provocation of Asthma

When an allergen is inhaled by an asthmatic patient, airway obstruction starts within minutes and the peak effect is observed within 20 to 30 minutes. This is an early phase reaction or early response and is due to the direct action of mast cell derived mediators on the smooth muscles of the airways. When inhaled allergens come in contact with mast cells located in airway mucosa, then histamine and arachidonic acid derivatives such as leukotrienes and PGF are released.

In some cases, the reaction soon terminates and resolution starts with the decrease in short-lived mediator concentration. Whereas in many cases, a second phase of airway obstruction occurs 6 to 10 hours later. This is called late phase reaction or late response and it is inflammatory in nature (**Figure 1**).

CLINICAL FEATURES

Symptoms

Episodic breathlessness, wheezing, cough and chest tightness are important symptoms of bronchial asthma. These symptoms show a characteristic pattern of diurnal variability of worsening during night and early morning. It may lead to disrupted sleep due to cough and wheeze. There is an increased mucous production, which is thick, mucoid and difficult to expectorate. History of recurrent episodes of asthma caused by one or more trigger factors is important for the diagnosis of bronchial asthma. However, between episodes, patients usually remain symptom-free. Asthmatics are frequently associated with other atopic conditions, such as eczema, urticaria, allergic rhinitis, and hay-fever.

Physical Examination

Rhonchi are heard as the most prominent sign of asthma, especially during expiration. At the time of asthma exacerbation signs such as increased respiratory rate, flaring of *alae nasi*, use of accessory muscles of respiration, and pulsus paradoxus may be detected. In view of the diurnal variation of airflow obstruction, asthmatic symptoms and signs vary with worsening during night and improvement during day. Therefore, physical examination during day may be normal, and hence, the absence of signs does not exclude the diagnosis of bronchial asthma.

DIFFERENTIAL DIAGNOSIS

Wheezing and dyspnoea are prominent symptoms of asthma, and conditions presenting with these symptoms may pose diagnostic problem. The differentiation of chronic obstructive pulmonary disease (COPD) from asthma can pose clinical difficulty. History of smoking, exertional dyspnoea, and lack of symptoms-free periods favour a diagnosis of COPD, whereas nocturnal worsening, chest tightness, episodic pattern and good response to bronchodilators and steroids favour diagnosis of asthma. Bronchodilator reversibility shown in spirometry is diagnostic of bronchial asthma.

Acute left ventricular failure may cause wheezing and dyspnoea especially during nights. Dyspnoea starting 1 to 2 hours after sleep, history of heart disease, inspiratory crepitations and gallop rhythm supports the diagnosis of left ventricular failure, whereas early morning dyspnoea and response to bronchodilators are characteristic of asthma.

Upper airway obstruction with a tumour or lymphadenopathy is occasionally mistaken for asthma. It usually presents with rapidly progressive airway obstruction and inspiratory stridor. Spirometry shows reduced inspiratory flow and tracings of flow-volume curve becomes flat instead of being curved normally.

Hyperventilation syndrome, foreign body aspiration, bronchiectasis pulmonary tuberculosis and acute pulmonary thromboembolism are also sometimes confused with asthma. Careful history and documentation of variable and reversible airway obstruction can differentiate asthma from these conditions.

DIAGNOSIS

Blood Examination

Usually, patients have an eosinophil count in the range of 5% to 15%, or the absolute eosinophil count is more than 400. Total serum IgE and specific IgE are elevated in bronchial asthma.

Sputum Induction

Sputum examination can provide a useful clue about the severity of airway inflammation. Sputum is induced after administration of hypertonic saline with a nebuliser. In patients with asthma, the number of eosinophils are increased in the induced sputum. Estimation of eosinophilic cationic protein in sputum or urine is also found to be a useful test for assessment of the severity of airway inflammation.

Airway Hyperresponsiveness

Increased airway hyperresponsiveness (AHR) is a characteristic of bronchial asthma. It can be measured by methacholine or histamine challenge test. This test is useful in the diagnosis of asthma when the patient is in remission with normal lung functions.

Chest Radiograph

Radiograph of the chest may show hyperinflation in a patient with asthma. It may also reveal complications of severe asthma such as rib fracture, pneumothorax, and pneumomediastinum.

High Resolution Computerised Tomography of Chest

Routinely, this investigation is not required in patients with bronchial asthma unless some associated lung disease is suspected. High resolution computerised tomography shows areas of thickening of the bronchial wall in patient with severe asthma.

Identification of Trigger Factors

A good history is important in identification of trigger factors. Particular care should be taken in evaluation of environmental factors and occupation of the patient. Household work, especially in the kitchen, is an important provoking factor in many housewives whereas agricultural work such as grain storage, cutting of crops, pesticide spray and exposure to cold during irrigation may be important in rural asthmatics. It is also important to ask about both nocturnal and exercise-induced symptoms.

Skin Prick Test

Sensitivity to a particular antigen can be identified by injecting a small amount of allergens into the skin. Wheal and flare appear at the site of injection of a sensitised allergen. Skin prick test to common inhalant allergens is usually positive in allergic asthma. Allergens can also be identified by estimation of specific IgE in

the blood through radioallergosorbent test (RAST). However, SPT is cheaper and more sensitive than RAST.

Measurement of Lung Functions

Various types of lung function tests are available, but measurements of peak expiratory flow rate (PEFR) by a peak flow meter and forced expiratory volume in one second (FEV1) by a spirometer are most useful in a making diagnosis and assessing the severity of asthma.

Peak expiratory flow rate

Peak expiratory flow rate represents maximal expiratory effort performed after full inhalation. Peak expiratory flow rate is reduced with increasing severity of airway obstruction. It can be measured with a handy tool called peak flow meter. This equipment is very useful in monitoring the severity of asthma and designing a treatment plan on an individual basis. Usually, PEFR values of a patient is compared with the predicted normal values. However, there is a large variation in normal predicted values, and therefore personal best PEFR value is taken as normal reference value. Personal best value is the highest recorded PEFR value of a person taken over a few days during asymptomatic period.

Normally, there is variation in PEFR values taken at different times of the day. The magnitude of variation between morning and evening PEFR values is called PEFR variability and it is proportional to the severity of asthma. Another useful index is PEFR reversibility. After baseline PEFR, beta-2 agonist drugs such as salbutamol or terbutaline are administered through an inhaler or nebuliser. The PEFR noted 15 minutes after the bronchodilator administration, shows the magnitude of reversibility. More than 20% reversibility or variability is diagnostic of bronchial asthma.

Spirometry

Asthma is diagnosed by demonstration of reversible airway obstruction in spirometry. A ratio of FEV1 and forced vital capacity (FVC) less than 0.7 is diagnostic of airway obstruction. After bronchodilator administration, FEV1 increases by more than 12% and 200 mL in asthmatic patients. It is called reversibility of airway obstruction which is characteristic of asthma.

Lung Volumes and Diffusing Capacity

Lung volumes, such as residual volume and total lung capacity, are increased in a patient with asthma. Carbon monoxide diffusing capacity (DLCO) is either normal or increased in the asthma patients. Diffusing capacity of the lung for carbon monoxide is reduced in patients with COPD, therefore, it is useful in differentiating COPD from asthma.

Oximetry

In assessing severity of acute severe asthma, pulse oximetry is a useful tool. It detects hypoxaemia in severe asthma. Normally, oxygen saturation should be more than 90%. Pulse oximetry is also helpful in monitoring oxygen therapy.

Arterial Blood Gas Analysis

Periodic measurement of arterial blood gases proves useful in monitoring of patients with acute asthma. Arterial blood gas analysis give basic information about pH, partial pressure of oxygen (PaO_2), partial pressure of carbon dioxide ($PaCO_2$) and bicarbonate (HCO_3). In severe asthma, PaO_2 decreases but $PaCO_2$ remains normal. When $PaCO_2$ starts rising, it is an indication of requirement for assisted ventilation.

ASSESSMENT OF SEVERITY

Severity of asthma is highly variable. Assessing the severity of asthma on the basis of one parameter does not represent a true picture. Therefore, GINA guidelines suggest a method of assessing asthma severity on the basis of parameters such as symptoms, activity limitation, lung function tests, inhaler use, and frequency of exacerbations. On the basis of these parameters, asthma is categorised into controlled, partly controlled and uncontrolled as described below.

Indices Determining Control of Asthma

- Day-time symptoms less than twice per week
- Short-acting beta agonist (SABA) inhaler use less than twice per week
- Without any night-time symptoms
- Without limitation of activity
- Normal PEFR and FEV1 values

Controlled

Asthma is said to be controlled if all indices are fulfilled and patient did not have an exacerbation in the last one year.

Partly controlled

Asthma is said to be partly controlled, if any of the indices is more severe than described above or the patient had an exacerbation during the last one year.

Poorly controlled

Asthma is said to be poorly controlled, when more than 3 indices are more severe than described above, or the patient had an exacerbation during the last week.

MANAGEMENT OF ASTHMA

Patient Education

It is aimed to enable asthmatic patient to treat himself under guidance of his doctor. It is achieved by proper education of the patient. Patient education is as important as drug treatment. Every patient with asthma should learn to take medicines regularly, correctly and understand the difference between relieving and preventive medicines. Identification and avoidance of risk factors and triggers involved in asthma are also important components of patient education. Monitoring the severity of the disease by symptom score or peak-flow meter, action plans for a situation like exercise-induced and acute attack, and misconception about the disease should also be addressed.

Identify and reduce exposure to risk factors

Asthma exacerbation can be caused by a variety of trigger factors. Early identification of a trigger factor and preventing its exposure improves asthma control and reduces requirement of medicines.

Assess, monitor and treat asthma

Asthma control is assessed and then patient is treated to achieve the control. Once adequate control is achieved, the patient is monitored regularly to maintain the control.

Manage exacerbation

The aim of treatment during management of an exacerbation is to relieve bronchospasm and hypoxia as quickly as possible.

A future plan is made to prevent recurrence of episodes of exacerbation.

Special Situation

At times, asthma management requires attention to special situations such as allergic rhinitis, pregnancy, aspirin sensitivity, occupational compulsions, and gastro-oesophageal reflux.

DRUG THERAPY

Mode of Administration

Asthma drugs are administered as injection, tablet, syrup, or in aerosol form. Aerosol administration through inhaler devices is the preferred mode of administration. With aerosols, the dose and the side effects of the drug are much less and the therapeutic effect is better. Drugs such as theophyllines and anti-leukotrienes are not available in aerosol form. In order to get optimal therapeutic effect, the technique of aerosol use should be correct.

Devices used for delivering inhaled medications include metered dose inhaler (MDIs), dry powder inhaler (DPIs) and nebulisers (jet nebulisers and ultrasonic nebulisers). With steroid MDIs and DPIs, hoarseness of voice and oral candidiasis are common in some patients. Rinsing the mouth after the use of inhaler, use of a spacer device with MDI and the use of MDIs and DPIs before food are some of the measures to prevent local adverse effects of inhaled corticosteroids. When used with spacer, delivery of MDI drug into airways also improves.

Commonly Used Drugs

Drugs for asthma are divided into two categories: bronchodilators or relievers, and controllers or preventers (**Table 1**). The bronchodilators work quickly and relieve the symptoms and acute attack of asthma rapidly. Beta-2-agonists, anticholinergics, and theophyllines are included in this category. The controller medicines prevent the onset of symptoms by controlling inflammation. Inhaled corticosteroids (ICS), systemic corticosteroids, anti-leukotrienes, and cromones are included in this category. The broad guidelines of asthma management are given in **Figure 2**.

Bronchodilators Drugs

Bronchodilators are the drugs which primarily act on smooth muscles of airways and cause rapid relief of symptoms. There are 3 classes of bronchodilator medicines—β-2 agonists, anticholinergics, and theophyllines.

Beta-2-agonists

The most commonly used bronchodilators are beta-2-agonists. Inhaled preparations are better because even in a small dose they cause equal or better bronchodilatation and the action is much quicker. Salbutamol and terbutaline are short-acting β-2 agonist (SABA) having a duration of action of 3 to 6 hours. Salmeterol and formoterol are long acting β-2 agonists (LABA) having a duration of action over 12 hours.

Short-acting β-2 agonists are very good for the treatment of an attack of asthma and for pre-treating the symptoms associated with exercise. Since long-term regular use of SABA is associated with poor control of asthma, therefore, SABA should not be used on a regular basis. Long acting β-2 agonists are also not used regularly as monotherapy. Since LABA does not control airway inflammation, therefore, it should be used in combination with ICS. However, recently use of LABA in combination with ICS has also been restricted. It has been advised that combination of LABA and ICS should be used only in those patients whose asthma fails to be controlled with controllers such as ICS alone.

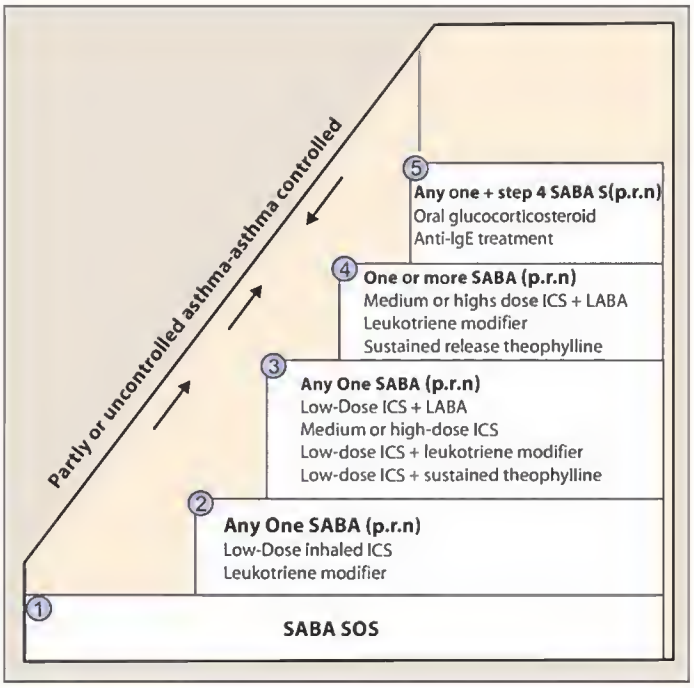

Figure 2: Steps of asthma management based on GINA guidelines. Goal of therapy is to achieve asthma control. SABA is used at all steps.

SABA = Short-acting β-2 agonist; ICS = Inhaled corticosteroids; LABA = Long-acting β-2 agonist; IgE = Immunoglobulin E; p.r.n. = as and when required.

Anticholinergics

Interestingly, *Datura* plant was used as the first inhaled medicine and the *hookah*, the local filtered tobacco inhaler, as the first inhaler device. These two were both discovered and invented in India. With the introduction of more selective anti-muscarinic drugs, interest in these drugs was renewed. Ipratropium bromide is a short-acting muscarinic antagonist of this class. It can be used as reliever therapy in patients who do not respond to beta-2-agonists.

Theophyllines

Two types of formulations of theophylline are available: short-acting and sustained-release. Short-acting theophylline has erratic absorption and therefore, can lead to rise in serum concentration to toxic levels unpredictably. Sustained-release theophylline has more uniform absorption and a longer half-life. It inhibits both early and late asthma reactions after an allergen exposure. It also has some anti-inflammatory properties.

Controller Drugs

Inhaled corticosteroids

Corticosteroids are the most effective controller and anti-inflammatory medicines reducing the number of inflammatory cells and their activation in the airways. It improves lung functions, decreases airway hyper-responsiveness, reduces and prevents symptoms. Inhaled corticosteroids are preferred over tablets or syrup for long-term therapy. Inhaled corticosteroids are safe and effective for long-term treatment of asthma. Beclomethasone, budesonide, fluticasone and ciclesonide are commonly used inhaled steroid preparations.

Systemic glucocorticosteroids

Systemic glucocorticosteroids are important in the treatment of exacerbation of asthma because they prevent its progression.

Table 1: Drugs Used in Management of Asthma

Drug Category and Name	Mode of Administration	Dose	Indication	Side Effects
Beta-2-agonist				
Short-acting β agonists (SABA)				
Salbutamol	Oral, inhalation	2 to 4 mg, 100 to 200 mcg	Reliever	Tremors, tachycardia
Terbutaline	Oral, inhalation	5 mg, 250 to 500 mcg	Reliever	
Long-acting β agonists (LABA)				
Formoterol	Inhalation	4.5 to 9.0 mcg/q 12 hourly	Controller	Mouth-throat irritation
Salmeterol	Inhalation	50 to 100 mcg/q 12 hourly	Controller	Hypokalaemia
Methylxanthines				
Theophylline	Oral	100 to 300 mg/q 8 hourly	Reliever	Cardiac arrhythmias
Aminophylline	Oral and slow IV	250 to 500 mg		Tachycardia
Doxophylline	Oral	400 mg/od		Mouth-throat irritation
				Hypokalaemia, hypotension
				Tremors, death
Anticholinergics				
Ipratropium bromide	Inhalation	40 mcg/qid	Reliever	Dry mouth, blurred vision, Glaucoma, urinary retention
Corticosteroids				
Prednisolone	Oral	20 to 40mg	Controller	Osteoporosis, diabetes
Dexamethasone	Oral	0.5 to 5 mg/qd	Controller	Arterial hypertension
	IV	4 to 20 mg/qd	Reliever	
Hydrocortisone	IV	100 mg bolus–100 mg/q 8 hourly	Reliever	Cataract, glaucoma
Beclomethasone	Inhalation	200 to 2,000 mcg	Controller	Adrenal suppression
Budesonide	Inhalation	200 to 1,600 mcg	Controller	
Fluticasone	Inhalation	100 to 1,000 mcg	Controller	Obesity, muscle weakness
Ciclesonide	Inhalation	80 to 1,280 mcg	Controller	
Mast cell stabilisers				
Sodium cromoglycate	Inhalation	1 mg/dose(2 puffs/q 8 hourly)	Controller	Cough, throat irritation
Ketotifen	Oral	1 to 2 mg/q 12 hourly	Controller	Sedation, dry mouth
Anti-IgE-antibody				
Omalizumab	Subcutaneous	150 to 375mg, 2 to 4/week	Severe allergic asthma uncontrolled with inhaled steroids	Headache, anaphylaxis sinusitis
Leukotriene modifiers				
Montelukast	Oral	5 to 10 mg/day at bed-time	Controller	Well-tolerated
Zafirlukast	Oral			
Zileuton	Oral			

IV = Intravenous; d = Day; od = Once a day.

During exacerbation, a short course of oral corticosteroid (40 to 60 mg prednisolone) is given daily for 5 to 10 days. When the patient symptomatically improves, the oral corticosteroid can be stopped or tapered off but ICS must be continued.

Leukotriene modifiers

The inflammatory cells like mast cells and eosinophils in asthmatic patients produce cysteinyl leukotrienes which are potent bronchoconstrictors. Cysteinyl leukotriene (CysLT1) receptor antagonist drugs like montelukast, pranlukast, zafirlukast and 5-lipoxygenase inhibitor zileuton can prevent such bronchoconstriction, improve symptoms and reduce airway inflammation. These medicines are used as add-on therapy. Leukotriene inhibitors are especially useful in patients with aspirin-induced asthma.

Cromones

Sodium cromoglycate and nedocromil sodium can cause inhibition of mast cell and sensory nerve activation, and therefore, are effective in trigger-induced asthma such as exercise-induced asthma, allergen and sulphur dioxide- induced asthma. These are very safe but have a short duration of action.

Anti-IgE-antibody

IgE mediates important allergen-induced reaction in asthmatic airways. Omalizumab is an antibody which neutralises circulating IgE and inhibits IgE-mediated reactions. This is used only in patients with severe allergic asthma having elevated levels of IgE and who remain uncontrolled with a maximal dose of ICS.

Antigen-specific immunotherapy

The role of antigen-specific immunotherapy in patients with asthma is limited. Proper immunotherapy requires identification of single clinically relevant allergen. Objective evidence suggests that immunotherapy with highly purified allergens is useful in dust mite, pollen and animal dander allergies. Some authorities believe that immunotherapy is more effective in patients having dominant nasal symptoms.

ALTERNATIVE THERAPIES

Majority of alternative or complementary therapies are not useful in asthma. Yoga, hypnosis, and acupuncture have shown small beneficial effects in some studies; however, well-planned randomised controlled trials are lacking.

DIFFICULT ASTHMA

Five per cent of asthmatic patients are difficult to control with the available conventional therapy for asthma. The most common reason for uncontrolled asthma is non-compliance of medication. There are several factors which make asthma more difficult to control, e.g. exposure to high concentration of allergens or exposure to unidentified occupational agents. Viral, bacterial, and mycoplasma infections can sometimes lead to refractory bronchospasm. Uncontrolled gastro-oesophageal reflux and simultaneous use of drugs such as beta-blockers, aspirin, and cyclo-oxygenase inhibitors are also important risk factors of difficult asthma. Refractory asthma is difficult to treat unless primary factors are adequately controlled. Compliance, proper use of inhalers, identification, and elimination of underlying triggering factors are important steps in the management of difficult asthma.

ACUTE SEVERE ASTHMA

This is an extreme stage of severity of asthma formerly termed as status asthmaticus. Clinical features of acute severe asthma include coughing, wheezing, shortness of breath, and chest wall recession (indrawing in the flesh between the ribs and sternum), inability to complete a sentence in one breath, use of accessory muscles, respiratory rate >25 per minute, pulse >110 per minute and presence of pulsus paradoxus.

Pulsus Paradoxus

In normal individuals the systolic blood pressure falls by 2 to 4 mm Hg with normal inspiration and 10 mm Hg with deep inspiration. When systolic pressure falls more than 10 mm Hg during inspiration, the pulse is called as pulsus paradoxus. Presence of pulsus paradoxus indicates presence of severe asthma and in such patients PEFR is usually less than 60% of the predicted or best. Pulsus paradoxus may also be present in other conditions such as cardiac tamponade, constrictive pericarditis, and superior vena cava obstruction.

If the condition worsens, airways become further narrowed and the movement of air decreases. In such situations, sometimes wheezing ceases. It indicates that the airways are extremely narrowed and very little air is moving in and out. This is also called silent chest type asthma.

Features of life-threatening asthma include silent chest, cyanosis, or feeble respiratory effort, bradycardia, hypotension and PEFR <30% of the predicted or best. Patient may be exhausted, confused and lapses into coma. Arterial blood gas analysis shows normal or high $PaCO_2$ (more than 45 mm Hg), severe hypoxia (PaO_2 <60 mm Hg) and a low pH. Acute severe asthma may lead to complications, such as dehydration, acute cor pulmonale and pneumothorax.

TREATMENT

The aim of treatment in acute severe bronchial asthma is to save life. Hypoxia is treated with high concentration of oxygen to maintain oxygen saturation above 90%. Usually, 40% to 60% oxygen is administered. In contrast to chronic obstructive pulmonary disease, carbon dioxide retention is not aggravated by administration of higher concentration of oxygen in bronchial asthma. Short acting β-2 agonist such as salbutamol 5 mg or terbutaline 10 mg are administered via oxygen driven nebuliser. It is repeated as frequently as every 15 to 30 minutes depending on the severity of the asthma. Ipratropium 0.5 mg may also be added to the salbutamol nebuliser solution and repeated every 6 hours. Prednisolone tablet 30 to 60 mg or hydrocortisone hemisuccinate 200 mg through intravenous route or both are given if the patient is very ill. In some patients, intravenous aminophylline 250 mg is administered over 20 minutes. If oral theophylline has been taken in the preceding hours, IV aminophylline should be avoided. Magnesium sulphate given intravenously or with nebuliser is also effective in some patients with acute severe asthma. Sometimes a patient is anxious and perspires, but sedative drugs are contraindicated due to apprehension of respiratory depression.

If any patient does not respond to treatment, one should suspect pneumonitis or pneumothorax. In such a situation, a chest radiograph is useful. The patient should be closely monitored with PEFR every 15 to 30 minutes after starting the treatment, and pulse oximetry to maintain oxygen saturation above 90%. If oxygen saturation is less than 90%, an arterial blood gas analysis should be done and repeated every 2 hours. Assisted mechanical ventilation is required in a patient showing deterioration (**Table 2**). Antibiotics have no role until unless there is an evidence of bacterial pneumonia.

The prognosis of acute severe asthma is good. Mortality is rare, and occurs usually when treatment is delayed or inadequate. Mechanical ventilation may be required.

Table 2: Indication Mechanical Ventilation

Mechanical ventilation is indicated when the spontaneous ventilation is inadequate to sustain life. Initially, some patients may respond to non-invasive ventilation (NIV), therefore a trial of NIV for a period of 1 to 2 hours is a logical approach in selected patients.

Indications

Absolute indication: Cardio-pulmonary arrest, deteriorating consciousness

Relative indications: Hypercapnia, acidosis, progressive deterioration with increasing distress or physical exhaustion

Complications

Hypotension, barotrauma and nosocomial pneumonia

23.6 Chronic Obstructive Pulmonary Disease

Surendra K Sharma

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease. The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines COPD as a disease state characterised by progressive development of chronic airflow limitation that is not fully reversible and includes chronic bronchitis, emphysema, and small airway disease. The airflow obstruction in COPD may be partly reversible and some patients may also manifest bronchial hyper-responsiveness. Excluded from this definition is bronchial asthma, which also produces chronic airflow obstruction and at times may be difficult to distinguish from COPD. Chronic bronchitis is characterised by chronic cough with expectoration for at least 3 months of the year for more than 2 consecutive years. Only a minority of patients with chronic cough and expectoration have associated airflow obstruction. Emphysema is defined as the permanent, abnormal distension of the air spaces distal to the terminal bronchioles, accompanied by destruction of their walls without fibrosis. Chronic bronchitis and emphysema frequently co-exist since both share common aetiological factors. After many years, chronic bronchitis gets complicated by emphysema.

EPIDEMIOLOGY

In India, COPD is the second most common lung disorder after pulmonary tuberculosis. The disease is frequently encountered in the middle-aged patients and is rare below the age of 35 years. COPD affects males more frequently because of smoking. It is equally prevalent in rural and urban areas. Various aetiological factors responsible for development of COPD are detailed in **Table 1**.

Table 1: Risk Factors for COPD

Tobacco smoking
Air pollution (particularly with sulphur dioxide and particulates)
Occupational exposure to inorganic or organic dusts or noxious gases
Recurrent respiratory infection in childhood
Familial and genetic factors (α_1-antitrypsin deficiency)
Low birth weight

AETIOLOGY

Tobacco Smoking

Tobacco smoking is the single-most important and the most prevalent risk factor for the development of COPD. Tobacco smoke contains numerous vapourised chemicals (92%) and particulates (8%), suspended in gaseous medium. Most of the toxic organic components of smoke are contained in the particulate fraction.

The greater the total tobacco exposure, more the risk of developing COPD. *Hukka* and *bidi* smoking are as harmful as cigarette smoking. Pipe and cigar smokers have higher morbidity and mortality from COPD than non-smokers, although it is lower than cigarette smokers. The cumulative amount of tobacco smoked is related to its adverse affects. This is expressed as pack-years and is calculated by multiplying the number of packs (1 pack = 20 cigarettes) with years of smoking. Since the net weight of tobacco in a *bidi* (150 to 240 mg) is about one-fourth of that in a cigarette, in *bidi* smokers, 'cigarette equivalent pack years' are computed by dividing the 'pack-years' calculated on the basis of smoking *bidis* by four.

Inhaled smoke in conjunction with underlying host susceptibility and environmental factors produces COPD in 15% of smokers. Prolonged cigarette smoking impairs ciliary movement, produces hypertrophy and hyperplasia of mucus-secreting glands. It also inhibits antiproteases and causes neutrophils to release proteolytic enzymes.

Environmental Tobacco Smoke

Although passive smoking and exposure to environmental tobacco smoke have been associated with reductions in pulmonary function, their role in the causation of COPD remains uncertain.

Environmental Pollution

The incidence of COPD is higher in heavily industrialised urban areas. Episodes of exacerbation of COPD correlate with periods of heavy pollution with sulphur dioxide and particulate matter. In India, indoor pollution caused by burning of cow-dung cakes and use of wood for cooking are important contributory factors.

Occupation

COPD is frequently observed in persons who are engaged in occupations exposing them to either organic or inorganic dusts or to noxious gases.

Respiratory Infections

Infections are often the precipitating cause of acute exacerbations of COPD (AECOPD) and contribute significantly to morbidity and mortality. Release of enzymes from the neutrophils found during infections may contribute to the lung damage. Viral respiratory infections in infancy may cause airways obstruction in later life.

Familial and Genetic Factors

Familial aggregation of chronic bronchitis has been well demonstrated and may be partly related to indoor air pollution and passive smoking. Few studies of monozygotic twins have suggested some genetic predisposition to the development of chronic bronchitis, independent of indoor pollution and passive smoking. The protease inhibitor (Pi) alpha-1-antitrypsin (α_1-AT) is an acute phase reactant and a potent inhibitor of serine proteases. Its serum level rises in association with many inflammatory reactions in all individuals except homozygotes. α_1-AT deficiency is the strongest genetic factor causally related to the development of COPD. The deficiency is related to

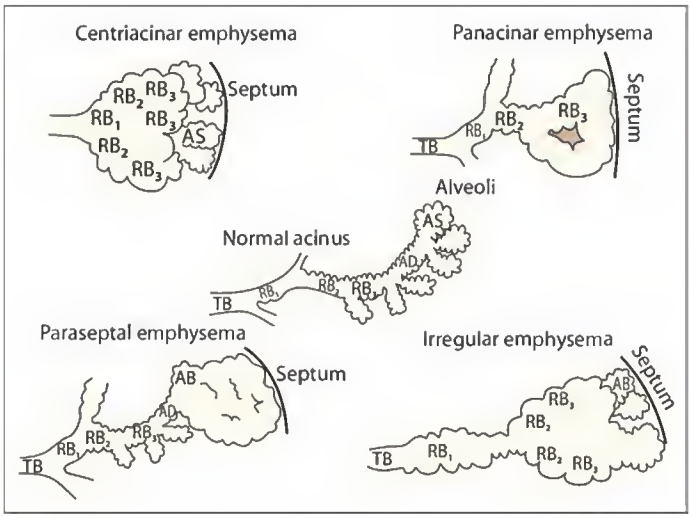

Figure 1: Types of emphysema. Centriacinar emphysema (upper panel left); panacinar emphysema (upper panel right); paraseptal emphysema (lower panel left); irregular emphysema (lower panel right).

TB = Terminal bronchiole; RB = Respiratory bronchiole.
Source: Adapted from Thurlbeck WM. Chronic bronchitis and emphysema - the pathophysiology of chronic obstructive pulmonary disease. New York: American Thoracic Society; 1974.

emphysema only and predominantly affects lower lobes and is panlobular or panacinar, whereas emphysema in cigarette smokers is centrilobular or centriacinar and initially involves the upper lobes. Incidence of α_1-AT deficiency in patients presenting with COPD is 1% to 2% but increases to about 50% in patients with severe disease who are under 40 years of age. The precise mechanism is unclear, in addition to elastase and collagenase, it inhibits several other enzymes. The commonest allele in all populations is PiM and the most common phenotype PiMM.

PATHOLOGY

In patients with chronic bronchitis, there is hypertrophy of the mucus secreting glands. These glands are found in the submucosa of large cartilaginous airways. In patients with COPD the mean Reid index (ratio of thickness of the submucosal glands to that of the bronchial wall) increases to 0.52 (normal 0.44). In COPD, the major site of obstruction is the small airways. Other findings include goblet cell hyperplasia, accumulation of inflammatory cells in the mucosa and submucosa, peribronchial fibrosis, intraluminal mucus plugs and increased smooth muscle. Classification of emphysema is based on the pattern of involvement of acini of the lung distal to the terminal bronchiole (**Figure 1**). *Panacinar* or *panlobular* emphysema involves both the central and peripheral portions of the acinus as compared to *centriacinar* or *centrilobular* emphysema where distension and destruction are mainly limited to the respiratory bronchioles with relative sparing of the peripheral portion of the acinus. *Paraseptal* emphysema involves airspaces at the periphery of the lobule adjacent to the pleura. *Irregular* emphysema involves the acinus irregularly and is almost always associated with scarring. This pattern is often evident in tuberculosis (TB). Pathogenetic mechanisms in COPD are shown in **Figure 2**.

PATHOPHYSIOLOGY

Chronic bronchitis and emphysema frequently co-exist; however, one process may dominate over the other. Both produce airways narrowing but can occur without evidence of obstruction. Airways obstruction is invariably present by the time patient experiences breathlessness. Besides basic disease process in the airways in chronic bronchitis, loss of elastic recoil

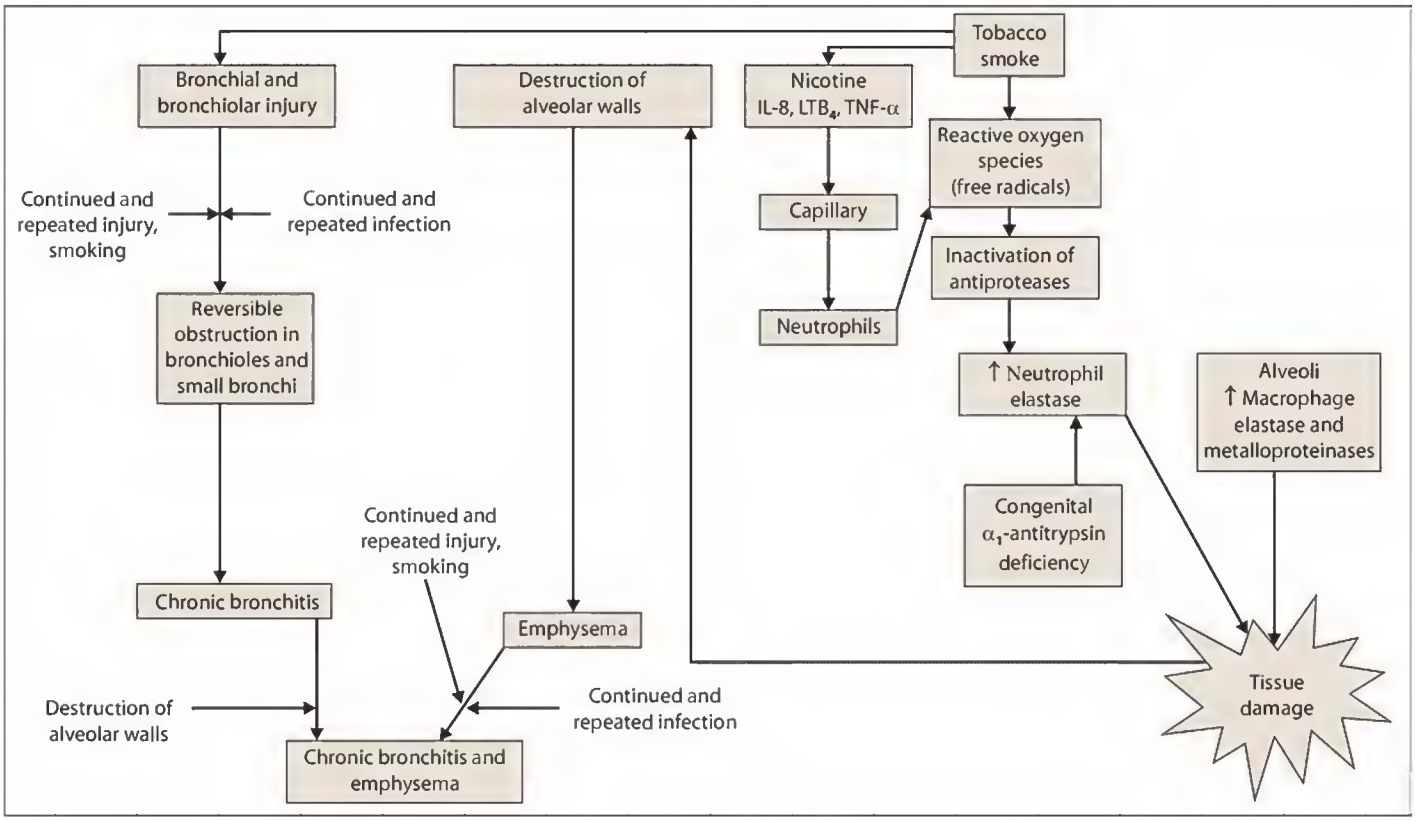

Figure 2: Pathogenesis of COPD. The protease-antiprotease imbalance and oxidant-antioxidant imbalance are additive in their effects and contribute to tissue damage. α_1-antitrypsin (α_1-AT) deficiency can be either congenital or 'functional' as a result of oxidative inactivation.

IL-8 = Interleukin 8; LTB_4 = Leukotriene B_4; TNF = Tumour necrosis factor.

in emphysema through loss of radial support on airways also produces airways narrowing. Patients with COPD experience increased work of breathing due to altered pressure airflow relationship. Because of prolonged time constants for expiration in COPD, lungs are unable to return to their mechanical equilibrium volume [functional residual capacity (FRC)] even during ordinary breathing. As a consequence of this, progressive increase in lung volume shifts tidal breathing to a higher, less compliant portion of the pressure-volume curve of the respiratory system. This results in increased work of breathing. The increased elastic recoil pressure associated with the higher end-tidal volume is known as intrinsic positive end-expiratory pressure (PEEP) or auto-PEEP. This auto-PEEP represents an added threshold load that must be overcome to initiate next inspiration. This contributes significantly to the work of breathing and dyspnoea in patients with COPD. Further, lung hyperinflation also increases the work of breathing as it results in several adverse effects on the inspiratory muscles. The flattening of the diaphragm that occurs in patients with emphysema causes this muscle to operate on unfavourable portion of its length-tension curve. Keeping with the heterogeneous nature of the disease process in the airways and lung parenchyma, non-uniform ventilation, and ventilation-perfusion mismatching are usually observed in COPD. Ventilation-perfusion mismatch produces altered arterial blood gases. The total cross-sectional area of the pulmonary vascular bed is reduced in patients with COPD as a result of anatomic changes, constriction of vascular smooth muscle of branches of pulmonary arteries and arterioles and destruction of alveolar septa with loss of capillaries. Hypoxia is a potent stimulus for pulmonary vasoconstriction. Acidosis due to respiratory failure and secondary polycythaemia from chronic hypoxia augment this pulmonary artery hypertension and right ventricular failure.

CLINICAL FEATURES

Although chronic bronchitis and emphysema frequently co-exist, rarely, features of one type may be predominantly present. **Table 2** provides differentiating features between the two conditions.

Predominantly Chronic Bronchitis

The patient with predominantly chronic bronchitis usually presents with a history of cough and sputum production for many years along with a history of heavy tobacco smoking. Initially, the cough is present only during winter months. Over the years the cough becomes continuous and episodes of illness increase in frequency, duration and severity. With severe degree of airways obstruction, the patient experiences exertional dyspnoea. Occasionally, the patient seeks medical help after the onset of peripheral oedema secondary to overt right ventricular failure. Patients with chronic bronchitis are overweight and cyanotic. Because of this appearance these patients are referred to as 'blue-bloaters'. The percussion note is normally resonant. Medium to coarse crepitations and rhonchi, which change in location and intensity after a deep and productive cough, are heard on auscultation.

Predominantly Emphysema

There is a long history of exertional dyspnoea with minimal cough associated with production of only small amounts of mucoid sputum. The patient appears to be distressed on physical examination. The body build is asthenic with evidence of weight loss. The patient uses accessory muscles of respiration, which serve to lift the sternum in an anterosuperior direction with each inspiration. Patient is tachypnoeic with relatively prolonged expiration through pursed lips. While sitting, the patient often leans forward, extending his arms to brace himself. The neck veins are distended during expiration and briskly collapse with inspiration. The lower intercostal spaces retract with each inspiration; by palpation, the lower lateral chest wall can be felt to move inward. The cardiac impulse, if at all visible, is seen only in the xiphoid and sub-xiphoid regions. Palpation frequently reveals a sustained forward and downward right ventricular impulse in the sub-xiphoid region. The percussion note is hyper-resonant and cardiac dullness is either absent or severely reduced. The upper border of liver dullness is at a lower level. The breath sounds are found to be diminished with faint, high-pitched rhonchi heard towards the end

Table 2: Comparison of Two Types of Chronic Obstructive Pulmonary Diseases

	Predominantly Chronic Bronchitis ('Blue-bloater')	Predominantly Emphysema ('Pink-puffer')
Predominant symptom	Cough	Dyspnoea
Sputum	Copious and purulent	Scant and mucoid
Episodes of bronchial infection	More frequent	Less frequent
Episodes of respiratory insufficiency	Frequent	Often terminally
Chest radiograph	Increased bronchovascular markings at lung bases, large heart	Hyperinflation, bullous changes, small and tubular heart
Lung compliance	Normal	Increased
Airways resistance	High	Normal to slight increase
Diffusing capacity	Normal to slight decrease	Decreased
Arterial blood gases	Abnormality early in course of disease	Normal until late
Pulmonary hypertension		
Rest	Moderate to severe	None to mild
Exercise	Worsens	Moderate
Chronic cor pulmonale	Common	Rare except terminally
Cardiac failure	Common	Rare except terminally

of expiration. A pre-systolic gallop accentuated during inspiration is commonly heard. Patients with this condition have been referred to a as 'pink-puffers' because of maintenance of arterial oxygen tension (PaO_2).

Patients with advanced disease may manifest wasting which is an independent poor prognostic factor in COPD. This could be due to both inadequate dietary intake as well as elevated levels of inflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α).

DIAGNOSIS

The diagnosis of COPD must be considered in patients with symptoms of cough, sputum production, or dyspnoea, or history of exposure to risk factors for the disease. The diagnosis requires spirometry.

Pulmonary Function Testing

A post-bronchodilator forced expiratory volume in one second (FEV_1)/forced vital capacity (FVC) less than 0.7 confirms the presence of airflow limitation that is not fully reversible (**Table 3**). Furthermore, an overall increase in lung volumes may be seen depending upon the degree of associated emphysema. Total lung capacity (TLC), functional residual capacity (FRC), and residual volume (RV) are increased but vital capacity (VC) is decreased in patients with COPD. Peak expiratory flow rate (PEFR) is also reduced and in contrast to asthma, little or no diurnal variation is observed in serial measurements. Carbon monoxide diffusing capacity (DLCO) is normal or slightly impaired in patients with chronic bronchitis and marked reduction suggests co-existing significant emphysema.

Table 3: Comparison of Spirometric Staging Criteria for COPD in the Current ATS-ERS, GOLD, and NCCCC-NICE Guidelines, Using Post-bronchodilator Forced Expiratory Volume in One Second (FEV_1)/Forced Vital Capacity (FVC)*

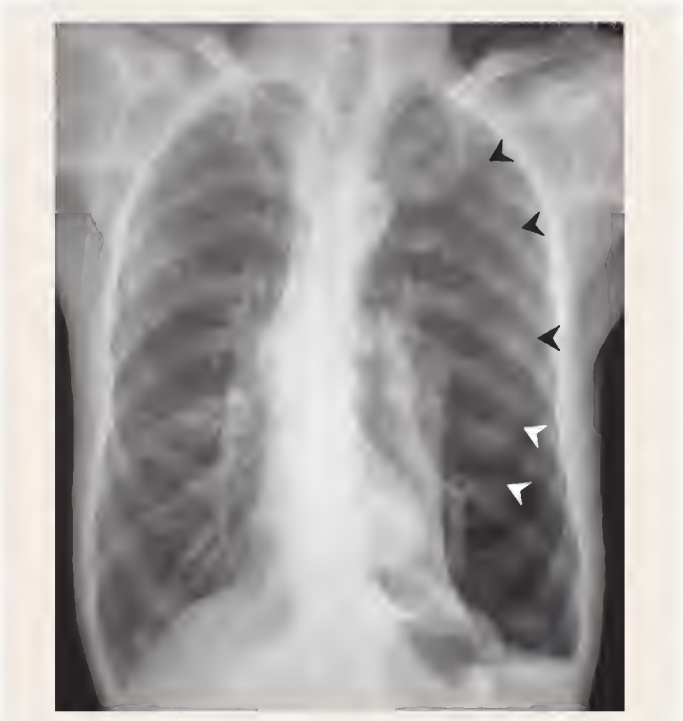
Stage or Severity	FEV1 as a Percentage of the Predicted Value		
	NCCCC-NICE	GOLD	ATS-ERS
At risk for COPD	†	≥80	≥80
Mild COPD	50 to 80	≥80	≥80
Moderate COPD	30 to 49	50 to 80	50 to 80
Severe COPD	<30	30 to 50	30 to 50
Very severe COPD	†	<50‡	<30

*= *All the guidelines define airflaw obstruction as a criterian far diagnasing COPD as FEV1/FVC ≤0.70; † = Stage not included in guideline; ‡ = FEV1 ≤50% af predicted if chronic respiratary failure with PaO_2 ≤60 mm Hg is alsa present; ATS = American Tharacic Saciety; ERS = European Respiratary Society; GOLD = Global Initiative far Chranic Obstructive Pulmonary Disease; NCCCC = Natianal Callabarating Centre far Chronic Canditians; NICE = Natianal Institute far Health and Clinical Excellence.*

Imaging

There is no characteristic abnormality on chest radiograph, it may be normal or show features of co-existing emphysema. It is also helpful in detecting an alternative disease or complication (**Figures 3 and 4**). Findings in patients with chronic bronchitis may include thickened bronchial walls manifested by tubular or 'tramline' shadows and increased bronchovascular markings. Chest radiograph in patients with predominant emphysema reveals hyperlucent lung fields with loss of peripheral vascular markings, bullae (**Figures 5A and B**), flat and low-level diaphragm and a tubular heart. In late stages, main pulmonary artery and its branches become prominent. High resolution computed tomography (HRCT) can detect emphysema with confidence (**Figure 6**) but is rarely used for routine diagnostic purposes.

Figure 3: Chest radiograph (pastera-anterior view) shawing COPD and old healed pulmanary tuberculasis af the left lung.



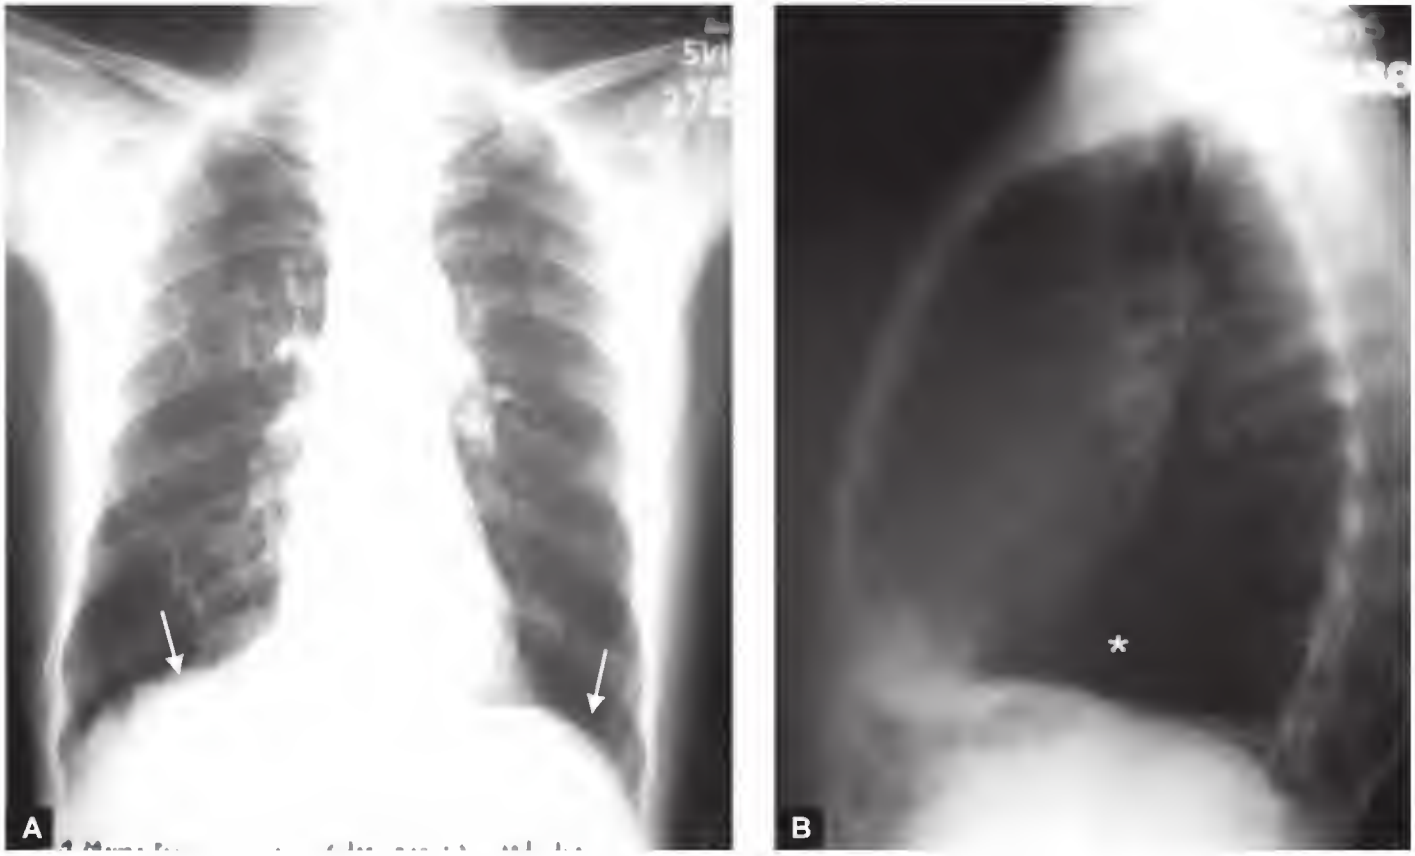


Figure 4: Chest radiograph (pastera-anterior view) shawing COPD with left pneumatharax (arrows point towards lung margin).

Figures 5A and B: (A) Chest radiograph (postero-anterior view) showing hyperlucent lung fields with loss of peripheral vascular markings (bullae) low flat diaphragm (arrows) and prominent pulmonary arterial shadows at both hila and a tubular heart. (B) Chest radiograph (lateral view) showing increased retrosternal lucent zone. Retrocardiac lucency is also increased (asterisk). These findings suggest hyperinflation of the lungs due to bullae.

Other Investigations

Table 4 lists additional investigations that are useful in diagnosing COPD.

Table 4: Other Investigations Useful in Diagnosing COPD

Sputum examination	Culture or molecular tests to identify bacteria, viruses and other pathogens, especially during acute exacerbation
Alpha-1-antitrypsin	Early onset, minimal smoking history or family history
Carbon monoxide diffusing capacity (DLCO)	If symptoms disproportionate to impairment spirometric
Arterial blood gases	If symptoms disproportionate to spirometric impairment and to identify type I respiratory failure (decreased PaO_2) or type II respiratory failure (decreased PaO_2 and increased $PaCO_2$)
Chest radiograph and HRCT	Assessment for suitability of surgery
Electrocardiogram	Assessment of cardiac status, if clinical features of chronic cor pulmonale
2D echocardiography	Assessment of cardiac status, if features of chronic cor pulmonale

COPD = Chronic obstructive pulmonary disease; PaO_2 = Partial arterial oxygen tension; $PaCO_2$ = Partial arterial carbon dioxide; HRCT = High resolution computed tomography.

Complications

Various complications which can occur in patients with COPD are listed in Table 5.

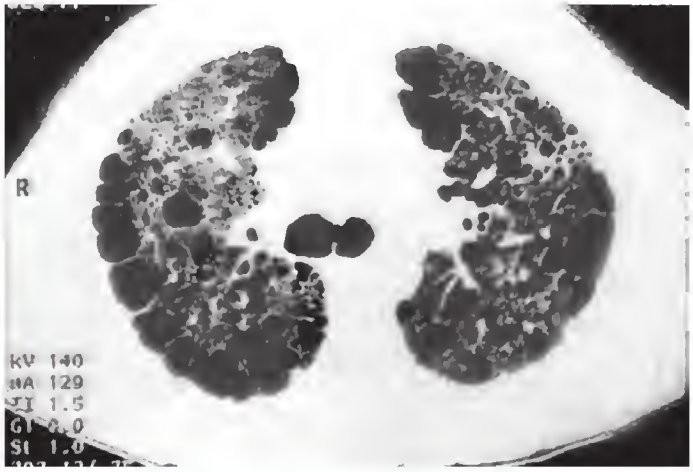

Figure 6: CT of the chest showing paraseptal emphysema involving mainly periphery of the lung.

Table 5: Complications of Chronic Obstructive Pulmonary Diseases

Recurrent episodes of acute exacerbation by viruses and bacteria
Pneumothorax
Secondary erythrocytosis (rare in India)
Weight loss in patients with severe emphysema
Chronic and acute on chronic respiratory failure
Pulmonary artery hypertension
Chronic cor pulmonale
Right heart failure

PROGNOSIS

COPD is usually a progressive disease, punctuated by acute exacerbations and remissions. Eventually it causes respiratory failure, pulmonary hypertension and right heart failure. Death usually ensues within a few years. Few patients with chronic bronchitis do not develop severe airways obstruction and have better prognosis. Six-minute walk distance test and St George's respiratory questionnaire may be used during follow up. **Table 6** lists markers of early disease and prognosis in COPD.

Table 6: Potential Markers of Early Disease and Prognosis in Chronic Obstructive Pulmonary Diseases

Alpha1-antitrypsin deficiency
Cystic fibrosis transmembrane conductance regulator (CFTR) in patients with co-existing cystic fibrosis
MBL-2 genes
Fibrinogen
C-reactive protein, copeptin, serum amyloid A protein (during acute exacerbation)

MANAGEMENT

Stable Phase COPD

Anti-smoking measures

Smoking cessation is the only measure that slows down the progression of COPD and adequate counselling should be done for this. Nicotine replacement therapy in the form of gum, transdermal patch, inhaler or nasal spray, sublingual tablet, or lozenge is helpful in quitting smoking. Use of bupropion, a noradrenergic anti-depressant, is associated with better abstinence rates. Varenicline (a nicotine acetylcholine receptor partial agonist) is helpful in relieving nicotine withdrawal symptoms. Dusty and smoke-laden environment should be avoided and this may involve a change of occupation.

Bronchodilator therapy

Bronchodilators are the mainstay of current drug therapy for COPD (**Figure 7**). As compared to bronchial asthma, the effects of bronchodilator drugs are smaller in patients with COPD because of structural changes in the airways. Bronchodilators produce relaxation of airway smooth muscle, decrease airways resistance, and hyperinflation and improve dyspnoea and exercise tolerance. The main bronchodilators include β_2-agonists, anticholinergic drugs and methylxanthines. The β_2-agonists have been shown to increase ciliary beat frequency and mucociliary clearance, which is impaired in COPD. Anti-inflammatory action of both β_2-agonists and particularly, methylxanthines has also received considerable attention. The β_2-agonists may be given by metered dose inhaler or by mouth. Their excessive use produces tremors and palpitations. Use of metered dose inhalers is associated with fewer side-effects. Patients who have co-ordination problems should use spacers or other ancillary systems for better drug delivery. Regular treatment with inhaled β_2-agonists (salbutamol 200 mg or terbutaline 500 mg 4 to 6 hourly) may be used to treat patients with mild to moderate disease. Long-acting inhaled β_2-agonists (LABAs) (salmeterol and formoterol) are also useful in COPD. Ipratropium bromide, an anticholinergic bronchodilator drug (40 to 80 mg, 6 hourly) should be added in patients with severe airflow obstruction. Tiotropium bromide (18 mg) has a prolonged duration of action and is suitable for once-daily inhalation. Combining inhaled short-acting β_2-agonists (SABAs) and ipratropium bromide produces a greater change in spirometry than either agent alone. Use of LABAs in combination with ipratropium bromide leads to fewer exacerbations than either drug alone.

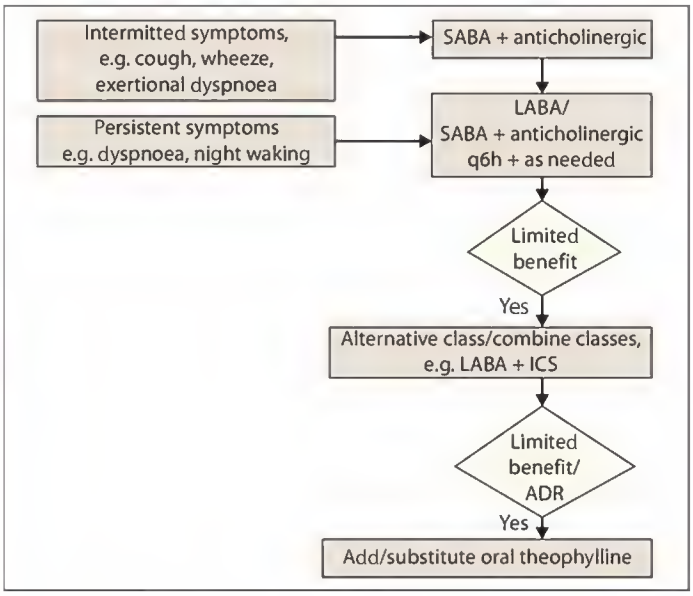

Figure 7: Algorithm for treatment of COPD. Effectiveness of treatment is assessed by response criteria. If forced expiratory volume in one second < 50% predicted and exacerbations of COPD requiring a course of oral corticosteroid or antibiotic occurred at least once within the last year, consider adding regular ICS.

COPD = Chronic obstructive pulmonory diseose; SABA = Short-octing β_2-agonist; LABA = Long-octing β_2-agonist; ICS = Inholed corticosteroids; ADR = Adverse drug reoction.

The role of theophylline or intravenous aminophylline has decreased because of toxicity and lack of efficacy when administered either orally or parenterally. Theophylline blood levels should be measured in those patients who fail to respond or show signs of toxicity. The therapeutic range of blood level is 10 to 20 mg/dL. Insomnia and nervousness occur frequently when levels are in the therapeutic range. Side effects, such as nausea, vomiting, seizures and tachyarrhythmia, occur when blood levels exceed 20 mg/dL. Lower dosages should be given to patients with congestive cardiac failure, liver disease and in elderly patients. Reduced dosage are also required with the concomitant use of ciprofloxacin, erythromycin, propranolol and verapamil. Smokers, patients with thyrotoxicosis, cystic fibrosis and those using phenytoin, barbiturates and rifampicin require higher dosages.

Corticosteroids

Approximately 10% of patients with stable COPD have some symptomatic and objective improvement with oral corticosteroids. There is no evidence that long-term treatment with high doses of inhaled corticosteroids reduces progression of COPD, even when treatment is started before the disease becomes symptomatic. Therefore, their use is not justified in patients with stable COPD in view of the risk of systemic side effects and the cost of using high-dose inhaled corticosteroids for several years.

Oxygen

Use of long-term oxygen therapy (LTOT) is justified from the results of two large trials [US Nocturnal Oxygen Therapy Trial (NOTT) and British Medical Research Council (MRC) study] that showed decreased mortality and improved quality of life (QOL)

in patients with severe COPD and chronic hypoxaemia (PaO_2<55 mm Hg). From these studies, it can be concluded that no oxygen is bad, some oxygen is better, and continuous oxygen is best. Supplemental LTOT has been shown to improve survival, exercise, sleep and cognitive performance in hypoxaemic patients. Oxygen should be administered for at least 15 hours a day. It can be administered by nasal cannula at a rate 1–3 L/min with an aim of achieving PaO_2 of 60 mm Hg. Recent studies have shown that oxygen does not increase survival in patients with less severe hypoxaemia, therefore, the selection of patients is important in prescribing this expensive therapy. Similarly, nocturnal administration of oxygen does not increase survival in patients with COPD who have nocturnal hypoxaemia. Use of oxygen concentrators appears to be cost-effective on long-term basis in patients with COPD. Oxygen concentrators are electrically powered devices for extracting oxygen directly from room air by separating it from nitrogen.

Non-invasive ventilation

The use of non-invasive ventilation (NIV) with a simple nasal mask, when used at home improves oxygenation, reduces hospital admissions in patients with severe COPD and hypercapnia and improves long-term survival. The combination of NIV and LTOT may be more effective.

Treatment of airway secretions

Adequate hydration, expectorants and mucolytic agents are indicated when the secretions are thick and tenacious. Steam inhalation for 10 to 15 minutes several times a day may be beneficial. Postural drainage helps in removing secretions from the bronchial tree.

Nutrition

Nutritional assessment is recommended in patients with COPD. Simple screening includes measurements of body mass index (BMI; kg/m^2) and weight change. Nutritional therapy should be combined with exercise or other anabolic stimuli.

Pulmonary rehabilitation

Pulmonary rehabilitation programme consisting of education, exercise and physiotherapy improves exercise capacity and QOL in severe COPD.

Lung volume reduction surgery

Surgical removal of the most emphysematous parts of the lung improves mechanical efficiency of the respiratory muscle and ventilatory function. Patients with localised upper lobe emphysema appear to do best. Careful selection of patients is essential. Surgical reduction in hyperinflation improves pulmonary functions, exercise capacity and QOL.

Lung transplantation

COPD is an important indication for lung transplantation in the Western countries and is recommended for patients under 65 years of age who have no co-morbid conditions if they have severe disability despite optimum medical management. It is not clear whether single or double lung transplantation is the better choice.

Acute Exacerbation of COPD

A summary of the principles of the management of AECOPD is detailed in **Table 7**.

Table 7: Hospital Management of Acute Exacerbations of COPD

Oxygen therapy: Controlled oxygen therapy monitored by serial arterial blood gas measurements

Bronchodilator therapy: Nebulised salbutamol (5 mg) or terbutaline (10 mg) in combination with ipratropium bromide (500 µg) six hourly

Corticosteroids: Patients treated with systemic steroids have fewer treatment failures, better spirometry and shorter hospital stay

Diuretic therapy: Frusemide (40 to 80 mg) orally or IV according to the extent of oedema. Alternatively, torsemide may be used as it is associated with lesser incidence of hypokalaemia

Appropriate antibiotic therapy: May be initiated in patients that have a change in their sputum characteristics (purulence and/or volume)

Choice should be based on bacteria resistance patterns prevalent locally and includes:

Amoxicillin/clavulanate

*Respiratory fluoroquinolones (gatifloxacin, levofloxacin, moxifloxacin)

If *Pseudomonas* spp. and/or other *Enterobacter* spp. are suspected, combination therapy should be used

Respiratory stimulants: Doxapram hydrochloride by IV infusion (1.5–4 mg/min) is used only when non-invasive ventilation is either not available or considered inappropriate

Physiotherapy: Chest physiotherapy helps in patients who are drowsy because of carbon dioxide narcosis.

Mechanical ventilation: when the patient is deteriorating despite maximum therapy

**In TB endemic countries to be used only when Mycobacterium tuberculosis has been ruled out.*

Oxygen

In patients with AECOPD, oxygen is administered through nasal cannula, simple face mark or Venturi mask. The goal of oxygen therapy is to maintain PaO_2 at 60 mm Hg.

Treatment of respiratory infection

Up to 25% of exacerbations in COPD are produced by viruses. The major bacterial organisms associated with exacerbations include *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*; *Mycoplasma pneumoniae* or *Chlamydia pneumoniae*. Choice of antibiotic depends on the clinical condition of the patient and the local patterns of antibiotic susceptibility. Augmentation therapy with α_1-Pi (Prolastin) is associated with a marked reduction in the frequency of lung infections in majority of the patients. The annual use of influenza virus vaccine (trivalent inactivated vaccine 0.5 mL by intramuscular route or live-attenuated intranasal 0.2 mL of vaccine) and the once in life-time inoculation with 23-valent pneumococcal polysaccharide vaccine may provide significant protection (although not an evidence-based recommendation).

Corticosteroids

Recent studies have demonstrated a beneficial effect of systemic corticosteroids in treating AECOPD with improved clinical outcome and reduced length of hospitalisation. Inhaled corticosteroids may slightly reduce the severity of AECOPD.

Assisted ventilation

Significant airways obstruction increases work of breathing. Further, unconsciousness, fatigue and weakness of respiratory muscles contribute significantly to acute ventilatory failure during AECOPD. Correction of reversible factors, such as electrolyte disturbances, abdominal distension or ascites and poor nutrition should be done. Use of sedatives, unless patient is receiving assisted ventilation, is contraindicated.

Non-invasive ventilation

Some patients with AECOPD do not show improvement with medical treatment and develop acute respiratory acidosis, severe hypoxaemia or both. Short-term use of assisted ventilation may be beneficial in these patients. NIV is useful for severely ill patients who do not require immediate endotracheal intubation. Although the best time to start NIV is not established, early intervention when the respiratory rate is >30 per min and the pH is <7.35 may be beneficial. Successful NIV is recommended for co-operative patients who are not sedated, are haemodynamically stable and do not have copious secretions. Guidelines for tracheal intubation are provided in **Table 8**. Mechanical ventilation (MV) is associated with barotrauma, infection and difficulty in weaning. During MV, it is useful to monitor auto-PEEP (intrinsic PEEP), and extrinsic PEEP should be set at 80% of the intrinsic PEEP.

Effect of commonly used medications on important clinical outcomes in COPD is shown in **Table 9**.

Table 8: General Guidelines for Endotracheal Intubation During Acute Exacerbations of COPD

NIV intolerance or failure
Inability to clear copious secretions
Inability to protect airway
Respiratory rate >35/min
Signs of progressive respiratory muscle fatigue
Persistent arterial hypoxaemia with failure to maintain PaO_2 of 55 to 60 mm Hg, or oxygen saturation of <88% to 90% despite maximum medical treatment
Worsening acute respiratory acidosis (pH <7.25) and/or $PaCO_2$ > 60 mm Hg
Deterioration of mental status
Hypotension or shock
Respiratory arrest

COPD = Chronic obstruction pulmonary disease; NIV = Non-invasive ventilation.

Table 9: Effect of Commonly Used Medications on Important Clinical Outcomes in COPD

	FEV_1	Lung Volume	Dyspnoea	HRQoL	Acute Exacerbation	Exercise Endurance

23.7 Pneumonia

Dhiman Ganguly, Sumit Sengupta

Pneumonia is an accumulation of inflammatory cells and secretions in the alveolar spaces of lung, caused by an infection. The infecting organism, the inflammatory response and the disturbance of gas exchange caused by alveolar involvement are responsible for clinical manifestations.

CLASSIFICATION

Pneumonia has been traditionally classified as *typical* and *atypical*. This is no longer a preferred classification, as clinical and radiological features that were once thought to be indicative of 'typical' or 'atypical' organisms *Mycoplasma pneumoniae*, *Chalmydia pneumoniae*, *Legionella* spp. causing pneumonia, are no longer considered to be specific of any organism.

The more useful classification is according to the probable origin of infection is as follows:

- Community acquired pneumonia (CAP)
- Hospital-acquired and ventilator-associated pneumonia (HAP and VAP)
- Pneumonia in the immunocompromised host

The spectrum of pathogens and, therefore, the antimicrobial treatment varies between the groups.

PATHOGENESIS

The lung, which serves its primary function of gas exchange, is the organ with largest epithelial surface area (approximately 70 m^2) which is in continuous contact with the external environment. In spite of this exposure, lower respiratory tract remains sterile, under normal circumstances.

An infecting organism may reach the lower respiratory tract (a) by aspiration of upper airway contents, (b) by aerosolisation, (c) through blood stream, or (d) from adjacent structures. The first mode is the commonest in the pathogenesis of pneumonia; viral infections, atypical organisms, tuberculosis (TB) and fungal pathogens are examples of aerosol-caused infections. Haematogenous spread is possible in severe bacteraemia. The pulmonary circulation acts as a filter for venous blood, which in some cases allows micro-organisms to lodge in the small vessels of the lungs and cause parenchymal infection. In most cases, infections originate from heart valves or from thrombophlebitis. Because bacteria are released in clusters from the source, they are likely to reach multiple parts of the pulmonary circulation simultaneously, causing dense infections that can cavitate. Haematogenous pneumonias, therefore, are often multifocal, peripheral lesions, that are susceptible to rapid cavitations. The precise mechanism by which the micro-organisms infect the usually sterile lower airways and lung parenchyma are complex, but any situation in which natural defences are impaired will predispose to pneumonia. Colonisation of the upper airway by potential pathogens can occur in normal hosts, especially seasonally or during epidemics with typical bacterial pathogens (i.e. *Streptococcus pneumoniae*). Prevalence of colonisation may increase in areas of crowding or co-housing, such as dormitories or army barracks. An increased incidence of isolation of Gram-negative bacilli from oropharynx has been correlated with increasing severity of the underlying illness of the host. These potential pathogens can be isolated from 2% of healthy hosts, but can be recovered with increasing frequency in patients with co-morbidities. Interestingly, if normal hosts are exposed to high concentration of Gram-negative bacilli in the oropharynx, the bacteria are cleared rapidly, and colonisation does not occur.

Once the colonisation occurs, aspiration of oropharyngeal secretion is the means by which the lower respiratory tract is inoculated. Aspiration of small quantities of oropharyngeal secretions occurs in approximately 50% of normal hosts during sleep and probably occurs more frequently in the setting of altered sensorium, alcohol or sedative drug use. The bacterial concentration of oropharyngeal secretions is very high, of the order of 10 organisms/mL, hence, aspiration of a small volume may provide a very high bacterial inoculum to the lung and once that occurs it depends on the efficiency of normal host defence mechanisms to prevent the development of pneumonia.

PATHOLOGY

Traditionally, pathology of pneumonia has been described as stages of red hepatisation followed by grey hepatisation—signifying congestion with increased vascularity of inflamed tissues and consolidation initially with more red blood cells and then with neutrophils. Because of use of early antibiotics, this natural progression of pathology is perhaps occurring less often these days.

COMPLICATIONS

Complications do occur in pneumonias fairly frequently (**Table 1**). Most common cause of bacterial infection of pleural space is parapneumonic effusion (**Table 2**) and this can create a lot of management problems.

Table 1: Complications of Community Acquired Pneumonia

Pleural infections
Simple parapneumonic effusion
Complicated parapneumonic effusion
Empyema
Lung abscess
Respiratory failure
Sepsis

MICROBIOLOGY

Typical Pathogens

Streptococcus pneumoniae (pneumococcus) is among the leading causes of illness and death from CAP worldwide for

young children, for persons who have underlying chronic systemic conditions and for the elderly. *S. pneumoniae* also causes HAP or pneumonia in immunocompromised host, but the percentage is lower in the latter two groups. *Pneumococcus* is a Gram-positive diplococcus and was re-classified as *S. pneumoniae* because it is genetically related to streptococcus. They are capsulated (the capsule enclosing each pair), non-motile and non-sporing. The importance of *S. pneumoniae* as a cause of pneumonia has acquired a greater clinical significance because non-susceptibility to penicillin has increased significantly over the past decade. Penicillin resistance is associated with resistance to beta-lactams and other classes of antibiotics, such as macrolides, tetracycline, and trimethoprim – sulfamethoxazole. The mode of resistance is not the production of β-lactamases, but alteration in the penicillin binding proteins on the bacterial surface.

Table 2: Comparative Features of Simple and Complicated Para-pneumonic Effusion

	Simple Parapneumonic Effusion	Complicated Parapneumonic Effusion
Appearance	May be turbid	May be cloudy
Biochemical markers	pH >7.30 LDH may be elevated Glucose >60 mg/dL or Glucose pleural/ serum ratio >0.5	pH <7.20 LDH >1,000 IU/L Glucose <35 mg/dL
Nucleated cell count	Neutrophils usually <10,000/μL	Neutrophils abundant (usually >10,000/μL
Gram's stain	Negative	May be positive
Culture	Negative	May be positive

Staphylococcus is a less common aetiology of CAP, but a more important causative organism in HAP. These are Gram-positive cocci appearing in clusters and the most constant association with virulence is coagulase positivity. *Staphylococcus aureus* is coagulase positive. Clinical manifestations are similar to those of CAP from other bacterial aetiologies, although mortality can be higher. Radiological patterns are protean, inclusive of cavity formation. Methicillin-resistant *Staphylococcus aureus* (MRSA) remains more of a concern for HAP, although it has been reported as a cause of CAP. MRSA pneumonia tends to produce significantly greater frequency of bacteraemia and septic shock and is associated with higher mortality.

Klebsiella species (Friedländer's pneumonia) is classically community acquired. But more recently it is being seen in elderly, immunocompromised hosts, and in chronically ill, as HAP. These are ubiquitous, non-motile, Gram-negative rods, that commonly colonise mucosal surfaces of mammals. The organism contains a thick gelatinous capsule, that appears to increase its virulence. The most medically important species of the genus is *K. pneumoniae*. The pneumonia caused by this organism is mostly located in the right upper lobe, and apex of the right lower lobe. Abscess formation and cavitations are also seen. The classic radiological 'bulging fissure' sign is not seen in all patients of this pneumonia, and may also be seen in pneumococcal pneumonia. Occasionally, a patient may recover from the acute phase of *K. pneumoniae* and pass into a chronic phase of infection characterised by cavitations and scarring resembling TB. Spread of plasmid mediated extended spectrum β-lactamases (ESBLs) has been reported in *Klebsiella* (and *Enterobacter* spp.) isolates in some parts of the world. Hence, each institution must establish and monitor the incidence of ESBLs producing organisms.

Haemophilus influenzae is a fastidious Gram-negative coccobacillus, and is a common cause of CAP and HAP identified in patients who require hospitalisation. Aminopenicillin resistance is common, and is due to β-lactamase production. This bacillus is difficult to culture. Most clinical isolates are non-typable strains. It is an exclusively human pathogen. *Haemophilus* pneumonia typically occurs in infants and is accompanied by empyema and sometimes meningitis as well. In older children and adults, the picture is of lobar pneumonia, higher prevalence being seen in patients with chronic obstructive pulmonary disease (COPD).

Adults with chronic lung disease have been reported to have higher rates of *Moraxella catarrhalis* respiratory tract colonisation compared to healthy adults. Both CAP and HAP are common with this pathogen. Although *M. catarrhalis* pneumonia causes a significant pneumonia in elderly patients, fulminant pneumonia, pleural effusion and empyema are uncommon. Most strains of this organism produce an inducible β-lactamase. This β-lactamase is more active against penicillins than cephalosporins and its activity is inhibited by β-lactamase inhibitors.

The Gram-negative bacilli, namely *Pseudomonas aeruginosa, Escherichia coli, Proteus, Serratia, Enterobacter* and *Acinetobacter* are the species that generally cause HAP. These are rare causes of pneumonia in ambulatory patients. *P. aeruginosa* and other members of this species have always been important causes of hospital infection because of their intrinsic resistance to most antibiotics and ability to survive and even multiply at low temperatures and in disinfectant solutions. They may also carry drug resistant plasmids.

Anaerobic Organisms

These are most common aetiologic agents of lung abscess and aspiration pneumonia, and these bacteria are relatively common isolates from empyemas. Risk factors that predispose to anaerobic bacterial pneumonia include aspiration, infection of gingival crevice, necrosis of tissue with abscess formation or bronchopulmonary fistula, infections complicating airway obstruction and infection of dependent pulmonary segment.

Atypical Pathogens

Mycoplasma (smallest living organisms) are a group of bacteria that are devoid of cell walls, and hence, highly pleomorphic (Myco, from fungus like form of branching filaments; plasma, denoting plasticity of their shape). Because of their plasticity, they can pass through bacterial filters and have often been mistaken for viruses. Extrapulmonary manifestations of this infection may include haemolytic anaemia, myocarditis, and diverse neurological syndromes.

Chlamydia pneumoniae is transmitted from human to human without any avian or animal host. It grows poorly in cell cultures. Considerable interest has been aroused recently linking *C. pneumoniae* with atherosclerosis and its clinical effects. However, more work will have to be done to settle this issue. It

is a recognised cause of both CAP and HAP. The preferred diagnostic test is an assay of acute and convalescent specimens to detect a four-fold increase in antibody titres, with supporting evidence based on throat swab polymerase chain reaction (PCR) or culture results. Nevertheless, with limitation and availability of diagnostic tests, treatment most often is empirical.

Legionella pneumophila pneumonia (legionnaires' disease) is an acute pneumonic illness caused by a Gram-negative bacterial organism of the genus *Legionella*. Although rare in immunocompetent adults younger than 30 years of age, legionellosis can be a major cause of lethal pneumonia. Person to person transmission has not been reported and epidemiologic risk factors include recent travel and overnight stay outside home, recent repair of domestic plumbing, recent exposure to hot tub and whirlpool type spas, renal or hepatic failure, diabetes and systemic malignancy. Although the course of illness is variable, the rate of resolution with legionellosis is slower. Clinical features of legionnaires' disease includes high fever, hyponatraemia, central nervous system manifestations, and elevated lactate dehydrogenase levels. Diagnostic tests include urine antigen assay and culture on selective media, which is technically demanding.

Fungal Pneumonias

Recognition of pulmonary infection caused by endemic mycosis is aided by an understanding of the epidemiologic factors associated with exposure to these fungi and the use of appropriate testing. *Histoplasma capsulatum*, a thermal dimorphic fungus is found in nature with a near worldwide distribution, but endemic areas with highest concentration are located in eastern half of the United States of America, and most of Latin America. After inhalation, spores germinate into yeast forms within the lung. Clinical presentations can be an acute, self-limiting disease, acute overwhelming pulmonary infection, chronic upper lobar cavitary disease, and rarely fibrosing mediastinitis. Patients with impaired cell-mediated immunity are at increased risk to develop progressive disseminated *histoplasmosis*. *Blastomycosis* and *coccidioidomycosis* are two other pathogens known to cause pneumonic illness.

Viral Pneumonias

Viral pneumonias are extremely important in two situations – community acquired and in the immunocompromised. Hospital acquired infections are extremely rare. Community acquired viral pneumonias are under-diagnosed and under-treated. Till recently, these were difficult to diagnose, but real-time PCR has changed our ability to diagnose and treat viral pneumonias substantially. The incidence of viral CAP varies. But in patients hospitalised with CAP, about 30% have a viral aetiology, and half of these patients have both bacterial and viral pneumonia. The usual aetiological agents are influenza (A/B), RSV, rhinovirus, parainfluenza, adenovirus, coronavirus [including severe acute respiratory syndrome (SARS)] and metapneumovirus. There is lack of data about Indian patients with viral CAP but there is no reason to suspect that there are any major differences from other countries. A huge community study in Nepal involving only children [utilising World Health Organization (WHO) clinical criteria for diagnosis of pneumonia] found about 40% patients had a viral aetiology. Influenza occurs all the year round in India and this is different from the winter peak seen in western countries.

The diagnosis of viral *versus* non-viral pneumonia is clinically extremely difficult as the two may co-exist. A coryzal illness is common and specifically nasal or laryngeal symptoms and myalgias are more suggestive of viral infections or an obvious viral infection like measles or chickenpox with pneumonia suggests the diagnosis strongly. In an epidemic setting like the SARS epidemic in 2004, and the recent influenza A virus subtype H1N1 epidemic, due to a new strain of swine origin, one can also make a probable diagnosis based on clinical features. A normal or low white cell count makes viral pneumonia more likely but *Chlamydial* or *Mycoplasma pneumoniae* and bacterial pneumonia in the elderly may not show leukocytosis. Plain chest radiology is not sensitive enough to differentiate between bacterial and viral pneumonias. However, a 'pure' (i.e. without any bacterial superinfection) viral pneumonia usually does not present with unilateral lobar consolidation. Apart from a few central laboratories, viral diagnostics are practically unavailable in India. Real-time PCR and fluorescent antibody tests are the most promising tests for the diagnosis, but at the moment are not easily available. Viral cultures are done only in specialised centres. Serology is useful in epidemiological studies but is of no use in clinical management of patients.

Treatment of viral pneumonia focuses on treatment of influenza. Oseltamavir/zanamavir is recommended in any patient with influenza-like illness and risk factors for poor outcome pending reports. Treatment should be started on suspicion as the benefit of antiviral treatment is almost entirely in the early phase. Benefits of treatment for any other community acquired viral infections are unproven. Viral pneumonias in the immunocompromised are not uncommon, especially in the transplant setting. Of therapeutic importance is cytomegalovirus (CMV) as treatment exists for this, but diagnosis is difficult as even PCR/viral culture of CMV from pulmonary secretions does not prove causation. Certain patterns on high resolution computed tomography may suggest viral pneumonias particularly in the immunocompromised patients, e.g. ground-glass and small nodules. Only biopsy or cytological evidence of cytopathic effect is diagnostic of CMV pneumonia.

COMMUNITY ACQUIRED PNEUMONIA

The diagnosis of pneumonia is to be considered in any patient who has newly acquired respiratory symptoms (cough, sputum production, and/or dyspnoea), especially if accompanied by fever and auscultatory findings of abnormal breath sounds and crackles. In a patient with advanced age or an inadequate immune response, pneumonia may present with non-respiratory symptoms, such as confusion, failure to thrive, worsening of an underlying chronic illness or falling down. In these patients fever may be absent, but tachypnoea is usually present, along with an abnormal physical examination of the chest.

Standard postero-anterior (PA) and lateral chest radiographs are valuable in patients whose symptoms and physical examination suggest possibility of pneumonia. Also, the radiograph is an useful tool to exclude other possibilities that can mimic pneumonia. Radiographs can raise the possibility of a necrotising pneumonia (lung abscess), TB, co-existing conditions like bronchial obstruction or presence of pleural effusion. In some patients, history and physical examination may suggest pneumonia, but the radiograph is negative. Clinical relevance of such findings is uncertain, as most studies on CAP

have required the presence of lung infiltrates on a routine chest radiograph, to define the presence of pneumonia. Radiography is also useful for evaluating severity of illness by identifying multilobar involvement.

Once the diagnosis is established, every attempt must be made to ascertain a specific aetiologic diagnosis. The tests include sputum smear Gram's stain, acid-fast stain, sputum culture, blood culture. However, even with extensive diagnostic testing most investigators cannot identify a specific aetiology for CAP, in more than 50% of patients. If an exact aetiology can be identified, then therapy can be focused and also cost-effective. On the other hand, if diagnostic testing leads to delays in the initiation of appropriate therapy, it may have an adverse effect on the prognosis. Also, there is always a possibility of co-infection with an atypical pathogen (which may take a long time to identify). In this case, the value of a focused therapy against the rapidly identified bacteria, is uncertain. But the value of a properly collected and examined Gram's stain of expectorated sputum is still considered helpful for focusing initial therapy in CAP. A lower respiratory tract sample that is not heavily contaminated by oral secretions will typically have <10 squamous cells and >25 neutrophils per low power field. The problems are: (1) not all patients can provide an adequate sample, (2) interpretation is observer dependent, (3) atypical pathogens (which are common either as single or as co-infecting agent) cannot be seen, (4) a positive result for *Pneumococcus* is poorly predictive of the ability to recover that organism from a sputum or blood culture. Routine bacterial cultures of sputum often demonstrate pathogenic organisms, but sensitivity and specificity are poor, and findings should be correlated with the predominant organism identified on Gram stain. However, recovery of organisms from cultures, that are not usually a part of normal respiratory flora may be meaningful. Evidence supporting presence of an atypical pathogen are usually derived by serologic testing, e.g. documenting a four-fold rise in titres to *M. pneumoniae, C. pneumoniae* or *Legionella* spp.

In addition to clinical and radiographic findings (**Figure 1**), routine laboratory tests (complete blood counts, serum electrolytes, hepatic enzymes and renal function) are of little value in determining the aetiology of pneumonia, but may have prognostic significance and influence the decision of hospitalisation. Assessment of oxygen saturation and arterial blood gas (especially in patients with chronic lung disease) are very important tools to assess severity, and document the degree of hypoxaemia and carbon dioxide retention.

The degree of social support available to the patient also influences hospitalisation decision. Absence of a responsible care giver and a primary care physician are strong indications for hospitalisation. Various professional bodies have tried to develop scoring systems based on the risk factors present in a particular patient, but even the expert committees feel that the admission decision remains an 'art of medicine'. Hence, when the overall appearance of the patient seems unfavourable, even if the above-mentioned criteria are not fully met, admitting the patient in hospital is justified, at least until the concerns are resolved.

Chest radiograph, total leucocyte count and C-reactive protein (CRP) are recommended in all patients with pneumonia. Further testing depends on the severity of the disease. In non-severe CAP being treated as an outpatient, further testing is generally not recommended except for sputum Gram's stain and culture in patients with risk factors for resistant bacteria (e.g. bronchiectasis) or sputum for acid-foot bacilli if there is suspicion of TB. In patients with moderate to severe CAP, sputum for Gram's stain and culture, blood culture, and urinary antigen tests for *Legionella* and *Pneumococcus* are recommended. The strength of recommendation for such testing is directly proportional to the severity of the disease. For clinically non-resolving pneumonia, a computed tomography followed by bronchoscopy is generally indicated and is helpful in diagnosing complications like empyema, lung abscess or any unusual pathogens. Rapid antigen tests for influenza-like illness confirmed by real-time PCR is indicated wherever available. There are a plethora of other PCR tests available especially for the diagnosis of viral and 'atypical' organisms from respiratory secretions. But these tests are not routinely used in the non-immunocompromised patients with CAP.

TREATMENT

The first thing to decide is suitability of treating a particular patient at home, at a hospital or in an intensive care unit, depending on the various risk factors (**Table 3**) for pneumonia. Therapy for pneumonia will be either empiric or pathogen-specific (**Table 4**). Even when empiric therapy is to be used, it can be individualised. The presence of other risk factors and the severity of the disease will also influence treatment decisions. For example, underlying COPD or bronchiectasis should lead to consideration for anti-pseudomonal therapy. All patients treated at home should be reviewed within 48 to 72 hours to ensure that there has been no clinical deterioration requiring hospitalisation.

Table 3: Risk Factors for Prognosis of Pneumonia

Advanced age (65 years)
